VOLUME 20, NEW SERIES
JANUARY-DECEMBER, 1949

A publication of the
AMERICAN INSTITUTE OF PHYSICS
57 East 55 Street, New York 22, New York

SUGGESTIONS FOR CONTRIBUTORS

Send **manuscripts** to Gaylord P. Harnwell, Randal Morgan Laboratory of Physics, University of Pennsylvania, Philadelphia, Pennsylvania. Textual material (abstract, body of the paper, tabular material, references, and figure captions) must be in English, typewritten (except mathematical expressions) double spaced with wide margins on a durable, white paper, preferably letter size. The original copy, not the carbon, should be submitted. For general style, spellings, abbreviations, and form, consult recent issues of this journal.

An **abstract** must accompany each article. It should be adequate as an index and as a summary.

All but the simplest **mathematical expressions** should be carefully printed in by hand. Be sure to distinguish between capital and small letters. Indicate clearly superscripts and subscripts by inverted carets and carets, respectively. Avoid complicated superscripts and subscripts. Avoid repetition of a complicated expression by representing it by a symbol. Identify in the margin Greek letters and unusual symbols. Use fractional exponents instead of root signs. Use the solidus (/) for fractions wherever its use will save vertical space.

References should appear as footnotes, numbered consecutively, and arranged thus:

[1] A. B. Smith, Phy. Rev. 41, 852 (1932).

[2] H. Lamb, *Hydrodynamics* (Cambridge University Press, Teddington, England), sixth edition, pp. 573, 645.

Tables may be typewritten on sheets separate from the running text. Each table must have a caption which will make the data in the table intelligible without reference to the text. Avoid complicated column headings.

Wherever possible **figures** should be planned for the width of a column (3 in.). A convenient reduction ratio is about 2:1 or 3:1. Lettering should be large enough on the original that when reduced it shall not be less than about $\frac{1}{16}$ in. (~1.5 mm.). Line drawings must be in *India ink* on white paper or tracing cloth. Coordinate paper is not desirable but if used must be blue lined and the coordinate lines which are to show must be inked over. Photographs should have maximum black and white contrast. Identify each original drawing or photograph on the back with the author's name and the figure number. Figures should be numbered consecutively. Captions should be typed on a separate sheet of paper.

A limited number of **alterations** in proof are unavoidable, but the cost of making extensive alterations after the article has been set in type will be charged to the author.

Proof and all correspondence concerning papers in the process of publication should be addressed to the Publication Manager, American Institute of Physics, 57 East 55 Street, New York 22, New York.

INFORMATION FOR SUBSCRIBERS

The Review of Scientific Instruments is a monthly journal published by the American Institute of Physics and devoted to scientific instruments, apparatus, and techniques. Its contents include original and review articles on instruments in physics and allied sciences and sections on laboratory practices, book reviews, new instruments, new materials, news, and current literature of physics. One volume is published annually.

Subscriptions and orders for back numbers should be addressed to the American Institute of Physics, 57 East 55 Street, New York 22, New York.

Subscription Price

	U. S. and Canada	Elsewhere
To members and associate members of the American Institute of Physics	$5.00	$6.00
To all others	7.00	8.00

Back Number Prices

Vol. 1, 1930–Vol. 6, 1935 (some issues out of print)	None
Vol. 7, 1936–Vol. 19, 1948	$104.00
Yearly rate:	
1930–1935	None
1936 and thereafter	$ 10.00
Single copies	$ 1.00

Advertising rates will be supplied on request.

American Institute of Physics

CONTENTS

JANUARY, 1949

Orbital Stability in a Proton Synchrotron . . . . R. Q. Twiss and N. H. Frank 1

Double-Channel, Direct Reading, Low Frequency Counting Rate Meter and Counting Rate Comparator . . . . Robert M. Kloepper and Frank E. Hoecker 17

Recording Mechanical Pressure Gauge of High Range . . . . Paul M. Higgs 23

Self-Contained Recording Pressure Gauge . . . .
David R. Brown, William C. Galloway, Jack B. Robertson, and Gene A. Silvey 27

Multiple-Reflection Optical Lever . . . . H. O. Hoadley 30

Improved Magnetic Focusing of Charged Particles . . . . Larkin Kerwin 36

Geiger-Mueller Counting Unit and External Quenching Equipment for the Estimation of C^{14} in Carbon Dioxide . . . . W. B. Mann and G. B. Parkinson 41

Apparatus for Cloud-Chamber Investigations with Free Balloons . . . .
. . . . E. J. Lofgren, E. P. Ney, and F. Oppenheimer 48

Statistical Theory of the Dead Time Losses of a Counter . . . . C. E. Clark 51

Apparatus for Determining the Effect of Centrifugal Force on the Potentials of Galvanic Cells
. . . . B. Roger Ray and D. A. MacInnes 52

Circuits for Minimizing Transient Effects on Energy Measurements in Calorimetry . . . . .
. . . . Harold J. Hoge 59

Accurate Gas Metering System for Laminar Flow Studies . . . .
. . . . J. W. Andersen and R. Friedman 61

Optical Properties of Surface Films. II . . . . Alexandre Rothen and Marjorie Hanson 66

Sampling Devices for Determining the Bacterial Content of Air . . . .
. . . . Matthew Luckiesh, A. H. Taylor, and Thomas Knowles 73

Wide-Range Saw-Tooth Generator . . . . Peter G. Sulzer 78

Laboratory and Shop Notes:

Distant Counting of Scintillations . . . . E. P. Blizard and S. DeBenedetti 81

Convenient Method for Checking the Linearity of an Electron Multiplier Circuit . . . .
. . . . George P. Kirkpatrick 81

Method of Linearizing the Voltage Rise of a Relaxation Oscillator . . . . R. J. Watts 81

High Temperature X-Ray Diffraction Techniques . . . . J. J. Lander 82

Regular Features:

New Instruments 83

New Materials 91

FEBRUARY, 1949

Trochotron Design Principles . . . . G. W. Monk and G. K. Werner 93

Servo Employing the Magnetic Fluid Clutch . . . . E. S. Bettis and E. R. Mann 97

Note on Analog Computer Design . . . . J. A. Bronzo and H. G. Cohen 101

Exposure Meter for Precision Light Dosage . . . . Herbert F. Launer 103

Capillary Collector for Measuring the Deposition of Water Drops on a Surface Moving through Clouds . . . . Bernard Vonnegut 110

Apparatus for the Production of Large Metallic Crystals by Solidification at High Temperatures
. . . . Louis Gold 115

Large Helium Liquefier . . . . J. G. Daunt and H. L. Johnston 122

Design of the Radiofrequency System for the 184-Inch Cyclotron . . . .
. . . . . . K. R. MacKenzie, F. H. Schmidt, J. R. Woodyard, and L. F. Wouters 126

Method for Measuring Very High Speed Transient Currents . . . .
. . . . A. M. Zarem and F. R. Marshall 133

Laboratory and Shop Notes:

Pulsed Oscillator for F-M Cyclotron . . . J. W. Burkig, E. L. Hubbard, and K. R. MacKenzie 135

Toggle-Operated Vacuum Valve . . . . Ralph O. McIntosh and John W. Coltman 135

Note on Constant Current Regulators . . . . E. E. Minett, D. A. MacRae, and J. Townsend 136

Lock-In *RC* Oscillator . . . . W. C. Elmore and D. Bancroft 136

D.C. Flat Card Resolver . . . . R. G. Murdick 137

Use of Characteristic Curves for Pump-Speed *vs.* Pressure . . . . Saul Dushman 139

Method of Assessing Transient Stresses in Photo-elastic Substances . . . . . . John S. Stanton 139

Kovar Glass Seals at Liquid Helium Temperatures . . . . C. T. Lane 140

Regular Features:

New Instruments 141

New Materials 145

Index to Advertisers xiii

MARCH, 1949

Counter Pulse Shape . . . . C. D. THOMAS 147
Developments in the Useful Circular Nomogram . . . . DOUGLAS P. ADAMS AND HOWARD T. EVANS, JR. 150
New Techniques Applied to the Buerger Precession Camera for X-Ray Diffraction Studies . . . . HOWARD T. EVANS, JR., S. G. TILDEN, AND DOUGLAS P. ADAMS 155
Conditions for Optimum Luminosity and Energy Resolution in an Axial β-Ray Spectrometer with Homogeneous Magnetic Field . . . . JESSE W. M. DUMOND 160
Tissue Stimulators Utilizing Radiofrequency Coupling . . . . OTTO H. SCHMITT AND DONALD R. DUBBERT 170
Absorption Corrections in X-Ray Studies of Preferred Orientation . . . . R. SMOLUCHOWSKI AND R. W. TURNER 173
Rapid Infra-Red Gas Analyzer . . . . RICHARD C. FOWLER 175
Scintillation Counter as a Proportional Device . . . . ROSALIE C. HOYT 178
Pulse Amplitude Analyzer for Nuclear Research Using Pretreated Pulses . . . . C. H. WESTCOTT AND G. C. HANNA 181
Magnetic Ion Source . . . . CARL BAILEY, D. L. DRUKEY, AND F. OPPENHEIMER 189
Theory of the Solenoid Beta-Ray Spectrometer . . . . E. PERSICO 191
Simplified Chronotron-Type Timing Circuit . . . . J. WARREN KEUFFEL 197
Parallel-Plate Counters . . . . J. WARREN KEUFFEL 202

PHYSICAL INSTRUMENTS FOR THE BIOLOGIST

Equipment and Experimental Methods for Interference Diffusion Studies . . . . LOUIS J. GOSTING, EDWIN M. HANSON, GERSON KEGELES, AND MARGARET S. MORRIS 209

Laboratory and Shop Notes:

Note on the Preparation of Beta-Ray Sources . . . . LAWRENCE M. LANGER 216
On the Design of a Radiofrequency Cockroft-Walton Accelerator . . . . PAUL LORRAIN 216
Rejuvenation of Geiger-Mueller Tubes . . . . L. SHEPARD 217
Thyratron Square Wave Generator . . . . LEONARD REIFFEL 218
New Principle in Controlled Vacuum Leaks . . . . C. H. BACHMAN 219
Absorption Cell and Loader for Use in Microanalysis by Infra-Red Spectroscopy . . . . SEYMOUR H. WOLLMAN 220
Octane Vapor Proportional Counter . . . . R. P. PEPPER 222

Regular Features:

New Materials 223
New Instruments 224
Index to Advertisers xlvi

APRIL, 1949

Errors in Second-Order Measuring Instruments . . . . ELLIOT T. BENEDIKT 229
Design and Performance of a Multicellular Geiger Counter for Gamma-Radiation . . . . DAVID A. LIND 233
Maxwell Bridge at Low Frequencies . . . . VINTON A. BROWN AND B. P. RAMSAY 236
Methods for Reducing Insulator Noise and Leakage . . . . F. M. GLASS 239
Conversion of a Motor Generator into a Low Noise Power Amplifier . . . . H. S. SOMMERS, JR., P. R. WEISS, AND W. HALPERN 244
Wide Range Capacitance-Conductance Bridge . . ROBERT H. COLE AND PAUL M. GROSS, JR. 252
Interferometric Study of Supersonic Channel Flow . . . . DANIEL BERSHADER 260
Cloud-Chamber Equipment for Study of Infrequent Cosmic-Ray Processes . . . . W. Y. CHANG AND J. R. WINCKLER 276
Magnetic Deflector for Mesons Produced in the 184-Inch Cyclotron . . . . WOLFGANG K. H. PANOFSKY AND ERNEST A. MARTINELLI 286
Pressure Regulated Thin Window Geiger-Mueller Counter . . . . MICHEL TER-POGOSSIAN, J. EUGENE ROBINSON, AND J. TOWNSEND 289
Electronic Apparatus for the Determination of the Physical Properties of Freely Falling Raindrops . . . . ROSS GUNN 291
Large Mass Spectrometer Employing Crossed Electric and Magnetic Fields . . . . THOMAS MARINER AND WALKER BLEAKNEY 297
Novel Recording Accelerometer . . . . ARTHUR S. IBERALL 304
Book Reviews 308
Author Index to Books Reviewed 317
Other Books Received 317

Laboratory and Shop Notes:

Electron Trajectories in a Gamma-Ray Spectrometer . . . H. Hurwitz, Jr. 318

Timer for Short Intervals . . . R. StuÀrt Mackay 318

New Discharge Tube for the Hydrogen Atom Spectrum . . W. P. van Oort and C. S. van Heel 319

Improving the Response Characteristic of Graphic Recorders . . P. G. Sulzer and A. H. Waynick 320

Vacuum Tube Relay for Thermostat Control . . . I. Sucher and H. S. Anker 321

Accurate, Simple Recording Microphotometer . . . P. Rosenblum and A. deBretteville, Jr. 321

Vacuum-Tube Current Integrator of Improved Design . . . L. H. v. d. Tweel 323

Modification of the Gouy Modulator . . . L. S. Darken 323

Flexible Vacuum Seal . . . Otto Retzloff 324

Device for Producing an Easily Identified Area on the Electron Microscope Specimen Screen . . . Francis W. Bishop 324

Current Integrator . . . H. T. Gittings, Jr. 325

Regular Features:

New Instruments . . . 326

New Materials . . . 331

Index to Advertisers . . . xlviii

May, 1949

Mass Spectrometer for Continuous Gas Analysis . . . Jack A. Hunter, Ralph W. Stacy, and Fred A. Hitchcock 333

Microwave Polarimeter . . . Alfred E. Schwaneke and Zaboj V. Harvalik 337

Photomicrography of Tracks in Nuclear Research Emulsions . . . Adair Morrison and Fred Morton 341

High Temperature X-Ray Diffraction Camera . . . James W. Edwards, Rudolph Speiser, and Herrick L. Johnston 343

Methane Flow Beta-Proportional Counter . . William Bernstein and Robert Ballentine 347

Ionization Flame Detectors . . . Hartwell F. Calcote 349

Experiments in the Possibility of Increasing the Efficiency of Gamma-Counters . . . Hilding Slätis 353

Improved Low Angle X-Ray Diffraction Camera . Barbara A. Wright and Peter A. Cole 355

PHYSICAL INSTRUMENTS FOR THE BIOLOGIST

Simple Calorimeter for the Simultaneous Determination of Heat Loss and Heat Production in Animals . . . Lawrence R. Prouty, Martha J. Barrett, and James D. Hardy 357

Laboratory and Shop Notes:

New Vacuum Gauge . . . Carlton F. Johnson 364

Simple Electronic Relay . . . Robert H. Linnell and Helmut M. Haendler 364

Apparatus for Producing Powder-Like X-Ray Diffraction Patterns from Single Crystals . . . F. W. Matthews and A. O. McIntosh 365

Large Straight Through Vacuum Valve for Van de Graaff Generators . . . B. Jennings 366

Cells Drawn from Tantalum, Molybdenum, and Platinum for High Temperature Research . . . George W. Ziegler, Jr., Rudolph Speiser, and Herrick L. Johnston 367

Non-Uniform Shrinkage of X-Ray Films . . . M. H. Jellinek 368

Use of Gas Traps in Barometers, Laboratory Mercury Lamps, etc. . . . E. L. Harrington 368

Vibration Absorber for Gas Holders . . . R. S. Craig and W. E. Wallace 369

Construction of Beta-Geiger Counters from Prefabricated Thin Wall Tubing . . . F. E. Senftle, W. Havercroft, and P. Hernandez 370

Percent Transmission Computer for Infra-Red Spectra . . . C. E. Zerwekh, Jr. 371

Use of Anodized Aluminum in the Construction of Calorimeter Heaters . . George W. Murphy 372

Method for Preparing Capillary Tube Samples for X-Ray Diffraction Powder Analysis . . . Paul J. Hagelston and Harris W. Dunn 373

Regular Features:

New Instruments . . . 374

New Materials . . . 379

Index to Advertisers . . . xlviii

June, 1949

Further Improvements in Magnetic Focusing . . Larkin Kerwin and Claude Geoffrion 381

Regulation of Temperature in the Application of High Frequency Induction Heating to Thermodynamic Measurements . . . Rudolph Speiser, George W. Ziegler, Jr., and Herrick L. Johnston 385

Instrumentation for Nuclear Studies with Externally Focused Deuteron Beam from Ten-Mev Cyclotron . . . B. R. Curtis, J. L. Fowler, and L. Rosen 388

New Method of Measuring the Stopping Power of Several Materials for Alpha-Particles . . . F. Emmett Hammer and Frank E. Hoecker 394

Cloud Chamber of Light Weight for Balloon Flights . . . R. P. Shutt, A. L. Johnson, and A. M. Thorndike 398
Magnetic Field Strength Meter Using the Proton Magnetic Moment . . . N. J. Hopkins 401
22-Inch Wilson Cloud Chamber in a Magnetic Field of 21,700 Gauss . . . Wilson M. Powell 403
Magnet Coils . L. G. Coonrod, W. E. Cecconi, C. Gedraitis, K. R. Harper, and R. M. Lewis 408
Counter Controllable High Pressure Cloud Chamber . . . G. E. Valley and J. A. Vitale 411
Differential Counting with Reversible Decade Counting Circuits . . Frederick H. Martens 424
Measurement of the Series-Resonant Resistance of a Quartz Crystal . . . L. A. Rosenthal and T. A. Peterson, Jr. 426
New High Sensitivity Remanent Magnetometer . . . Ellis A. Johnson, Thomas Murphy, and P. F. Michelsen 429
Effect of Temperature on the Steady-State Sensitivity of Vacuum Radiation Detectors . . . I. Amdur and N. L. Brown 435

PHYSICAL INSTRUMENTS FOR THE BIOLOGIST

Modified String Flowmeter for Measuring Breath Velocity . . H. Specht and H. F. Brubach 442
Erratum . . . 447

Book Reviews . . . 448
- Author Index to Books Reviewed . . . 456
- Other Books Received . . . 456

Laboratory and Shop Notes:

- Lead-In Seals for Kinetic High Vacuum Systems Using Rubbers . . . Ralph C. Taylor and Carnot W. Ward 457
- Measurement of the Thickness of Thin Nylon Films . . . A. I. McPherson and D. G. Douglas 457
- Ultimate Vacua of Diffusion Pumps . . . G. W. Sears 458
- Device for Producing Rate-Proportional Damping Signal in Servo Systems . . . L. W. Herscher 459

Regular Features:

- New Instruments . . . 459
- New Materials . . . 465
- Index to Advertisers . . . xlii

July, 1949

Direct Reading Pulse Length Meter and Shape Analyzer . . . Robert Rudin 467
Design for a Metal Mass Spectrometer Tube . . . W. M. Hickam 472
Rotor Balancing with an Electronic Capacitor Gauge . . . H. D. Warshaw 474
Counting Volume of a Cylindrical Ionization Chamber . . . Nelson M. Blachman 477
Instrument for Rapid Determination of Crystal Orientation . . . R. H. Gillette and M. H. Jellinek 480
Erratum: A New Discharge Tube for the Hydrogen Atom Spectrum . . . W. P. van Oort and A. C. S. van Heel 479
Characteristics of Halogen Counters . . . Sidney H. Liebson 483
Circuit for the Study of the Operation of the Geiger-Müller Counter . . . Mario Alves Guimarães and Palmyra Amazonas Sampaio 485
Magnetic Susceptibility Balance for Use at Liquid Helium Temperatures . . . T. R. McGuire and C. T. Lane 489
Large Cloud Chamber Using Rear Illumination . . . E. W. Cowan 492
Ten-Channel Electrostatic Pulse Analyzer . . . Dean A. Watkins 495
Precision Automatic Electrometer . . . N. T. Seaton 500
New Technique for the Determination of Heats of Sublimation of Slightly Volatile Substances . . . O. C. Simpson and R. J. Thorn 504
Measurement of the Spin of a Projectile in Flight . . . H. D. Warshaw 507
Stress-Strain-Time Apparatus for Fiber Testing . . . C. H. Reichardt, H. Scharvitz, and J. H. Dillon 509
Amplitude Bridge for Detection of Nuclear Resonance . H. A. Thomas and R. D. Huntoon 516

PHYSICAL INSTRUMENTS FOR THE BIOLOGIST

Cardiotachometer Based on the Plethysmogram . . . E. E. Suckling 518
Syringe Oxygen Cathode for Measurement of Oxygen Tension in Solution and in Respiratory Gases . . . Julian M. Tobias and Nadine Retondo 519

Laboratory and Shop Notes:

Dry Box for Handling Alkali Metals and Other Extremely Hygroscopic Materials . . . . Eugene E. Ketchen, Forrest A. Trumbore, W. E. Wallace, and R. S. Craig 524
Several Improvements on the "Philip's Gauge" . . . C. Hayashi, K. Hashimoto, K. Kaneki, K. Okamoto, and R. Sagane 524
Some Statistical Considerations on Coincidence Counting . . . . Arthur Sard and R. D. Sard 526
Instrument for Measuring Curvature of Cloud-Chamber Tracks . . . E. R. Gaerttner and M. L. Yeater 526
Cadmium Trap for Arresting Mercury Vapor . . . T. Wilner 527
Device to Deposit Automatically the Proper Thickness of Metals Used in Shadow-Casting in Electron Microscopy . . . Francis W. Bishop 527
Technique for the Production of Silica-Filmed Electron Microscope Screens in Quantity . . . Francis W. Bishop 529
Pantograph and Tilting Stage for Use with Nuclear Plates . . . Ian Barbour 530
Simple Punch for Precision Cutting of Photographic Film in a Cylindrical X-Ray Diffraction Camera . . . E. J. Grill and A. H. Weber 532
Magnetic Beam-Splitting Focusing Device for the Electron Microscope . . . Francis W. Bishop 532
Vibration Detection by a Quartz Oscillator . . . Y. L. Yousef and F. Sultan 533
Lead Brick for Shielding . . . Luther E. Preuss 534

Regular Features:

New Instruments . . . 535
New Materials . . . 539
Index to Advertisers . . . xxxviii

AUGUST, 1949

Precision Vacuum Gauge . . . G. C. Fryburg and J. H. Simons 541
Scintillation Counter. I. The Existence of Plateaus . . . Lawrence B. Robinson and James R. Arnold 549
Use of Multigrid Tubes as Electrometers . . . J. R. Prescott 553
High Current Ion Source . . . Richard B. Setlow 558
Scintillation Counter for Laboratory Counting of Alpha-Particles . . . J. D. Graves and J. P. Dyson 560
Improved Synchronous Detector . . . Walter C. Michels and Esther D. Redding 566
Counting with Geiger Counters . . . Homer E. Newell, Jr. and Eleanor C. Pressly 568
Sample Scanning Mechanism for X-Ray Diffraction . J. W. Hickman and A. G. Kleinknecht 573
Design of Equipment for Thermal Studies . . . Robert J. Teitel 575
Preparation and Use of Tritium and Deuterium Targets . . . E. R. Graves, A. A. Rodrigues, M. Goldblatt, and D. I. Meyer 579
Microsampling and Microanalysis of Metals . Donald F. Clifton and Cyril Stanley Smith 583
Transistor Trigger Circuit . . . Herbert J. Reich and Robert L. Ungvary 586
Fast Recycling Cloud Chamber and Pulsed Magnetic Field Equipment for Use with Pulsed Accelerators . . . E. R. Gaerttner and M. L. Yeater 588
Dynamics of a Synchrotron with Straight Sections . . . Nelson M. Blachman and Ernest D. Courant 596
Operational Features of a New Electron Diffraction Unit . . . Robert G. Picard, Perry C. Smith, and John H. Reisner 601
Erratum: Conditions for Optimum Luminosity and Energy Resolution in an Axial β-Ray Spectrometer with Homogeneous Magnetic Field . . . Jesse W. M. DuMond 616

PHYSICAL INSTRUMENTS FOR THE BIOLOGIST

Frequency Analyzer for Bioelectric Potentials in the Sub-Audio Range . . . Charles Markey, Robert L. Schoenfeld, and Paul F. A. Hoefer 612
Apparatus for Electrode Reversal in the Tiselius Electrophoresis Equipment . . . H. Tint 617

Laboratory and Shop Notes:

"Opener-Upper" for Gas Samples . . . Francis J. Norton 620
System for Preparing Semitransparent Mirrors . . . Claude Frémont 620
Method of Asymmetrical Pulse Duration Modulation . . . Richard John Watts 622
Note on the Preparation of Uniform Metallic Foils . . . S. D. Warshaw 623
Note on Removing the Deuteron-Induced Color from Quartz Target Plates . . . A. A. Schulke and R. E. Nuelle 623
Welder for Attaching Fine Wires to Massive Metal Bodies . . . W. J. Trott 624

New Instruments . . . 625
New Materials . . . 631
Index to Advertisers . . . xliv

SEPTEMBER, 1949

Operation of Voltage-Stabilizing Elements with Current-Stabilized Supplies . . . . J. J. GILVARRY AND D. F. RUTLAND 633
Optimum Conditions for a 180° Beta-Ray Spectrometer . . . . CLAUDE GEOFFRION 638
Calibration of Photographic Emulsions for Low Energy Electrons . . . . L. CRANBERG AND J. HALPERN 641
Microwave Secondary Electron Multiplier . . . . M. H. GREENBLATT 646
Theoretical Background of the Multiple Pressure Tube Anemometer . . . . PAUL R. GOUDY AND HENRY F. COLVIN III 651
Detection of Ca^{45}, I^{131}, P^{32}, and Zn^{65} by Photographic Film . . . . DANIEL STEINBERG AND A. K. SOLOMON 655
Inductance Apparatus for Diamagnetic Measurements . . . . S. BROERSMA 660
Tachometer . . . . A. E. BENFIELD 663
Wet Bulb Temperatures without a Wick . . . . KENNETH H. JEHN 668
Electrolytic Thermistors . . . . F. GUTMANN AND L. M. SIMMONS 674

PHYSICAL INSTRUMENTS FOR THE BIOLOGIST

Versatile Microinjection and Micropipetting Syringe . . . . JOHN B. BUCK 676
Direct Experimental Comparison of Several Surface Temperature Measuring Devices . . . . ALICE M. STOLL AND JAMES D. HARDY 678

Book Reviews 687
- **Author Index to Books Reviewed** 695
- **Other Books Received** 695

Laboratory and Shop Notes:

- **Modification of X-Ray Diffraction Micro-Camera to Permit Study of Long Spacings** . . . . M. E. BERGMANN AND I. FANKUCHEN 696
- **High Power Short Duration Spark Discharge** . . . . LESLIE S. G. KOVÁSZNAY 696
- **Simple Stable D.C. Amplifier for Measurement of Bioelectric Potentials** . . . JOHN W. MOORE 698
- **Geiger Tube Quenching Circuit for a Negative High Voltage Supply** . . RICHARD JOHN WATTS 699
- **Extended Range D.C. Bias Control of Thyratron Plate Current** . . . . LEONARD REIFFEL 699

Regular Features:

- **New Instruments** 702
- **New Materials** 707
- **Index to Advertisers** xlii

OCTOBER, 1949

Wide Range Radiation Instrument . . . . LEONARD REIFFEL AND GLENN BURGWALD 711
Variable Temperature Dielectric Cell of Wide Frequency Range for Solids and Liquids . . . . EDWARD B. BAKER 716
Automatic Scanning and Recording Photometer for Night Sky Studies . . . . DOUGLAS MARLOW AND J. C. PEMBERTON 724
Stabilized High Voltage Power Supply for Electrostatic Analyzer . . . . R. L. HENKEL AND B. PETREE 729
Low Temperature Single Crystal X-Ray Diffraction Technique . . . . H. S. KAUFMAN AND I. FANKUCHEN 733
Construction and Calibration of a Cylindrical Electrostatic Analyzer . . . . . S. K. ALLISON, S. P. FRANKEL, T. A. HALL, J. H. MONTAGUE, A. H. MORRISH, AND S. D. WARSHAW 735

Laboratory and Shop Notes:

- **Effect of Space Charge on the Focusing Properties of a 180° Mass Spectrometer** . . . . CHARLES F. ROBINSON 745
- **Vacuum Lock for Continuously Evacuated Systems** . . . . D. SAXON AND J. RICHARDS 745
- **Electronic Instrument for Rapidly Tracing the Plateaux of G-M Counters** . . . . . . G. H. VAZE 746
- **Empirical Balancing Procedure for FP-54** . . . . F. C. ARMISTEAD 747
- **Electrometer Amplifier** . . . . V. J. CALDECOURT 748
- **Improved Magnetic Focusing of Charged Particles** . . . . H. HINTENBERGER 748
- **Mercury Vapor Trap to Protect Laboratory Workers** . . . . JAMES J. BROPHY 750
- **Improved Multivibrator Quenching Circuit** . . . . C. V. ROBINSON 750
- **Note on the Accuracy of the Buerger Precession Camera** . . . . HOWARD T. EVANS, JR. 751
- **Equipment for Measuring Light Scattering** . . . . M. BIER AND F. F. NORD 752
- **Absorption Corrections in X-Ray Studies of Preferred Orientation** . . . . . . J. F. H. CUSTERS 752

Regular Features:

- **New Instruments** 753
- **New Materials** 759
- **Index to Advertisers** xlvi

November, 1949

New Type of Diffusion Pump . . . E. L. Harrington 761
X-Ray Camera for Obtaining Powder Pictures at High Pressures . . . A. W. Lawson and N. A. Riley 763
Fast Neutron Detector . . . W. G. Moulton and C. W. Sherwin 766
Instrumental Distortions in the Shapes of Continuous Beta-Spectra . . . George E. Owen and C. Sharp Cook 768
Simplified Emission Regulator for Mass-Spectrometer Ion Sources . . . E. B. Winn and Alfred O. Nier 773

Orbital Stability in a Proton Synchrotron[*]

R. Q. Twiss and N. H. Frank[**]
Research Laboratory of Electronics, Massachusetts Institute of Technology, Cambridge, Massachusetts

(Received May 27, 1948)

The theory of the electron synchrotron has been amply covered elsewhere, but the proton synchrotron exhibits a number of distinct but important differences particularly at low energies. In the present paper the theory for this latter accelerator is developed with particular reference to the problems of injection and stability in the initial acceleration period. This theory is used to set up criteria relating the dimensions of a proton synchrotron to the conditions for stability and to the beam intensities obtainable.

I. INTRODUCTION

The theory of orbital stability in an electron synchrotron has been discussed by a number of writers.[1] Since the energies of the electrons which are accelerated by synchrotron action lie in the extreme relativistic range, attention has been focused largely on the case where the electron speeds are very close to that of light. There then result a number of simplifications of the general theory; in particular, the frequency of the accelerating r-f voltage may be taken as constant. In the proton synchrotron, however, particles are to be accelerated from initial energies, small compared to their rest energy, and hence the frequency of the accelerating voltage must be increased monotonically and synchronously with an increasing magnetic field. It is just this last feature which chiefly distinguishes the proton from the electron synchrotron, and requires that particular attention be given to the effects on the particle motions of departures from the desired time dependence of radio frequency.

No attempt will be made here to describe the basic principles in detail as these have been amply covered in the papers on the synchrotron listed in reference 1. However, an outline of the process by which the equations of motion are derived will be presented. In order to simplify reference to previous publications, the notation employed here will conform, as far as practicable, to that employed by one of us[2] in an article on the electron synchrotron. An analysis of the proton synchrotron has been presented by a group[3] working at Dr. Oliphant's Laboratory at Birmingham, England.

II. THE EQUATIONS OF MOTION

It has been shown[2] that the equations of motion of a charged particle in an axially symmetric magnetic field $\mathbf{B}=(-B_r, 0, -B_z)$ are

$$\left.\begin{aligned} d/dt(m\dot r) &= mr\dot\theta^2 - er\dot\theta B_z, \\ d/dt[mr^2\dot\theta - (e\Phi/2\pi)] & \\ &= (eV/2\pi)\sin\left(\theta - \int\omega dt\right), \\ d/dt(m\dot z) &= er\dot\theta B_r, \end{aligned}\right\} \quad (1)$$

where m is the relativistic mass, e the proton charge,

$$\Phi = 2\pi\int_0^r rB_z dr$$

is the total magnetic flux linking a circle of radius r, V and ω are the peak voltage and angular frequency, respectively, of the r-f field across an accelerating gap at $\theta=0$. Radiation effects are omitted since, in the proton case, they are negligible for energies less than 10^5 Mev.

Circular motion in the median plane $z=0$ is possible for the particles if the parameters in these equations vary with time according to certain definite laws. Particles moving in this circle, of radius r_0, will always arrive at the accelerating gap with the same phase ψ_0 relative to that of the accelerating voltage. This quasi-steady motion is given by the equations

$$\left.\begin{aligned} m\dot\theta &= eB_z, \\ d/dt[r_0^2B_0 - (\Phi_0/2\pi)] &= V/2\pi \sin\psi_0, \\ \psi_0 &= \theta - \int\omega dt. \end{aligned}\right\} \quad (2)$$

Here B_0 and Φ_0 are the magnetic field at, and the flux linking, the circular orbit of radius r_0.

From these equations there follow directly expressions for the kinetic energy E and the required angular radiofrequency ω_0 in terms of B_0 and r_0. They are

$$\left.\begin{aligned} E/m_0c^2 &= (1+(eB_0r_0/m_0c)^2)^{\frac{1}{2}} - 1, \\ r_0\omega_0/c &= \frac{(eB_0r_0/m_0c)}{(1+(eB_0r_0/m_0c)^2)^{\frac{1}{2}}}, \\ m\omega_0 &= eB_0, \end{aligned}\right\} \quad (3)$$

where, for protons, $m_0c^2=938$ Mev. These expressions are plotted as functions of eB_0r_0/m_0c in Figs. 1 and 2. To provide an idea of the orders of magnitude involved, there are presented, in Table I, the design data for a proton synchrotron intended to yield particles of 10^4-Mev energy.

If the machine is to be run during any part of its operating cycle as a betatron with no r-f acceleration, the particles will remain in a stable circular orbit of radius r_0 if

$$r_0^2B_0 = \int_0^{r_0} B_z r dr, \quad (4)$$

the well-known betatron condition.

To find the oscillations about the stable orbit and phase in the general case one sets

$$\left.\begin{aligned} r &= r_0 + x, \\ \omega &= \omega_0 + \omega_1, \\ \dot\psi &= \dot\theta - \omega = \dot\varphi - \omega_1, \end{aligned}\right\} \quad (5)$$

where ω_1 is the departure of the angular radiofrequency from its correct value ω_0, and $\dot\varphi$ is the perturbation in the particle angular velocity caused by the correct r-f field. We take x, ω_1, and $\dot\varphi$ as first-order small quantities, the squares and products of which will be neglected.

If the vertical magnetic field B_z in the median plane $z=0$ decreases with radius in the neighborhood of r_0 according to the law

$$B_z = B_0(r/r_0)^{-n}, \quad (6)$$

then n must satisfy the inequality

$$0<n<1,$$

if the orbit r_0 is to be stable for both vertical and radial oscillations. In the following it will be assumed that n is independent of r.

Substituting from (5) and (6) into (1), for the case when the particle is moving in the plane $z=0$, we obtain, after some algebraic manipulation, the following equations describing the phase and radial oscillations:

$$\left.\begin{aligned} \frac{d}{dt}\left(\frac{B_0\dot x}{\omega_0}\right) &= r_0\omega_0B_0\left\{\left(\frac{eB_0}{m_0\omega_0}\right)^2 - (1-n)\right\} \\ &\qquad\times\left\{\frac{x}{r_0} + \eta\frac{\dot\varphi}{\omega_0}\right\}, \\ \frac{d}{dt}\left[\frac{r_0}{\omega_0}\frac{d}{dt}\left(\frac{B_0\dot x}{\omega_0}\right) + (1-n)r_0B_0x\right] & \\ &\qquad + \frac{V\sin\psi_0}{2\pi} = \frac{V\sin\psi}{2\pi}, \end{aligned}\right\} \quad (7)$$

where

$$\eta = \frac{(eB_0/m_0\omega_0)^2}{(eB_0/m_0\omega_0)^2-(1-n)} = \frac{(m/m_0)^2}{(m/m_0)^2-(1-n)}, \tag{8}$$

with m the relativistic and m_0 the rest mass of the particle, respectively.

From Eq. (8), it is clear that η is a very slowly varying function of time, decreasing monotonically from $1/n$ to 1 as the particle kinetic energy increases from zero to infinity. In the nonrelativistic range of energies, it may be taken as constant and equal to $1/n$. In Fig. 3 η is plotted as a function of eB_0r_0/m_0c.

In the important case where the inequality

$$\frac{4V}{2\pi r_0^2 B_0\omega_0\eta(1-n)^2} \ll 1 \tag{9}$$

is satisfied, the equations of motion (7) can be regarded as describing two independent oscillations; the so-called betatron oscillations, which are independent of V, satisfy the pair of equations

$$\left.\begin{aligned} x/r_0+\dot{\varphi}/\omega_0&=0,\\ \frac{d}{dt}\left(\frac{B_0\dot{x}}{\omega_0}\right)+(1-n)\omega_0B_0x&=0,\end{aligned}\right\} \tag{10}$$

for those particles, the angular momenta of which are such that they can perform stable betatron motion in the circle of radius r_0. The much lower frequency forced oscillations known as the synchrotron oscillations satisfy the following pair of equations:

$$\left.\begin{aligned} x/r_0+\eta(\dot{\varphi}/\omega_0)&=0,\\ (1-n)r_0^2\frac{d}{dt}\left(\eta\frac{B_0}{\omega_0}\dot{\varphi}\right)+\frac{V}{2\pi}\sin\psi&=\frac{V}{2\pi}\sin\psi_0,\\ \dot{\varphi}&=\psi+\omega_1.\end{aligned}\right\} \tag{11}$$

TABLE I. Preliminary design data for a 10-Bev proton synchrotron.

Final energy of the protons	10 Bev
Injection energy of the protons	4 Mev
Orbital radius	24.3 meters
Final magnetic field at orbit	15,000 gauss
Magnetic field at orbit at injection	110 gauss
Final radiofrequency	1.96 Mc/sec.
Radiofrequency at injection	183 kc/sec.
Frequency range	10.65 to 1
Acceleration period	1 second
Average energy gain per revolution	5500 ev

When the inequality (9) is not fully satisfied, the two oscillations are coupled, but the effect

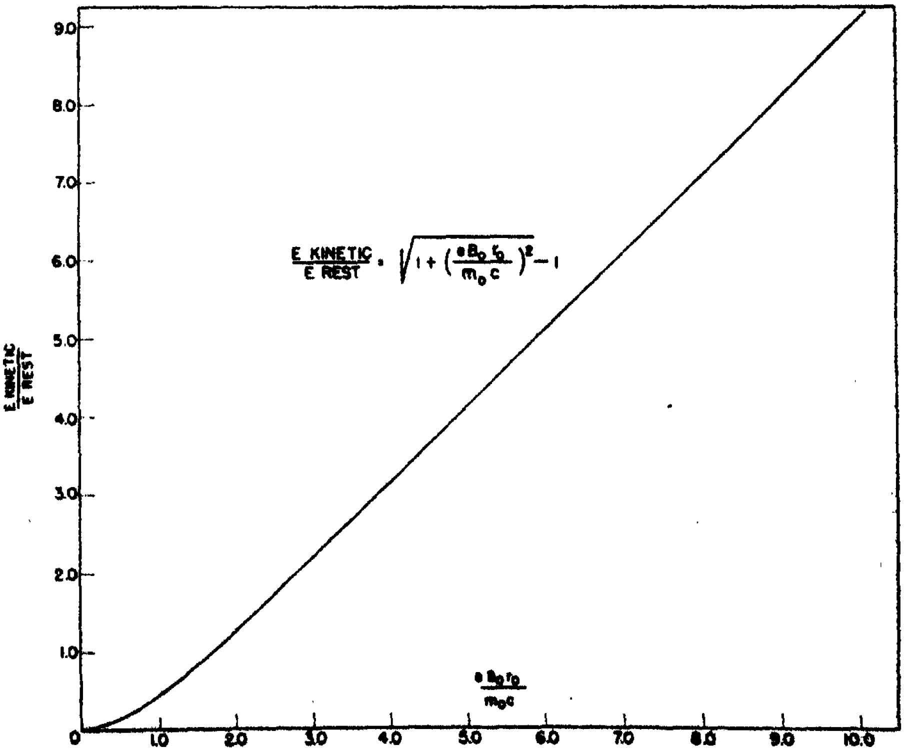

FIG. 1. Kinetic energy of particles as a function of magnetic field.

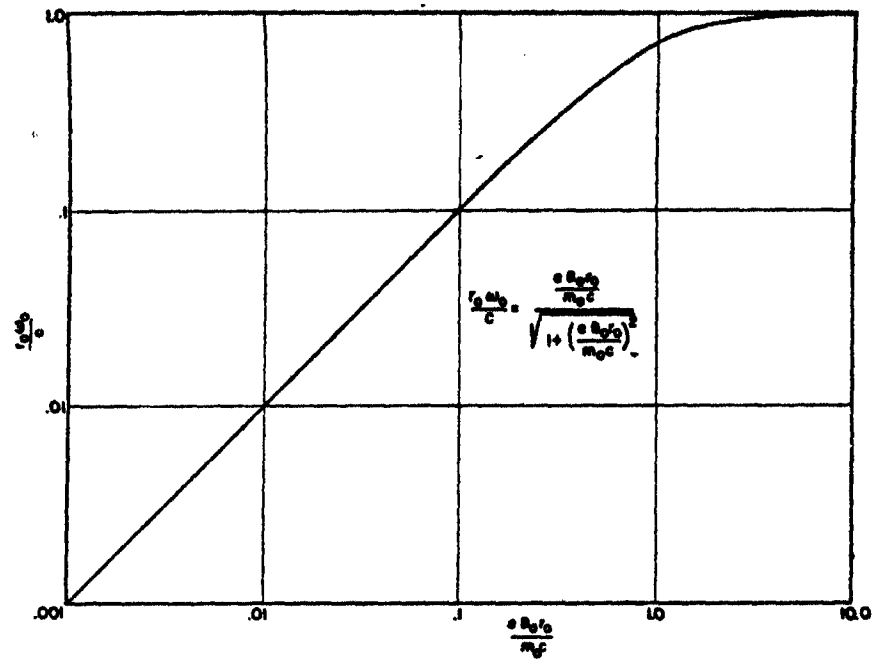

FIG. 2. Angular velocity of particle as a function of magnetic field.

of the small coupling term thus obtained is also small and does not modify appreciably the physical behavior of the protons in the accelerating chamber.

Equations (10) are the well-known equations of oscillation for betatron particles with both B_0 and ω_0 slowly varying functions of the time. The radial oscillations are essentially sinusoidal oscillations of slowly varying frequency $(1-n)^{\frac{1}{2}}\omega_0$ and amplitude which is damped proportional to $B_0^{-\frac{1}{2}}$. Thus, if x_i and $\dot{x}_i$ are the initial values of x and $\dot{x}$, respectively,[***]

$$x(t)=\left(\frac{B_i}{B_0}\right)^{\frac{1}{2}}\left[x_i\cos\left((1-n)^{\frac{1}{2}}\int\omega_0dt\right)\right.$$
$$\left.+\frac{\dot{x}_i}{(1-n)^{\frac{1}{2}}\omega_i}\sin\left((1-n)^{\frac{1}{2}}\int\omega_0dt\right)\right],\quad(12)$$

where ω_i and B_i are initial values. In view of the fact that the betatron oscillations have been fully analyzed elsewhere, (see reference 1) no further discussion of them will be given here and we shall concern ourselves with Eq. (11).

The equation that determines the phase oscillations may be written in the form:

$$(1-n)r_0^2\frac{d}{dt}\left(\frac{B_0}{\omega_0}\eta-\dot{\varphi}\right)+\frac{V}{2\pi}\sin\psi$$
$$=\frac{V}{2\pi}\sin\psi_0-(1-n)r_0^2\frac{d}{dt}\left(\eta\frac{B_0\omega_1}{\omega_0}\right).\quad(13)$$

In general, B_0, ω_0, η, V, and ψ_0 will be slowly varying functions of the time. We exclude for the present the exceptional case of transition from betatron to synchrotron operation, during which V and ψ_0 may vary in a manner which cannot be considered slow. Following McMillan, one may interpret Eq. (13) as the equation of motion of a circular pendulum of slowly varying mass and length, acted on by a unidirectional tangential force together with an irregular forcing term depending on $d\omega_1/dt$. The motion of such a pendulum will be oscillatory if ψ never exceeds the critical angle $\pi-\psi_0$. If it does, the motion will be rotatory in an anticlockwise direction with increasing angular speed under the action of the forcing term $(V/2\pi)\sin\psi_0$. Physically, the particle slips in phase relative to the accelerating voltage and moves continuously from an accelerating to a decelerating phase and back to an accelerating phase, repeating this process. It thus gains no energy from the r-f voltage on the average. The magnetic field, however, is increasing continuously and hence the particle orbit shrinks inward until the particle is lost to the walls, according to the first of Eqs. (11).

[***] x_i is measured from that orbit radius which corresponds exactly to the initial kinetic energy.

III. THE NATURE OF THE SYNCHROTRON OSCILLATIONS

1. Conditions of Acceptance of a Particle into the Acceleration Cycle

Since a necessary condition for continuous acceleration of a particle is that its phase may not exceed $\pi-\psi_0$, restrictions on the initial phase and phase velocity with which a particle is injected into the synchrotron accelerating cycle follow therefrom. An exact calculation would require knowledge of the time variations of η, B_0, ω_1, and V. However, sufficiently accurate information can be obtained by taking $\omega_1=0$ and neglecting the time dependence of η, B_0, ω_0, and V. (This is particularly the case during the initial non-relativistic stages of operation if the magnetic field varies linearly with the time when $\eta B_0/\omega_0$ is constant.)

A first integral of (13) can now be obtained as

$$\dot{\psi}^2=\frac{2\Omega_0^2}{\cos\psi_0}[\cos\psi+\psi\sin\psi_0-\cos\psi_i-\psi_i\sin\psi_0]+\dot{\psi}_i^2, \quad (14)$$

where

$$\Omega_0^2=(V\omega_0\cos\psi_0)/(2\pi r_0^2(1-n)\eta B_0), \quad (15)$$

and ψ_i and $\dot{\psi}_i$ are initial values. Ω_0 is the angular frequency of small synchrotron phase oscillations about the equilibrium phase ψ_0. The equivalent pendulum will oscillate between two limiting values of ψ providing the representative point in phase space lies within the boundary determined by the equation:

$$\cos\psi_i+\psi_i\sin\psi_0-\frac{\dot{\psi}_i^2\cos\psi_0}{2\Omega_0^2}=(\pi-\psi_0)\sin\psi_0-\cos\psi_0. \quad (16)$$

Figure 4 shows the boundary curves for a number of values of ψ_0. The extreme phase angle limits of the oscillatory motion are given by $\psi_1\leq\psi\leq\pi-\psi_0$, where ψ_1 is that solution of

$$\cos\psi_1+\psi_1\sin\psi_0=(\pi-\psi_0)\sin\psi_0-\cos\psi_0,$$

which satisfies the inequality $-\pi\leq\psi_1\leq\psi_0$. In Fig. 5 the total acceptance angle $(\pi-\psi_0-\psi_1)/2\pi$ is shown plotted as a function of ψ_0.

2. Oscillation Periods

Equation (14) cannot be integrated directly except in the special case that $\psi_0=0$. However, it can be integrated numerically for given values of ψ_0, ψ_i, and $\dot{\psi}_i$. In Fig. 6 the normalized oscillation period (the ratio of the period T_0 to $2\pi/\Omega_0$) is plotted as a function of $\psi_i-\psi_0$ for various values of ψ_0 with $\dot{\psi}_i=0$. It will be noted that the period increases monotonically with ψ_i and tends to infinity as ψ_i approaches $\pi-\psi_0$. To get the order of magnitude of the periods involved, we

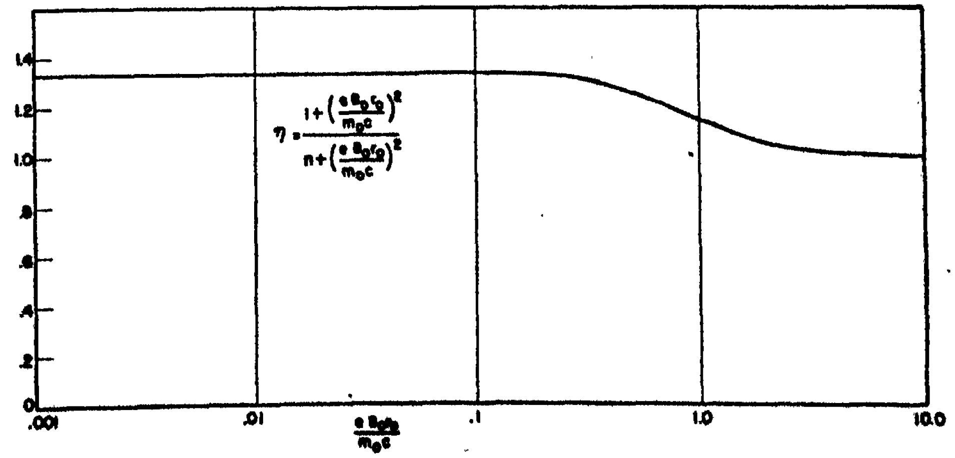

FIG. 3. η as a function of magnetic field.

use the values,

$V = 5500$ volts,
$\omega_0 = 4\pi \times 10^5/\text{sec.}$,
$\psi_0 = \pi/4$,
$n = 3/4$,
$r_0 = 24.3$ m,
$B_0 = 110$ gauss $= 1.1 \times 10^{-2}$ weber/m^2.

This gives $\Omega_0 \cong 2\times 10^{-2}\omega_0 = 8\pi \times 10^3/\text{sec.}$ during the initial stages of operation; i.e., one phase oscillation period occurs in about 50 revolutions of the particle.

3. The Stability of the Phase Oscillations

First consider small oscillations about the equilibrium phase, setting

$$\psi = \psi_0 + \vartheta, \quad \vartheta \ll 1.$$

The equation of undisturbed phase motion becomes

$$\frac{d}{dt}\left(\eta \frac{B_0}{\omega_0}\dot{\vartheta}\right) + \frac{V\cos\psi_0}{2\pi r_0^2(1-n)}\vartheta = 0,$$

and the W.K.B. approximation to the solution of this equation yields

$$\psi = \left(\frac{V\cos\psi_0\eta B_0}{\omega_0}\right)_i^{\frac{1}{4}} \left(\frac{V\cos\psi_0\eta B_0}{\omega_0}\right)^{-\frac{1}{4}} \times \left\{\vartheta_i \cos\int \Omega_0 dt + \frac{\dot{\vartheta}_i}{\Omega_i}\sin\int \Omega_0 dt\right\}, \quad (17)$$

with $\vartheta_i = \psi_i - \psi_0$ and $\dot{\vartheta}_i = -\omega_0 x_i / r_0 \eta$; x_i is the initial radial distance of the mean betatron orbit from the stable synchrotron orbit.

Thus the amplitude A of the phase oscillations varies as

$$A \sim \left(\frac{V\cos\psi_0\eta B_0}{\omega_0}\right)^{-\frac{1}{4}}, \quad (18)$$

where

$$V\sin\psi_0 = d/dt[r_0^2 B_0 - (\Phi_0/2\pi)]. \quad (19)$$

Since $\Phi_0/\dot{B}_0$ will be essentially constant, independent of time, one may write alternatively,

$$A \sim [\eta(\dot{B}_0 B_0/\omega_0)\cot\psi_0]^{-\frac{1}{4}}. \quad (20)$$

The two limiting cases of the non-relativistic motion with $m = m_0$ and the extreme relativistic case with the particle speed practically equal to that of light are of particular interest.

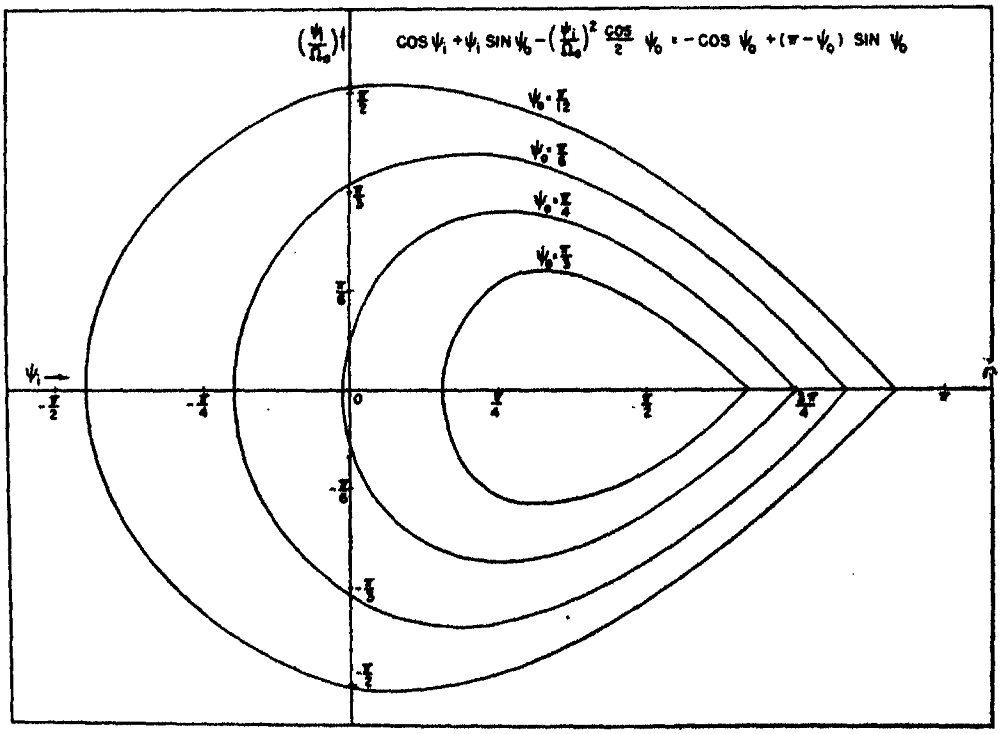

FIG. 4. The acceptance domain in phase space at injection for various values of stable phase ψ_0.

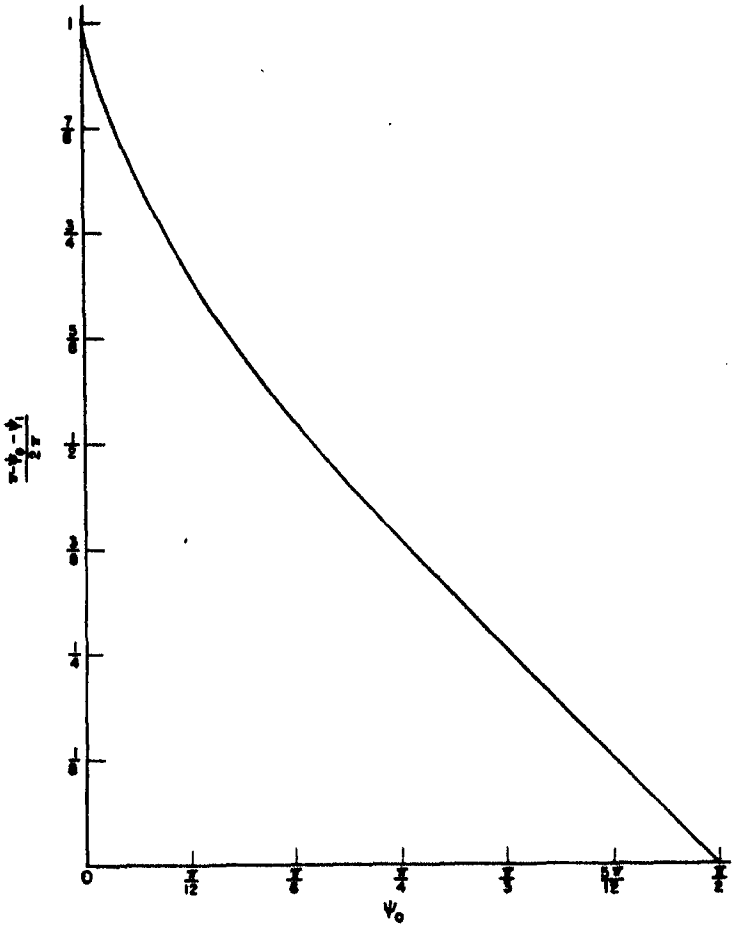

FIG. 5. The normalized injection acceptance angle as a function of the stable phase ψ_0.

The Non-Relativistic Case

In this case $\eta B_0/\psi_0$ is constant and positive amplitude damping will occur only if $V\cos\psi_0$ increases with the time. In practice, $\dot{B}_0$ will increase with time, the initial curvature being due to eddy currents in the magnet core. Injection may occur at the start of this cycle or at any subsequent time. Since $V\sin\psi_0$ is proportional to dB_0/dt, some positive damping can be attained in the early stages of the acceleration cycle even if ψ_0 is kept constant. However, this effect is small and to obtain appreciable damping it is necessary that V be increased more rapidly than $\dot{B}_0$. The effect of the change in ψ_0 is to alter the damping only slightly if $\cos\psi_0$ is near unity.

If V is kept constant, there will be a small increase in oscillation amplitude, proportional to $(\cos\psi_0)^{-\frac{1}{4}}$, so that it is desirable to increase V during the initial non-relativistic stages of acceleration. (A very small additional damping is obtained from the slowly increasing mass during these early stages if $n > \frac{3}{4}$.)

An additional reason for the desirability of positive damping is that of radiofrequency error. Such an error leads to a forcing term $-r_0^2(1-n)(d/dt)(\eta B_0\omega_1/\omega_0)$. The effects of this term will be more or less random, sometimes increasing and sometimes decreasing the oscillation amplitude. As time goes on, there will be an ever-increasing probability that the fluctuating amplitude will exceed the critical limits of Eq. (16) and then the particle will be lost. This probability is of course enormously reduced if steady positive damping is present.

The Extreme Relativistic Case

In this case, ω_0 is constant and the phase oscillation amplitude varies as $(V\cos\psi_0 B_0)^{-\frac{1}{4}}$. The increasing magnetic field provides sufficient damping so that V may be kept constant. As a

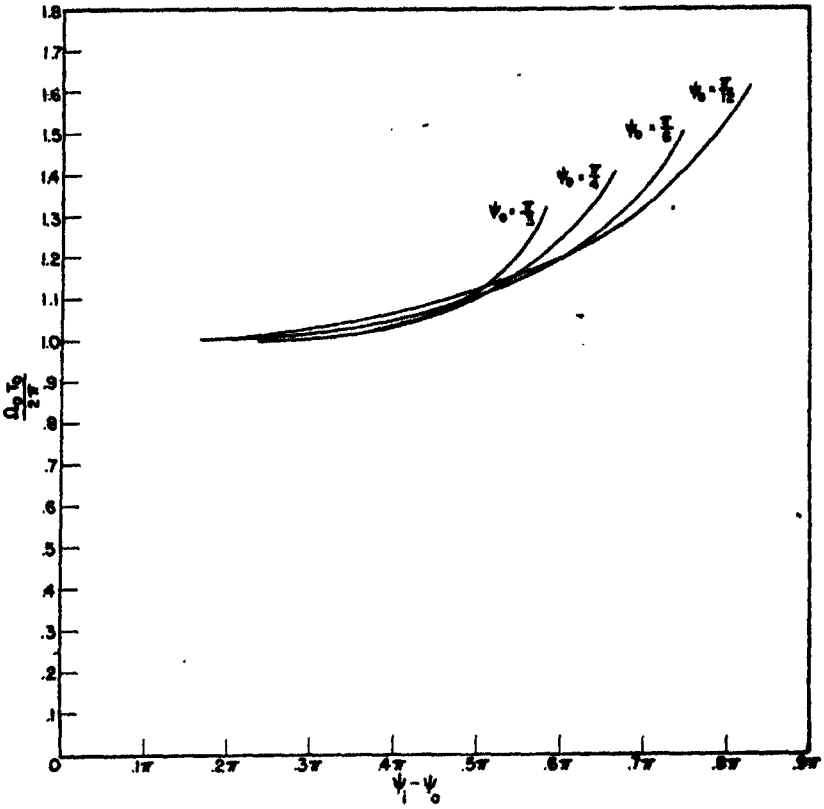

FIG. 6. The period of a synchrotron oscillation as a function of the injection phase.

numerical example of the magnitude of the damping for the whole cycle, we take

$\psi_0=$ constant,
V increasing from 7700 to 10,000 volts,
B_0 increasing from 110 to 15,000 gauss,
$\omega_0/2\pi$ increasing from 180 kc/sec. to 2.00 mc/sec.,
$n=3/4$,
and η decreasing from 4/3 to unity.

Then, according to Eq. (18), the ratio of initial to final amplitude is about 1.9 to 1.

For large amplitudes, the damping may be obtained with the help of the adiabatic theorem. This states that the $\oint p_\psi d\psi$ taken over a complete libration period of ψ is an invariant for slow variations of the parameters in the Hamiltonian of the system, with p_ψ the generalized momentum associated with the coordinate ψ. Now the equation of phase oscillation can be derived from a Lagrangian function

$$L=\frac{1}{2}\left[\frac{r_0^2(1-n)\eta B_0}{\omega_0}\dot{\psi}^2\right]+\frac{V}{2\pi}(\cos\psi+\psi\sin\psi_0),\quad (21)$$

if effects of frequency error are neglected. Hence

$$p_\psi=\frac{\partial L}{\partial\dot{\psi}}=\frac{r_0^2(1-n)\eta B_0\dot{\psi}}{\omega_0},\quad (22)$$

and one has

$$\oint\frac{\eta B_0}{\omega_0}\dot{\psi}d\psi=\text{constant}.$$

If now, at any time, ψ oscillates between ψ_1 and ψ_2, these limiting angles are determined by

$$\int_{\psi_1}^{\psi_2}\left(\frac{\eta B_0 V}{\omega_0\cos\psi_0}\right)^{\frac{1}{2}}[\cos\psi+\psi\sin\psi_0 - \cos\psi_2-\psi_2\sin\psi_0]^{\frac{1}{2}}d\psi=\text{constant},\quad (23)$$

where ψ_1 and ψ_2 are related by

$$\cos\psi_2+\psi_2\sin\psi_0-\cos\psi_1-\psi_1\sin\psi_0=0;$$
$$-\pi<\psi_1<\psi_0<\psi_2<\pi-\psi_0.$$

In the special case $\psi_0=0$, Eq. (23) can be evaluated in terms of complete elliptic functions, and gives

$$k[\sin(\psi_m/2)]=\text{constant }(\omega_0/\eta B_0 V)^{\frac{1}{2}},$$

with $h(k)=E(k)-(1-k^2)K(k)$, K and E being complete elliptic functions of the first and second kind. Figure 7 is a plot of $h(\sin\psi_m/2)$ against ψ_m, the maximum amplitude, and shows that the damping for finite amplitudes is in general less than for small amplitudes in this case.

4. The Stability of the Radial Oscillations

From the solution of the equation for phase oscillations, one obtains the radial oscillations immediately from the first of Eqs. (11). For small oscillations, one has

$$\frac{x}{r_0}=\frac{B_i}{B_0}\frac{(\eta V\cos\psi_0 B_0/\omega_0)^{\frac{1}{4}}}{(\eta V\cos\psi_0 B_0/\omega_0)_i^{\frac{1}{4}}}\times\left\{\frac{x_i}{r_0}\cos\int\Omega_0 dt+\frac{\dot{x}_i}{\Omega_0 r_0}\sin\int\Omega_0 dt\right\},$$

so that the amplitude A is damped according to the law

$$A\sim[\eta(V\cos\psi_0 B_0/\omega_0)]^{\frac{1}{4}}\cdot 1/B_0. \qquad (24)$$

The Non-Relativistic Case

In this case $\eta B_0/\omega_0$ is constant and the radial oscillation amplitude varies as $(V\cos\psi_0)^{\frac{1}{4}}/B_0$. The increase of $V\cos\psi_0$ with time needed to obtain a small phase damping must be less than the increase of $B_0{}^4$ with time to insure positive radial damping. This restriction is purely academic, however, because of the impracticality of attaining such a rapid rate of voltage increase.

The Extreme Relativistic Case

Here ω_0 is constant and the radial oscillation amplitude varies as $(V\cos\psi_0)^{\frac{1}{4}}/B_0{}^{\frac{3}{4}}$. Considering the same numerical example as in the case of phase oscillations, one finds the ratio of initial to final amplitude of radial oscillation to be 48 to 1.

5. The Effects of Frequency Error

From the outset, it should be noted that frequency variations which are rapid compared to the synchrotron oscillations have a negligible effect and will be ignored in the following. Departures in frequency from the correct law affect both the radial and phase motions of the particles. The average position of the particle is displaced according to the formula

$$x/r_0=-\eta(\psi+\omega_1/\omega_0) \quad \text{or} \quad \bar{x}/r_0=-\omega_1\eta/\omega_0. \qquad (25)$$

If this displacement is too great, the particle will be lost to the walls and hence a definite limit exists of the maximum allowed absolute value of the frequency error. With A the *total* oscillation amplitude and $2b$ the width of the accelerating chamber, the fractional frequency error must satisfy the inequality

$$\frac{\omega_1}{\omega_0}<\left(\frac{b-A}{r_0}\right)\frac{1}{\eta}\cong\left(\frac{b-A}{r_0}\right)n \text{ at low energies.} \qquad (26)$$

This requirement is most severe at injection, as then A is a maximum and $1/\eta=n$, a minimum. Thus n should be as large as possible in the proton synchrotron if frequency errors are to be minimized. This is opposite to the betatron case where, to minimize errors in satisfying the betatron flux condition, $(1-n)$ should be large and hence n small.

The general analysis of the effect of frequency error on the phase oscillations is extremely complicated because of the non-linear character of the oscillations. However, the very important practical case of a linear variation with time of the frequency error ω_1 allows a solution. If $\omega_1=\alpha t$, the equation of phase motion becomes

$$r_0{}^2(1-n)\frac{d}{dt}\left(\eta\frac{B_0\dot{\psi}}{\omega_0}\right)+\frac{V}{2\pi}\sin\psi=\frac{V}{2\pi}\sin\psi_0-r_0{}^2(1-n)\frac{d}{dt}\left(\frac{\alpha\eta B_0 t}{\omega_0}\right). \qquad (27)$$

In the low energy range, $\eta B_0/\omega_0$ is constant and (27) takes the form

$$r_0{}^2(1-n)\eta\frac{B_0}{\omega_0}\ddot{\psi}+\frac{V}{2\pi}\sin\psi=\frac{V}{2\pi}\sin\psi_0', \qquad (28)$$

with

$$\frac{V}{2\pi}\sin\psi_0'=\frac{V}{2\pi}\sin\psi_0-\frac{r_0{}^2(1-n)\eta\alpha B_0}{\omega_0}. \qquad (29)$$

Thus the effect of a frequency error is to produce a change in the stable phase angle. This will change the amplitude of oscillation and also alter the limits of stable oscillation from

$$\psi_1<\psi<\pi-\psi_0 \quad \text{to} \quad \psi_1'<\psi<\pi-\psi_0',$$

where

$$\left.\begin{aligned}\cos\psi_1+\psi_1\sin\psi_0&=(\pi-\psi_0)\sin\psi_0-\cos\psi_0,\\ \cos\psi_1'+\psi_1'\sin\psi_0'&=(\pi-\psi_0')\sin\psi_0'-\cos\psi_0'.\end{aligned}\right\} \quad (30)$$

The range of ψ for stable phase oscillations will increase if $|\psi_0'|<\psi_0$, hence if

$$0<\alpha<\frac{\omega_0 V\sin\psi_0}{\pi r_0^2(1-n)\eta B_0}.$$

Thus an increase in radiofrequency from the proper value is less serious than a corresponding decrease. Increasing frequency implies a smaller orbital radius and hence a smaller r-f energy gain per revolution is required to maintain this orbit than an expanded orbit. Particles will be lost if their altered amplitudes exceed the limits of stable phase oscillation corresponding to the new stable phase; i.e., if the representative points in phase space fall outside the appropriate boundary of Fig. 4.

In general the oscillation amplitude will decrease if $|\psi_0'|<\psi_0$, but the amount of this decrease depends on the exact phase when the frequency begins to depart from the correct law. Finally, the speed with which the average radial position follows the frequency change is limited by the period of synchrotron oscillations. Thus essentially no change in radius will occur until an elapsed time equal to an appreciable fraction of the synchrotron period.

As pointed out, a negative frequency error increases the stable phase angle and decreases the stable phase range with a resulting loss of particles.

The principal conclusions may be summarized as follows:

i. The synchrotron oscillation frequency is small compared to the accelerating radiofrequency, from 50–200 times smaller in the case under discussion.

ii. The radial oscillations are heavily damped;

$$A\sim\left(\frac{V\cos\psi_0\eta B_0}{\omega_0}\right)^{\frac{1}{4}}\cdot\frac{1}{B_0}\cong(B_0)^{-\frac{3}{4}}.$$

iii. The phase oscillations are very lightly damped;

$$A\sim\left(\frac{V\cos\psi_0\eta B_0}{\omega_0}\right)^{-\frac{1}{4}}.$$

In the non-relativistic region there is no damping unless V increases with time.

iv. A number of constraints exist on the allowable frequency error. The most important is that the long term error satisfy the inequality

$$\frac{\omega_1}{\omega_0}<\frac{1}{\eta}\left(\frac{b-A}{r_0}\right)\cong n\left(\frac{b-A}{r_0}\right)$$

for the non-relativistic case. This constraint becomes less severe as time increases because A decreases as $1/B_0$.

v. It is desirable to make n as near unity as possible from the standpoint of synchrotron oscillations.

IV. INITIAL BETATRON ACCELERATION

In the majority of existing electron-synchrotrons the machine is operated initially as a betatron in order to obviate the necessity for frequency modulation of the r-f accelerating voltage. It has been suggested that a stage of betatron acceleration be utilized in the proton synchrotron not, of course, to remove the necessity for frequency modulation, but to reduce the range. This will be particularly valuable in a machine that employs a resonant tuned accelerating cavity and yet requires a large accelerating voltage over the whole frequency range. It is correspondingly less useful if an untuned accelerating system is used.

The maximum particle energy attainable in the betatron phase will be determined by economic considerations; the minimum initial energy will depend upon the injection system and will be limited by the necessity of avoiding excessive gas scattering.

There are, however, additional arguments in favor of a betatron acceleration phase, and as some of them are peculiar to the proton synchrotron, they will be discussed in greater detail. It should be emphasized from the outset that we are now only concerned with the case where the betatron phase carries the particles up to energies of a few Mev.

It has been stated above that the amplitude of the horizontal oscillation in a synchrotron is the sum of the high frequency betatron and of the low frequency synchrotron oscillations. If particles are injected into the betatron phase, the low frequency oscillations will not be present, and we can use this fact either to lower the tolerance on the injection energy or to increase the number of particles accepted into the acceleration cycle.

The use of a betatron phase also enables us to get increased phase damping in the early stages. If the r-f voltage be turned on while the betatron condition is satisfied, synchrotron oscillations will take place about a stable phase angle of zero. Under these conditions the stable acceptance angle is equal to 2π. If now the r-f voltage increases linearly with the time to a limiting value V in time T_0, then the particles will be bunched about zero phase.

If

$$\Omega_0^2=\frac{V\omega_0\cos\psi_0}{2\pi r_0^2(1-n)\eta B_0},$$

then the phase of a particle at time T is given by

$$\psi=\frac{\psi_i\Omega_{0i}^{1/3}\Gamma(2/3)}{3^{1/3}T_0^{1/6}}(t)^{1/2}J_{-1/3}\left(\int_0^t\left(\frac{\Omega_0^2\tau}{T_0}\right)^{1/2}d\tau\right),$$

where ψ_i is the injection phase, and we have made the approximate assumption that ψ_i is small. If $T_0\Omega_0$ is $\gg 1$ an asymptotic expansion may be used to yield

$$\frac{\psi_F}{\psi_i}=\frac{1}{(\pi)^{1/2}}\left(\frac{\Omega_{0i}}{\Omega_{0F}}\right)^{1/3}\frac{3^{1/6}\cdot\Gamma(2/3)}{(\Omega_{0F}T_0)^{1/6}}\left(\frac{T_0}{t}\right)^{1/4}$$

$$=\frac{1}{(\pi)^{1/2}}\left(\frac{\Omega_{0i}}{\Omega_{0F}}\right)^{1/3}\frac{3^{1/6}\Gamma(2/3)}{(\Omega_{0F}T_0)^{1/6}}\quad\text{if}\quad t=T_0,\qquad(31)$$

where subscript i refers to initial values and subscript F refers to final values.

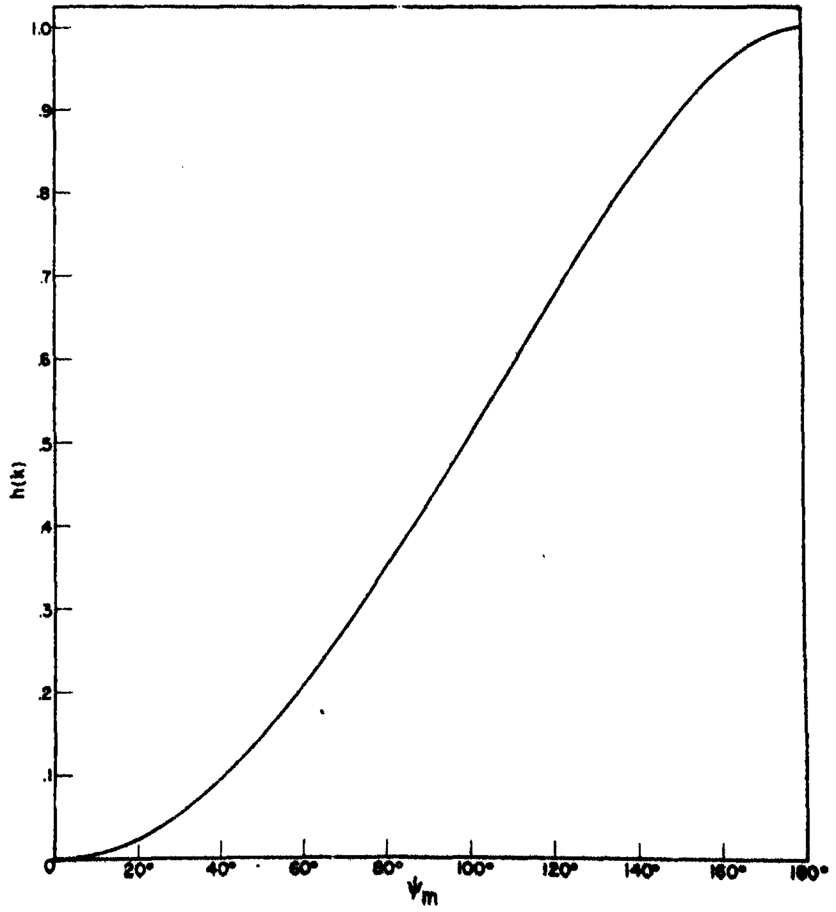

FIG. 7. $H(k)$ as a function of injection angle ψ_m.

In the numerical case quoted above where V is taken to be 10,000 volts and T_0 is the time required to raise the energy of the particle to 8 Mev,

$$\psi_F/\psi_i = 1/2.3,$$

a larger damping than that obtained during the entire synchrotron acceleration period. The damping for large phase angles will be less than this, but even so, by far the great majority of the particles injected will be accepted into the synchrotron acceleration cycle if this prebunching is employed. In addition a much smaller percentage will be lost because of random frequency errors.

It will be noted, from Eq. (31), that the amount of damping obtained depends very little upon the amplitude of the r-f voltage; in fact, $\psi_F \sim V^{-1/12}$. Thus the bunching can be obtained with an r-f voltage only a small fraction of that which would be needed in the synchrotron phase. This may be important if the r-f accelerating system is a resonant one.

To conclude this section we shall give a brief discussion of the effect of an error in the betatron flux condition. In the so-called flux-forcing scheme, prescribed by D. W. Kerst, the betatron coil is placed partly in series, partly in parallel with the field coils, the whole system being powered from the same generator. Under these conditions it can be shown that there is a self-compensation mechanism which automatically preserves the correct field-flux ratio. However a complicated switching problem arises if this scheme is to be incorporated into the proton synchrotron, where the current in the betatron coils has to be turned off at some point in the acceleration cycle. Accordingly, it may be necessary to power the betatron flux coils from a separate generator, and then the possibility arises that the flux is out of phase with the field in the accelerating chamber. One way of avoiding this trouble is to provide an additional field-compensating coil, the current in which is automatically adjusted to give the correct flux-field ratio. Alternatively, the correct orbit can be maintained by a small r-f voltage.

Let it be supposed that the betatron flux departs by a small amount $\Delta\Phi_0$ from the correct value and that the r-f frequency error is ω_1, then the particles in the acceleration chamber will oscillate about a stable phase angle ψ_B given by

$$V \sin\psi_B = \frac{d}{dt}[\Delta\Phi_0 - 2\pi r_0^2 B_0(1-n)\omega_1\eta/\omega_0], \quad (32)$$

and ψ_B can be held small, even with small V, if $\Delta\Phi_0$ and ω_1 are small. If prebunching is used, it may thus be unnecessary to employ any automatic flux compensation even if

$$\Delta\Phi_0/\Phi_0 \gtrless [(1-n)(b-A)]/r_0, \quad (33)$$

where A is the amplitude of the betatron oscillations and $2b$ the width of the acceleration chamber. The inequality (33) gives the condition that the particle be lost to the walls in the absence of an r-f voltage.

V. INJECTION METHODS

A number of injection methods have been proposed for the proton synchrotron. For injection directly into the synchrotron stage of operation, it is convenient to classify these methods into one or more of the four following categories. One attempts to avoid loss of injected particles on subsequent revolutions to the gun by

(1) Adiabatic damping of the oscillations before the particles return to the gun,

(2) Rapid decrease of the free-oscillation amplitude by the use of auxiliary transient fields,

(3) Rapid decrease of synchrotron phase and radial oscillations by rapid alteration of the stable phase angle,

(4) Adiabatic shift of the stable orbit by frequency modulation of the r-f accelerating voltage. With a preliminary betatron stage, methods (1) and (2) are pertinent in addition to the possibility of an adiabatic shift of the betatron orbit.

Most likely injection will take place with energies in excess of 1 Mev, into an initial magnetic field greater than 50 gauss, from an auxiliary accelerator by means of a suitable gun. In practice, intensities will be so low that the effects of space charge, even during injection, can be neglected. We shall not concern ourselves with the nature of this primary accelerator. When injecting directly into the synchrotron phase, it is desirable to minimize the horizontal betatron oscillations by making the injection momentum correspond to the value of B_z at the injection orbit. If particles are injected over a number of r-f cycles while the magnetic field is increasing, one should increase the injection energy in step with the magnetic field. This is not too difficult if the initial accelerator is a low energy transformer but it is much harder if a Van de Graaff accelerator is used and probably impossible if a cyclotron or linear accelerator is employed.

We shall now discuss four alternative injection proposals, chosen to illustrate the four basic methods stated above. The first one is discussed in somewhat more detail than its importance warrants because it serves to clarify the difficulties inherent in injection. The numerical estimates for the number of particles accepted into the acceleration cycle are derived for the machine described by the data in Table I.

1. Adiabatic Damping of Oscillations before Particles Return to the Neighborhood of the Gun

In this system the gun is located vertically above the central orbit and particles are injected over several r-f cycles. It is highly desirable that the particle energy on injection just equal the energy appropriate to the central orbit, so that for maximum intensity the injection gun's energy must be modulated. Let us start by supposing that the injection energy has just the correct value and consider the effects of departure from this energy later. Furthermore let us for the moment neglect the fact that the injected beam has a certain angular spread.

Consider a particle arriving at the acceleration gap with a phase ψ. The initial value of the radial velocity $\dot{x}_1$ is given approximately by

$$\frac{\dot{x}_i}{r_0} = -\frac{\dot{\psi}}{\omega_0 n} = \frac{V(\sin\psi - \sin\psi_0)}{2\pi r_0^2(1-n)B_0},$$

so that during a single revolution the particle moves radially a distance x_1 given by

$$x_1 = \frac{V(\sin\psi - \sin\psi_0)}{(1-n)r_0 B_0 \omega_0} = \frac{eV(\sin\psi - \sin\psi_0)r_0}{(1-n)2E_i},$$

with E_i the injection energy.

If the accelerating gap is located near the gun, x_1 is the radial distance the particle traverses before returning to the neighborhood of the gun. If $x_1 > s$, the half-width of the gun, the particle will certainly not be lost in the second revolution. Another circumstance which allows the particle to miss the gun is that the frequency of the vertical betatron oscillations is $(n)^{1/2}f_0$, where f_0 is the particle rotation frequency. If the particle is injected at a height h above the median plane, it returns to the neighborhood of the gun at a height $h\cos(2\pi(n)^{1/2})$. Thus if $h(1-\cos 2\pi(n)^{1/2}) > t$, the half-thickness of the gun, the particle will not be lost even if $|x_1| < s$. In practice one can choose n so that the particle first returns to the vicinity of the gun after about five revolutions, although ideally it is possible to increase this to $2\pi/\cos^{-1}(1-t/h)$ revolutions if h is increased suitably to allow for the length of the gun and the finite spread of the input beam. This assumes that all but a few particles miss the gun on the first few revolutions.

The particles escaping the gun during the first few revolutions will not return to the gun for a half-period of a synchrotron oscillation. In this time the amplitude of the vertical oscillation will be damped to

$$h\left(\frac{B_i}{B_i + (1/2\Omega_0)(dB/dt)}\right)^{1/2} = h\left[1 - \frac{f_0 V \sin\psi_0}{4\Omega_0 E_i}\right],$$

and if $(hV\sin\psi_0/4E_i)(f_0/\Omega_0) < t$, the particles will not be lost to the gun on subsequent revolutions. In practice, this is impossible to achieve and a certain proportion of the particles will be lost, equal very roughly to $(1/\pi)[\cos^{-1}(1-t/h)]$.

The oscillation period of a particle depends on its injection phase as well as upon B_0, ω_0, and V, all of which change continuously with time. Since the synchrotron period is much larger than a period of vertical betatron oscillations, we can regard their relative phase as a random quantity. With these assumptions, the total number of particles accepted into the machine of Table I is

$$N = 2.5\times 10^7 SI\left(\frac{4}{E_0}\right)\left(2 - \frac{\psi_0}{\pi/4}\right) \times \left[1 - (1/\pi)\cos^{-1}\left(1 - \frac{t}{h}\right)\right]^l,$$

where

$$l\frac{hV\sin\psi_0}{4E_i}\left(\frac{f_0}{\Omega_0}\right) = t,$$

S is the total number of cycles over which injection takes place, E_i the injection energy in Mev, and I the injection current in microamperes.

TABLE II. Number of particles accepted with different injection schemes.

Injection scheme	No. of particles	Gun energy modulated	Injection period
5.2	1.9×10^{10}	No	4 μsec.
5.3	4.6×10^{10}	No	125 μsec.
5.4	7.5×10^{10}	Yes	250 μsec.

If particles are not injected with the correct energy they will have, superimposed on the horizontal synchrotron oscillations, horizontal betatron oscillations of frequency $(1-n)^{\frac{1}{2}}f_0$. This means that the particles will reappear in the vicinity of the gun at intervals during the time required for the radial synchrotron oscillation to move a radial distance equal to the sum of the gun thickness and twice the amplitude of the horizontal betatron oscillations. Thus the possibility of losing particles to the gun is very greatly increased.

2. Single-Shot Injection

In this system an auxiliary electric field is maintained for a time interval less than the rotation period of the particles to remove completely the vertical betatron oscillations. The gun is located exactly as in case (1) and a uniform vertical electric field is established over an arc of the acceleration chamber. The field strength and arc length are to be so chosen that the injected particles emerge into the field-free region with zero vertical velocity, and by tilting the gun the arc length may be shortened. These particles will remain in the median plane until they return to the gun. If by this time the vertical electric field has been removed, the particles will continue to move in the median plane and none will be lost to the gun.

When the finite spread of the injected beam is taken into account, one can show that, as far as subsequent oscillations are concerned, the electric field serves to move the gun into the median plane. In this system particles can be injected only over a single cycle and the resulting loss of intensity may require compensation by the use of an exploded ion source. An important advantage is that initially the particles are essentially all grouped along the central line of the acceleration chamber, while pulsing the source will ensure that no wasted particles are introduced into the chamber. This arrangement is very desirable from the point of view of an automatic frequency control system, which is particularly necessary during the initial stages of operation, and it may well become the determining factor in the choice of an injection system.

If upon injection the particle energy is E_i Mev, one can show that the total number accepted into the acceleration cycle will be equal approximately to

$$2.50\times10^7 I\left(\frac{4}{E_i}\right)^{\frac{1}{2}}\left(1-\frac{2\psi_0}{\pi}\right), \qquad (34)$$

with I the injection current in microamperes and ψ_0 the stable phase angle.

3. Rapid Change of the Stable Phase

If the stable phase angle for synchrotron oscillations be suddenly changed, the particles will execute new oscillations with decreased or increased amplitudes depending on their phase at the instant of change of the stable phase. Thus some of the particles will have their maximum phase velocity and hence their maximum radial displacement from the stable orbit decreased, and one has a mechanism for capturing particles into synchrotron acceleration without hitting the injecting gun.

Since the sine of the stable phase angle is proportional to the time rate of change of magnetic field and inversely proportional to the accelerating voltage, a sudden change in either of these quantities will provide the necessary sudden change in stable phase. Particles are injected from a gun placed on the inside of the accelerating chamber in the median plane (to keep the vertical aperture a minimum).

During injection the r-f voltage is maintained at a constant frequency with a constant magnetic field, so chosen as to keep the stable orbit centered in the accelerating chamber. The machine thus acts as a d.c. cyclotron or as a synchrotron with $\psi_0=0$. The sudden jump in ψ_0 occurs when the a.c. magnetic field is turned on. A particle arriving at the accelerating gap during the injection period with a positive phase will pick up energy and move inwards into the chamber. If the radial displacement in a single revolution exceeds half the gun width, the particle will not hit the gun on the second revolution. In a practical case this radial shift is so large that practically all the particles arriving at the gap with positive phase will miss the gun and all those arriving with negative phase will be lost to the inner walls or to the gun.

During injection the phase motion of the protons is that of the free oscillations of a pendulum with arbitrary initial phase and initial phase velocity given by $\dot{\psi}_i = -n\omega_0 d/r_0$, with d the distance of the gun from the stable orbit of radius r_0. Thus the phase angle ψ is an elliptic function of the time. In particular, if the a.c. magnetic field is turned on at a definite instant of time, the phase ψ_F and phase velocity $\dot{\psi}_F$ at this instant can be written in terms of ψ_i and $\dot{\psi}_i$. If now ψ_0 is the final stable phase angle, it follows readily that the particle will be accepted into the acceleration cycle if the following inequalities are satisfied:

$$\left.\begin{aligned} &\psi_i > 0, \\ &\left(\frac{d}{r_0}\right)^2 \geq \left(\frac{\dot{\psi}_F}{n\omega_0}\right)^2 + 2\left(\frac{\Omega_0}{n\omega_0}\right)^2 \\ &\qquad \times[(\cos\psi_0 - \cos\psi_F) - (\psi_F - \psi_0)\sin\psi_0], \\ &\cos\psi_0 - \cos\psi_F - (\psi_F - \psi_0)\sin\psi_0 \\ &\qquad + \frac{1}{2}\left(\frac{\dot{\psi}_F}{\Omega_0}\right)^2 \lessgtr \cos 2\psi_0 - (\pi - 2\psi_0)\sin\psi_0, \end{aligned}\right\} \quad (35)$$

with $\Omega_0 = n\omega_0 V/[2\pi r_0^2(1-n)B_0]$, the angular frequency of small free oscillations during injection. The first inequality states that the particle does not hit the the gun or inner walls on the first revolution. The second is the condition the amplitude of the new radial oscillations be less than the distance of the gun from the stable orbit, and the third condition ensures that the particle does not move out of the stable phase range for oscillations on subsequent revolutions.

Inserting the expressions for ψ_F and $\dot{\psi}_F$ into the conditions (35) then gives the acceptable injection phase angle as a function of the time of injection of the particle relative to the instant when the magnetic field is turned on. Summing over all injection times for which the acceptable injection phase angle is positive, one then can obtain the total range of acceptable phase angles Θ for all the particles which are injected. This process will not be carried out here in detail but an approximate expression for Θ, obtained by replacing the elliptic functions by trigonometric functions, may be written as

$$\Theta = \frac{f_0}{\Omega_0}\int_0^{\pi}\left[\psi_0 \sin y\left(\frac{2dn\omega_0}{r_0\Omega_0} - \psi_0 \sin y\right)\right]^{\frac{1}{2}} dy, \quad (36)$$

which is valid when $2dn\omega_0/r_0\Omega_0 > \psi_0$. ($f_0$ is the frequency of rotation of the particles.)

If numerical values taken from Table I are inserted, it can be shown that the total number of particles accepted into the stable phase range is given by

$$N \cong 6.3\times 10^7 I\left(\frac{4}{E_i}\right)^{\frac{1}{2}},$$

with I the injection current in microamperes, E_i the injection energy in Mev; ψ_0 has been taken as $\pi/4$, and it may be noted that N varies slowly with ψ_0.

The chief advantages of this scheme are the following:

(a) No auxiliary equipment is required.
(b) It is not necessary to energy-modulate the gun.
(c) There are no critical timing circuits.
(d) The attainable intensity is at least as great as that for any of the proposed alternatives.

4. Adiabatic Shift of the Stable Synchrotron Orbit by F-M Techniques

The scheme described here is essentially that proposed by D. M. Dennison for the electron synchrotron at the University of Michigan. The very different conditions at injection in a proton synchrotron, however, result in considerable difference in detail.

Consider particles injected from a gun at the outside of the accelerating chamber. Initially the radiofrequency is chosen so that the stable orbit passes through the gun and this frequency is so modulated that the stable orbit moves in toward the center at a steady predetermined rate. Particles are injected in bursts over a time interval encompassing a number of revolutions so that energy modulation of the injector is necessary to attain maximum beam intensity.

Particles will miss the gun during the next few revolutions provided they arrive at the accelerating gap with negative phase. Furthermore, if the time required for the stable orbit to reach the center of the chamber is not much longer than the synchrotron oscillation period, particles will not be lost to the gun. If they are lost at all, they will be lost to the inner wall.

The phase acceptance angle ψ_i on the first revolution must lie within the limits $\psi_0' < \psi_i < \pi - \psi_0'$, where ψ_0' is the stable phase angle during injection. As the stable orbit moves inward the phase acceptance angle will decrease, for a given amplitude of synchrotron oscillation, vanishing when the stable orbit reaches the center of the chamber since the maximum amplitude of radial synchrotron oscillation equals the distance d of the gun from the central orbit.

If the frequency error ω_1 has the form

$$\omega_1 = \omega_0[-(nd/r_0) + \alpha t], \tag{37}$$

the first of Eqs. (11) yields

$$x/r_0 = d/r_0 - (\psi + \omega_0 \alpha t / n\omega_0), \tag{38}$$

and the second, in the non-relativistic range which applies at injection, yields for the equation of phase oscillation:

$$\frac{(1-n)r_0^2 B_0}{n\omega_0}\ddot{\psi} + \frac{V}{2\pi}\sin\psi = \frac{V}{2\pi}\sin\psi_0', \tag{39}$$

with

$$\sin\psi_0' = \sin\psi_0 - \frac{2\pi r_0^2(1-n)B_0\alpha\omega_0}{n\omega_0 V}. \tag{39a}$$

From Eq. (38), one sees that the stable orbit, which initially lies at a distance d from the center of the chamber, moves toward the center at a constant rate, so that the frequency law (37) accomplishes the desired result. If the stable orbit is to reach the center in a time less than one synchrotron period, α must satisfy the inequality

$$\alpha > \frac{nd}{r_0}\frac{\Omega_0'}{2\pi} \quad \text{with} \quad \Omega_0'^2 = \frac{\omega_0 n V}{2\pi r_0^2(1-n)B_0}.$$

If furthermore $|\psi_0'|$ is not to exceed $|\psi_0|$, then $\alpha < (\Omega_0'/\omega_0)2\Omega_0' \sin\psi_0$, so that we have, as an additional requirement,

$$\frac{2\Omega_0' \sin\psi_0}{\omega_0} > \frac{nd}{2\pi r_0}.$$

For the 10-Bev machine this inequality is certainly fulfilled and allows a decrease of V during injection with a consequent decrease of Ω_0' and increase of the number of particles accepted into the stable phase range.

We now consider the particles to be injected in bursts with a recurrence frequency f_0 equal to the rotation frequency of the particles. If the phase of a particle injected in the sth burst is ψ_i and the energy is appropriate to the injection orbit, then the particle will not be lost to the gun on subsequent revolutions if

$$\left[\left(\frac{\alpha s}{f_0}\right)^2 + \frac{\{\cos\psi_0' - \cos\psi_i + (\psi_0' - \psi_i)\sin\psi_0'\}nV}{2\pi r_0^2(1-n)B_0\omega_0}\right]^{\frac{1}{2}} < \frac{nd}{r_0}.$$

From this one sees that there is no point in injecting particles after the orbit for which

$$s = (f_0/\alpha)(nd/r_0).$$

The total number of particles accepted is given approximately by

$$N \cong 10^7 I\left(\frac{4}{E_i}\right)^{\frac{1}{2}}\left(1 - \frac{2\psi_0}{\pi}\right)\frac{nd}{r_0}\cdot\frac{f_0}{\alpha},$$

with E_i the average injection energy in Mev, ψ_0 the stable phase, and I the beam current in microamperes.

Since the above expression is inversely proportional to α, the maximum number of particles will be obtained when $\alpha = nd/r_0 \cdot \Omega_0'/2\pi$. In this case

$$N \cong 10^7 I\left(\frac{4}{E_i}\right)^{\frac{1}{2}}\left(1 - \frac{2\psi_0}{\pi}\right)\frac{\omega_0}{\Omega_0'}$$

$$= 4\times 10^8 I\left(\frac{4}{E_i}\right)^{\frac{1}{2}}\left(1 - \frac{2\psi_0}{\pi}\right).$$

It is virtually impossible to attain this value in practice and a much more realistic value is that for which $\alpha = (\Omega_0'^2 \sin\psi_0)/\omega_0$, i.e., with $\psi_0' = 0$. In this case

$$N \cong 10^8 I\left(\frac{4}{E_i}\right)^{\frac{1}{2}}\left(1 - \frac{2\psi_0}{\pi}\right).$$

If the gun is not energy-modulated, injection will start when the energy required in the *central* orbit equals the injection energy, and will cease when the energy appropriate to the *injection* orbit equals the injection energy. The accepted number of particles will then be very much reduced and is probably no greater than that obtained by single-shot injection.

The numerical results obtained in this section are displayed in Table II. In all cases we have taken, $E_i=4$ Mev, $\psi_0=\pi/8$, $I=1$ milliampere. Since the period over which injection takes place varies widely from scheme to scheme it may seem unfair to assume that the peak injection current is the same in all cases. However, the general problem of obtaining high density proton beams at several Mev is still too uncertain to warrant any other assumption.

We have now given one example of each of the four main alternative injection schemes. Of these, if intensity is not the primary consideration, the single-shot scheme is most attractive. In contrast to the other methods, the injected ions are caught into the acceleration cycle and lie initially in the central orbit. This is highly desirable in view of the proposed frequency-control system which, with this injection system, can operate right from the beginning when control requirements are most critical. In the other schemes, a large number of particles not caught into the accelerating phase will drift to the inner wall. Until all these have been removed, the frequency-control system cannot begin to function properly.

If maximum intensity is the primary factor, probably scheme (3) is next best because of its simplicity. No energy modulation of the gun, no auxiliary electric fields or special frequency-modulation techniques are required, and the timing of the various steps in the injection process is not critical.

It must be emphasized once again, however, that a large number of alternative injection schemes of greater or lesser complexity can be evolved, each with advantages peculiar to itself. In a practical case a choice can only be made when all the relevant factors are taken into account.

THE REVIEW OF SCIENTIFIC INSTRUMENTS VOLUME 20, NUMBER 1 JANUARY, 1949

A Double-Channel, Direct Reading, Low Frequency Counting Rate Meter and Counting Rate Comparator*

ROBERT M. KLOEPPER AND FRANK E. HOECKER
Department of Physics and Astronomy, University of Kansas, Lawrence, Kansas

(Received August 30, 1948)

A two-channel, direct reading counting rate meter for measurement of low frequency (average random or uniform) pulse rates in either channel or in both channels simultaneously is described. The outputs of two degenerative vacuum-tube voltmeter integrating circuits are combined into a bridge circuit whereby the equality of pulse rates in the two channels may be determined on a null-reading galvanometer. An impulse register amplifier is provided on each channel for operation of impulse counters for monitoring and/or calibration. The five ranges provided are 0–100, 200, 500, 1000, and 5000 pulses per minute. Although primarily designed for the specific purpose of adjusting two atmospheric pressure wire plate alpha-particle detectors (W. Y. Chang and S. Rosenblum, Phys. Rev. 67, 221 (1945)) to equal average pulse rates, the circuit design may be modified to detect pulse rate ratios other than unity, pulse rate differences, and/or pulse rate ranges other than those enumerated above.

1. INTRODUCTION

THE instrument to be described was developed for the purpose of matching the counting rates of two atmospheric-pressure alpha-particle detectors used in measuring the range of alpha-particles in various substances. Two alpha-particle detectors were used in order to balance out the effects of factors which might affect the counting rate of a single detector such as fluctuations in supply voltage, temperature,

*** Must be adjusted by trial.

humidity, and atmospheric pressure. This was accomplished by using the counting rate of one of the detectors having a fixed source and source-distance as a reference to which the counting rate of the measuring detector was adjusted, both detectors being operated from the same high voltage source. The adjustment of counting rate of the measuring detector was effected by varying the distance between the alpha-particle source and the detector.

Pulses from the two alpha-particle detectors are fed into the separate channels of the two-channel pulse rate comparator. The circuit of this instrument consists of two essentially identical channels, each composed of an input amplifier, a pulse equalizer, and a pulse amplifier of variable gain for range selection which is directly coupled to an RC integrating circuit and to a vacuum-tube voltmeter. The vacuum-tube voltmeter circuits are coupled to form a pulse rate comparison bridge. The bridge balance indicates equality of average pulse rates.

2. THE CIRCUIT

The two channels of the counting rate meter are essentially identical as may be seen by reference to the circuit diagram, Fig. 1. Switch Sw1 permits the input pulses from either input jack to be placed in both channels simultaneously, principally for calibration or for calibration checking, or to be placed through their channels individually. The tubes V1, V2, and V3 comprise the input amplifiers and pulse equalizer circuits which are essentially those of Kip *et al.*[1]

The theory of the integrating RC "tank" circuit and its associated statistical limitations are adequately discussed elsewhere.[1–3] It may be shown[1] that the voltage on the integrating condenser is proportional to the frequency of the impressed pulses, the value of the RC tank leakage resistor, and the size of the pulses impressed upon the integrating condenser.

* Capacity of C is 2 microfarads.

The method of range switching and of coupling the pulses from the integrator tube (V4) to the vacuum tube voltmeter (VTVM) circuit is adapted from that of Kip *et al.*[1] The rotary switch RANGE CH A[4] (see Fig. 1) consists of Sw5 and Sw6, ganged on a common shaft. The gain of the integrator tube (and, therefore, the amount of charge transferred to the RC tank circuit per pulse) is controlled by variation of the screen voltage of the tube (V4). Sw5 selects the output voltage of the potentiometer appropriate to the screen voltage of the integrator tube for the range chosen. At the same time that the gain control is selected by Sw5, Sw6 changes the value of the leakage resistor R24–27: since the integrating condenser C14 remains constant, this change in leakage resistance modifies the time constant of the memory circuit in accordance with the values of Table I, selecting those values of RC which are a compromise between long equilibrium times and large fractional probable errors resulting from statistical fluctuations. A ganged Sw5–6 is provided for each channel. The OFF position of Sw5–6 puts a direct short across the tank condenser at the same time that the integrator screen voltage is lowered nearly to cathode potential so that the stage gain is zero.

The location of the tank circuit requires that the VTVM grid operate at the plate potential of

FIG. 2. Simplified diagram of the integrator and vacuum-tube voltmeter circuits, showing method of bias application to the latter.

the integrator. Rather than allow the VTVM to "float" at a potential of 105 volts above ground, the cathode of the integrator tube was lowered to 105 volts below ground potential. This circuit places the plate of the integrator tube only slightly above ground potential by the amount of positive bias on the VTVM grid. This circuit has the additional necessary advantage over that of Kip *et al.*[1] that the bias and, consequently, the plate current of the VTVM may be adjusted.

The plate voltage of the VTVM is that between ground and the +150-volts supply. R30 is the VTVM degenerative resistor; its value of 3000 ohms gives a voltmeter sensitivity of approximately full-scale deflection of the meter (5 ma) at a tank condenser voltage of 15 volts. It serves the additional function of a bridge arm resistor in the bridge rate comparator circuit.

The design of this circuit allows the "negative" power supply to furnish not only plate voltage to the integrator tube but also bucking voltage to the meter circuit. The negative pulses as applied to C14 by the integrator tube, V4, cause the VTVM plate current to decrease with rising frequency (rising tank voltage). The bias adjustment is used to adjust the VTVM plate current to 8 ma.

The METER SWITCH Sw7 is a rotary three-position, four-circuit gang switch; it controls the meter-switching in both channels simultaneously. With the METER SWITCH in the OFF position, the meters are shorted. In the PL ma position the meter switch inserts the shunts R32 A–B across the meters and inserts these shunted meters in series with the cathode leads with the correct polarity to read the cathode and plate current of the triode-connected VTVM tubes (6AC7). The shunts are wound on one-watt, 100,000-ohm resistors as forms and are carefully adjusted so that the meters require nearly (within about 3 percent) 10 ma for full-scale deflection but more particularly that they require the *same* currents within ½ percent for full-scale deflection when the shunts are used. In the PPM position the following changes take place: (1) the shunts are removed from the meter circuits, (2) the polarity of the meters is reversed, (3) the bucking current circuit is closed and the meter circuit function becomes that shown in Fig. 2. The bucking circuit is not completed in any other meter switch position.

In use, as the plate current falls with rising frequency the constant bucking current source causes the meter to read upscale. This upscale reading will be a linear function of frequency if the VTVM responds linearly to voltage on the integrating condenser and if the bucking current is constant. In this circuit this linearity is realized within ½ percent.

It is entirely possible to use the bucking circuit to set the counting-rate meter at zero against any reasonable background count and, therefore, to record one counting rate in the presence of another.

The bridge circuit is shown in a simplified form without the complicating bucking circuits in Fig. 3 as if Sw7 were in the PL ma position. With identical voltages on C14A and C14B the plate currents may be adjusted by the BIAS ADJUST controls to equal values as read by the two plate meters. By variation of the BRIDGE ZERO control R31 the resistances of the two arms, composed mainly of the cathode degenerative VTVM resistors R30, may be made equal as indicated by a null of the galvanometer G when Sw9 (BRIDGE ON-OFF) is closed.

Counting rates may be read directly from the appropriate channel meter with due regard for the statistical limitations[1,2] as set by the value of the time constant RC of the memory circuit, counting rate and equilibrium time t_0. Table I will be found helpful in judging the operation limitations of the counting-rate meter. The equilibrium time may be reduced by artificial adjustment of the vacuum-tube voltmeters nearly to equilibrium values. The CHANNEL RESET switch Sw8 is placed in series with R35 across the tank condenser C14 to permit this adjustment by rather rapid discharge of C14 to any desired value.

If identical voltages are placed on C14A and on C14B by identical pulse rates in the separate channels, a null-reading of the galvanometer will indicate this identity. Resistor R29 damps the oscillation of the galvanometer on random pulses. A high impedance voltmeter, used to replace the galvanometer in this bridge circuit, could be calibrated directly in terms of pulses per minute difference of pulse-rate in the two channels.

A convenient and rapid method of determining whether the rates are identical is to set the vacuum-tube voltmeters artificially to the same reading (bridge galvanometer at zero) and to observe the direction of drift of the galvanometer.

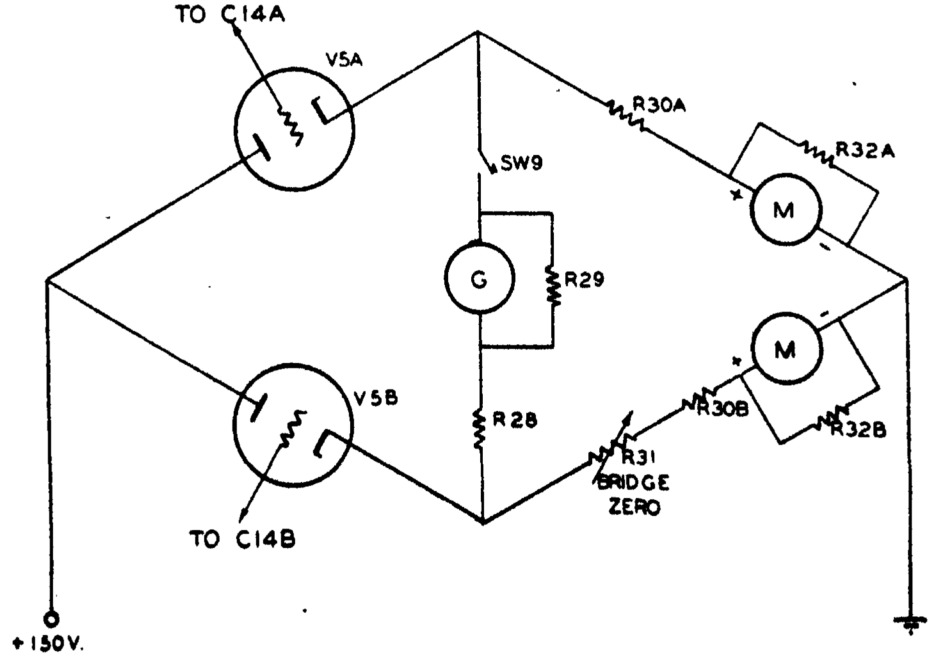

FIG. 3. Simplified pulse rate comparator bridge circuit.

If the impedance of the galvanometer circuit is comparable to the bridge arm resistor values, the counting rate indications of the meters will be erroneous when the BRIDGE ON–OFF switch is on because the galvanometer circuit has a tendency to equalize the meter indications.

The impulse register circuits are driven by the input amplifiers. The positive pulses at point *A* are fed through the coupling capacitor C4 to the grid of a 6AG7, V6. This tube was chosen because it has a very high transconductance, 8000 micromhos, and operates into a low plate load resistance; therefore, it is ideally suited for coupling to an impulse register. The variable resistor R13 (ADJUST OUTPUT) in the V6 cathode return affords a convenient method of varying the current output to the register to permit application of various types of registers as well as relays of varying sensitivities. Another use to which the OUTPUT TO REGISTER terminals may be put is the operation of a speaker for aural monitoring. Normally, no plate current may flow to the 6AG7 unless some resistive connection is made across the OUTPUT terminals. One of these terminals in each channel is maintained at about +300 volts; this provides the high voltage supply to the calibrator.[1]

The calibration may be conveniently checked on the 5000 PPM scale for variations in time by pressing the appropriate 3600 PPM INPUT button. If the channel meter rises to 3600 PPM, there is good assurance that the other channel calibrations have not changed.

Adequate shielding and decoupling must be provided between the two channels to prevent interaction. Care must be taken to prevent voltage fluctuations due to an impulse register load from affecting the output of the pulse-equalizer circuits. If the sensitivity of the input amplifier is increased by lowering the value of R11, shielding becomes of primary importance.

The rate of approach (rise or fall of the VTVM plate current) to equilibrium may be different in the two channels even though identical pulse rates are impressed upon both channels. Such operation is neither unusual nor unreliable. The equilibrium value of the VTVM plate current is dependent upon the value of the leakage resistor of the RC integrating circuit but is independent of the size of the integrating condenser. Hence, the fact that the time constants (and, therefore, the rates of approach to an equilibrium value) of the two channels differ does not indicate that the equilibrium values will differ.

It should be pointed out that a cathode-ray oscilloscope, in general, disturbs the pulse shape enough so that the counting-rate meter cannot be calibrated with a cathode-ray oscilloscope on the circuit.

A 5-ma pen and ink recording milliammeter may be inserted directly in series with the VTVM plate meter. No circuit or calibration modifications are necessary *if* the resistance of the pen recorder is so low that its insertion does not appreciably affect the total value of the cathode degeneration resistance; if it does, recalibration is required because of the changed VTVM sensitivity.

If this plate current is similarly applied across a two or three-ohm standard resistor, the resulting potential drop will actuate a Leeds and Northrup recording potentiometer (20-Mv full scale) without any circuit modifications. This inserted resistance is insignificant and no recalibration is necessary.

THE REVIEW OF SCIENTIFIC INSTRUMENTS VOLUME 20, NUMBER 1 JANUARY, 1949

A Recording Mechanical Pressure Gauge of High Range*

PAUL M. HIGGS
Applied Physics Laboratory, University of Washington, Seattle, Washington

(Received March 23, 1948)

An instrument of rugged construction for recording very large and rapidly fluctuating pressures in liquids and gases is described. The pressure sensitive element is a thick, flat, circular diaphragm, rigidly mounted and fluid damped. The pressure *versus* time record is engraved upon the surface of a rotating polished metal disk by a stylus fastened directly to the diaphragm. The record may be read with a precision of better than one percent of full deflection. The instrument will record pressures up to 1000 pounds per square inch at frequencies from zero to five hundred cycles per second.

INTRODUCTION

THE recording pressure gauge was designed to measure large and rapidly fluctuating pressures of the order of hundreds of pounds per square inch as a function of time and at all frequencies below 200 cycles per second, *including zero*, both in air and under water. Since pressures having these characteristics occur only in the vicinity of abnormally large explosive charges, further design requirements were that the instrument should be self-contained, stable, and sufficiently rugged to withstand the rough treatment it would receive in use. These same requirements almost precluded *a priori* the use of electronic components since reliable operation under the relatively unknown conditions of use was essential. It was also desired that the record be made in as indestructible a form as possible to prevent the loss of data from damaged instruments and possible delay in the recovery of instruments after tests. This is particularly important where sea water with its corrosive effects is involved. An instrument of this or similar design may prove useful in the general study of large scale blast phenomena or where a detailed record of large and rapidly fluctuating fluid pressures is required. A suggested application is the study of transient phenomena in hydraulic systems.

GENERAL DESCRIPTION

Figure 1 is a schematic drawing showing the details of the essential parts of the instrument with the exception of the record disk drive mechanism which is clearly seen in the photograph, Fig. 2. In Fig. 1, (*A*) is the pressure sensitive element of the gauge, a flat circular disk of 24-ST aluminum. This diaphragm is 10 inches in diameter and is clamped over a one-inch face around the periphery, leaving a free or effective diameter of 8 inches. Since the use of gaskets in the diaphragm assembly was not permissible, joints were made liquid tight by painting the bearing faces with red glyptol at the time of assembly. No difficulty due to leakage under high pressures was encountered. Three thicknesses of diaphragms were used in the instruments to give an expanded range of sensitivities. Table I gives the approximate characteristics of these diaphragms.

Figure 3 is a plot of experimentally determined deflections of the gauge diaphragms for applied steady hydrostatic pressures for diaphragms that had been pre-stressed by the application of pressures equal to the maximum allowable. The

TABLE I. Diaphragm characteristics.

Diaphragm thickness	Pounds per square inch to produce 0.001-inch deflection	Maximum allowable pressure in pounds per square inch
¼"	2.48	300
$\frac{5}{16}$"	4.70	600
⅜"	8.13	1000

relationship

$$d = PR^4/4Et^3$$

(where d = deflection at center of diaphragm, in inches, P = pressure in pounds per square inch, R = radius of diaphragm to supporting edge in inches, E = modulus of elasticity = 1.0×10^7, and t = thickness of diaphragm in inches) is found to hold to a close approximation for the experimental data. It should be pointed out that the diaphragm is not clamped with perfect rigidity; there is some elastic yield of the entire structure under the application of pressure. If the diaphragm thickness is known, the above equation may be relied upon to give an accuracy of about 5 percent.

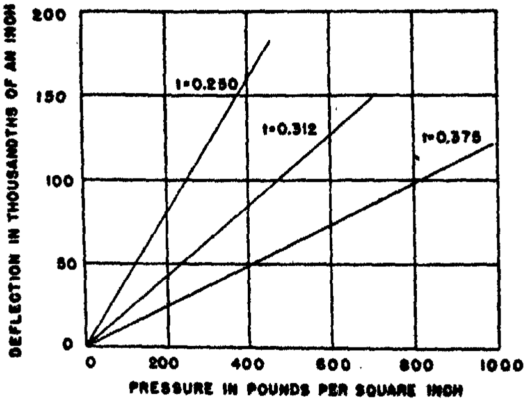

FIG. 3. Deflection of diaphragm as a function of static pressure and thickness of diaphragm.

As a simple clamped diaphragm of the above dimensions would be far under-damped it is necessary to provide a controlled damping mechanism to give the device the proper frequency response characteristics. Damping is provided by a fluid system using Dow Corning Fluid No. 200 as the damping medium. A grade of this silicone fluid having a kinematic viscosity of approximately 1000 centistokes was chosen. One characteristic of this material is a low variation of the coefficient of viscosity with temperature. The damping liquid is in contact with the outer or pressure face of the diaphragm (A), Fig. 1, and receives pressure from the air or water surrounding the instrument through a perforated baffle plate (B), a neoprene barrier diaphragm (C), and a perforated protective cover plate (D). The $\frac{1}{16}$-inch space between the diaphragm and the baffle plate is completely filled by the damping fluid which communicates with the fluid-filled space between the baffle plate and the barrier diaphragm through 30 $\frac{11}{64}$-inch holes drilled through the baffle plate which is $\frac{7}{16}$-inch thick at this section. The design of this damping or baffle plate was based upon computations involving the constants of the diaphragm and the associated damping mechanism. By a proper choice of the damping liquid viscosity and damping orifice dimensions it is possible to adjust the response characteristics of the instrument to an optimum value. The space between the barrier diaphragm and the cover plate is filled with water when the instrument is submerged for use. If the gauge is to be used for *air blast* measurements, the ports in the cover plate should be considerably enlarged over those shown in the drawing or the cover plate should be replaced by a diaphragm retaining ring, leaving the face of the barrier diaphragm exposed. The combination of the small ports in the protective cover with the enclosed air-filled cavity under the cover results in an acoustic filter which greatly attenuates the higher frequencies in the case of an air blast.

When this cavity is filled with water its influence upon the over-all frequency characteristic is small.

Figure 4 shows the response of an instrument having a ⅜-inch diaphragm to a step pulse produced by suddenly dropping a steadily applied hydraulic pressure of 300 pounds per square inch, gauge, to atmospheric pressure. This was accomplished by bursting a heavy lucite window or port in a pressure chamber. The system shows a natural damped frequency of about 360 cycles per second. The diaphragm reaches full deflection in about 2 milliseconds and has practically ceased vibrating in 5 milliseconds. There is very little overshooting. A high frequency vibration corresponding to a coupled motion of the diaphragm plus the baffle plate probably accounts for the slight irregularity of the motion of the recorder stylus during the steep part of the pulse. Figure 5 shows a smoothed plot of this experimental step pulse response plotted on an expanded time axis.

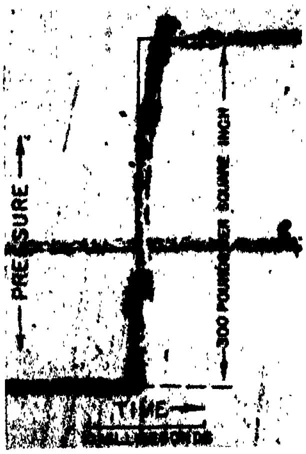

FIG. 4. Record of response of gauge to a step pulse change of pressure.

The over-all characteristic of the moving system is that of a low pass filter having small steady state response to frequencies above 500 cycles per second but permitting approximately full response to a step pulse in about two milliseconds.

The metal parts of the entire diaphragm assembly with the exception of screws and other minor parts are of dural. This gives a light strong structure with no difficulties caused by such effects as differential thermal expansions.

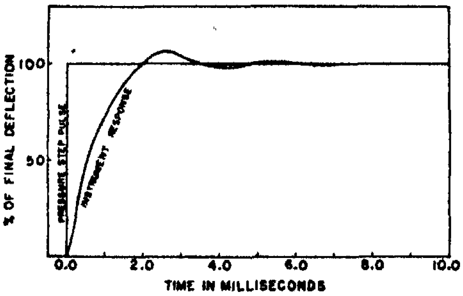

FIG. 5. Smoothed plot of gauge response to pressure step pulse.

The pressure *versus* time record is engraved in the form of a polar coordinate curve upon the polished surface of a chromium plated steel disk. The record disk, which is cut from photographic ferrotype sheet is 3 inches in diameter and has a thickness of about 0.020 inch. Another successful technique involves the use of a glass disk with a thin uniform coating of graphite deposited from Acheson Graphite Dispersion No. 41. The stylus engraves a sharply defined transparent line in this opaque coating and the method is satisfactory where extreme ruggedness and the maximum of resolution is not required. The record disk is shown at (*E*) in Fig. 1. The record disk is mounted upon the turntable (*K*) by means of a ⅛-inch thick backing plate (*F*) and a locking nut (*G*).

The engraving or "writing" tool of the instrument is the tip of a "permanent" type of phono-

FIG. 6. Two gauges installed in case for under water blast pressure measurements.

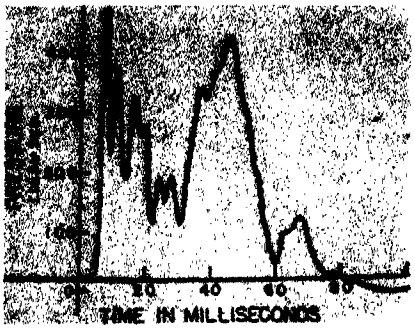

FIG. 7. Record of a water hammer transient in a hydraulic system.

graph needle such as is used in coin-operated automatic phonographs. The needle tip is a smooth, almost spherical surface of hard metal alloy which will press a sharply defined groove in the hard polished surface of the record disk. The stylus tip is soldered through a hole in a flat steel spring (*H*) which is clamped in a slot in the end of the stylus holder (*I*), which is rigidly attached to the diaphragm (*A*). The stylus assembly is steadied against lateral vibration by an accurately fitting bearing sleeve (*J*).

The turntable (*K*) is driven by an electric motor (*L*) through a combination spur and worm gear train. The motor used in the field instrument was an automobile accessory motor modified to increase its ruggedness and speed stability. The motor was powered by "Hot Shot" dry batteries. Under laboratory conditions it would be desirable to use a small a.c. synchronous motor. The mechanical design of this turntable drive was worked out with the guidance of field tests where the submerged recorder was mined with 600-pound charges of T.N.T. at short range. The turntable is carried in a cone bearing and is held firmly seated by a heavy-duty ball thrust bearing.

In the interest of ruggedness and simplicity of construction, no traverse motion is provided to separate the records produced for successive revolutions of the turntable, so in the absence of a pressure variation the stylus will follow a single circular track around the record disk. This is of an advantage in the case of records of less than one revolution duration, as the trace during the quiescent portion of the run will provide a reliable fiducial line for pressure measurement. Overstrain of diaphragms or other damage affecting calibration is also immediately evident.

In the measurement of very large scale, underwater blast pressures the motor circuit is closed and the gauge put into operation by switches actuated by radio control or by the direct action of the explosion, whichever occurs first. The motor is stopped after the turntable has made a predetermined number of revolutions by means of the simple device shown at (*M*) in Fig. 1. A nut floats on the threaded extension of the turntable shaft. It is held from turning by a loop of wire threaded through a hole in the nut and secured by lugs to two binding posts. The nut travels back along the shaft as the turntable rotates until it jams against the turntable bearing lock-nut; it then rotates, breaking the wire loop and opening the motor battery circuit.

Figure 6 is a photograph of one of the cases in which the instruments were installed for the measurement of large scale blast pressures. Two gauges are shown mounted in position on the lid. The case is of heavy construction, weighing approximately 1200 pounds and designed to withstand external hydrostatic pressures in excess of 1000 pounds per square inch. The case furnishes a substantial mounting surface for the gauges and houses the recording mechanism of the instruments. Other applications of the gauge would, in general, not require such ponderous or elaborate installations.

In order to obtain a publishable record as made by the instrument the gauge was installed in a 12-inch water main the flow in which could be stopped by the sudden closure of a valve. Figure 7 is a record of the resultant "water hammer" transient. In addition to the initial transient of the type shown persistent pressure fluctuation due to reflections from remote parts of the hydraulic system was recorded over periods of several seconds duration.

ACKNOWLEDGMENTS

The author wishes to acknowledge the valuable assistance given by various members of the staff of the Applied Physics Laboratory, University of Washington; the cooperation of the Thirteenth Naval District in furnishing necessary manufacturing and testing facilities; and the interest and help given by the Hydraulics Laboratory of the University of Washington in the application of the instrument to the measurement of hydraulic transients.

THE REVIEW OF SCIENTIFIC INSTRUMENTS VOLUME 20, NUMBER 1 JANUARY, 1949

A Self-Contained Recording Pressure Gauge*

DAVID R. BROWN,** WILLIAM C. GALLOWAY,*** JACK B. ROBERTSON, AND GENE A. SILVEY
Applied Physics Laboratory, University of Washington, Seattle, Washington

(Received March 23, 1948)

This instrument is a self-contained time *versus* pressure recording device capable of measuring pressures up to 1200 pounds per square inch at frequencies from 0 to 200 cycles per second over a period of five seconds. The instrument is set in operation by the arrival of a pressure wave above a predetermined threshold, triggering a locking mechanism and permitting compressed springs to drive the record surface past an engraving stylus actuated by a pressure-sensitive diaphragm.

INTRODUCTION

THE self-contained recording pressure gauge was designed as a companion instrument to other pressure-measuring devices such as that described in the preceding paper.[1] In the interest of reliability of operation and ease of installation and recovery, it was decided that this instrument should be relatively small, rugged, and self-contained to the extent of being independently triggered by blast pressures and not dependent upon auxiliary starting devices.

DESCRIPTION

The pressure-sensitive element of the recorder is a rigid, peripherally mounted, circular dural diaphragm (1) (see Fig. 1) with an effective diameter of six inches. Damping is obtained by a sponge rubber pad (2) compressed into a counter-bore between the diaphragm and the steel housing (3). Construction time for the particular use of the instrument did not permit the use of a more elaborate damping system such as used in the recorder described by Higgs.[1] An

FIG. 2. Pressure gauge showing one method of mounting.

over-all view of the gauge appears in the photograph, Fig. 2, showing the instrument with its steel mounting feet. The instruments were secured either by welding the mounting feet to the supporting structure for air blast measurement or by suspending them by means of wire cables for underwater measurements. The pressure *versus* time curve is recorded on the flattened portion of the dural plunger (4), Fig. 1. The stylus arm (5), fastened to the diaphragm, serves as a mount for the stylus (6) which scribes directly onto the flattened portion of the plunger which was polished to minimize machine marks. The stylus is made from a commercial phonograph recording needle ground thin near the tip to give a spring action to hold the cutting point in contact with the recording surface.

The time axis is obtained from a motion given to the plunger by two compressed helical springs (7) oppositely wound, which drive the plunger through an accurate bore in the steel housing past the engraving stylus. The two springs force the piston face against entrapped silicone stopcock grease[2] which escapes through a carefully dimensioned orifice that is bored through the piston face of the plunger. The rate of motion is controlled by four factors:

1. Spring pressure.
2. Diameter of bore.
3. Viscosity of fluid.
4. Diameter of orifice in plunger.

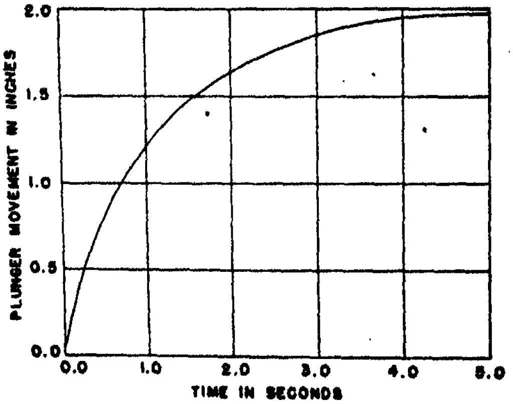

FIG. 3. Displacement of plunger as a function of time.

A plot showing the displacement of the plunger as a function of time is given in Fig. 3. Two oppositely wound springs, a right and a left, are used in pairs to minimize the torque on the dural plunger as the springs elongate. The force exerted by the springs, when fully compressed, is of the order of 230 pounds. It is necessary to select springs whose force constants are matched and lie within a narrow range if uniform performance for several such instruments is desired.

The plunger movement is initiated when the diaphragm is first displaced inwardly, as would occur when the first pressure wave arrives. The inward displacement of the diaphragm closes the firing circuit when the stylus holder contacts the insulated lead contact (8). As the force to be measured is large compared to the force necessary to indent the insulated contact, the damping effect was found to be negligible. The contact plug (9) screws into the flanged plug (10) which is held to the housing by a phenolic insulator (11). The gap setting is determined as follows: first, by advancing the contact plug containing the lead contact until it touches the set screw on top of the stylus holder as indicated by a meter across these points; the points are then separated a predetermined distance by backing off the contact plug, making allowance for the depth of water at which the instrument is to be operated. For these particular instruments, the contacts were set to complete the circuit when the diaphragm was deflected inward one-tenth of its maximum allowable pressure range above the static pressure in which it operates. The gap is fixed after this setting by the locking plug (12).

When the contact points are closed, a current passes through a detonating cartridge held in a steel cartridge plug which ejects the firing pin

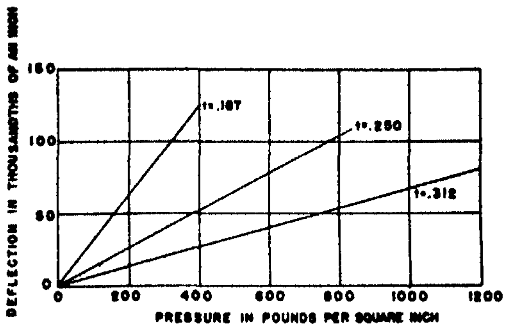

FIG. 4. Deflection of diaphragm as a function of static pressure and thickness of diaphragm material.

(13). This releases the plunger from a locked position. The energy to fire the detonating cartridge is supplied from two small flashlight batteries wired in series and contained in a separate bore in the housing.

The two seal plugs (14), the diaphragm, the bottom plate, and the end cap (16) with their respective gaskets are fastened to the housing, thereby forming the water seals. Because these instruments were used under water for the most part, at depths up to one hundred feet for extended periods of time, it was necessary to give special attention to the seals used. The gaskets found to be satisfactory for the bottom plate and the end cap were rings approximately one-fourth-inch wide placed just inside the bolt circles, and were made of $\frac{1}{32}$-inch thick, hard, service-type sheet asbestos. The seal plug gaskets were made of thin copper pressed over an asbestos core, similar to automobile spark plug type gaskets, and were lubricated with white lead before tightening the seal plugs. At the metal-to-metal contact of the diaphragm to the housing, non-hardening gasket cement[3] was used.

TABLE I.

Diaphragm thickness in inches	Pounds per square inch to produce 0.001-inch deflection	Maximum allowable pressure in pounds per square inch
0.187	3.23	400
0.250	7.76	800
0.317	14.90	1200

Diaphragms were provided in three thicknesses to extend the range of sensitivities. In Table I the approximate characteristics of each thickness of diaphragm is tabulated. Figure 4 is a graph of experimentally derived data plotting the deflection of the three thicknesses of diaphragms as a function of pressure. It was found during the course of this investigation that the diaphragm had to be pre-stressed by the uniform application of pressure equal to the maximum allowable pressure in order to give a linear deflection with pressures up to the elastic limit of the diaphragm material. The following is an experimentally determined relationship:

$$d = (PR^4/4Et^3),$$

where d = deflection at center of plate in inches, P = pressure in pounds per square inch, R = effective radius of diaphragm in inches, E = modulus of elasticity in pounds per square inch, and t = thickness of diaphragm in inches. The above relationship was found to be accurate within five percent for the particular geometry and plate material used.

Figure 5 shows a publishable record made with this recorder during a test of "water hammer" effects caused by the sudden closing of a check valve in water flowing through an eight-inch pipe at approximately six feet per second. The initial peak indicates a maximum pressure of

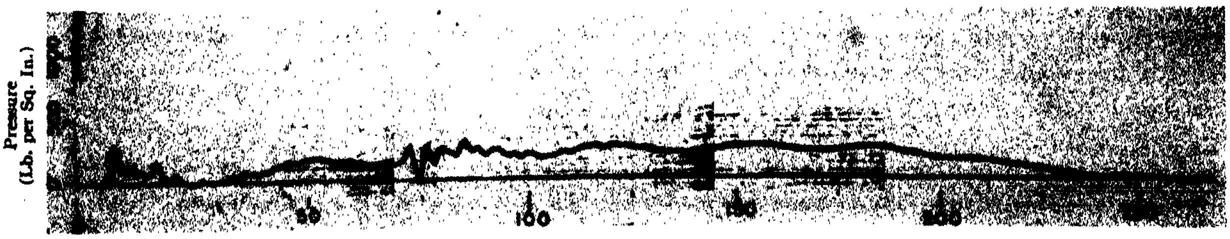

FIG. 5. Record obtained of pressure variation due to sudden closing of a check valve in a hydraulic system.

A Multiple-Reflection Optical Lever*

H. O. Hoadley
Kodak Research Laboratories, Rochester, New York

(Received October 2, 1948)

A detailed description is given of the principles of an optical lever which secures increased sensitivity by means of multiple reflections from a single small mirror. It is of particular use where space is limited, or where the mirror must have minimum size and mass, as in a galvanometer. Its limitations are an inherent restriction of the measurable range, and a comparatively rapid loss of light with increasing number of reflections. A model system was constructed, which demonstrates that no special difficulty is met with in making an optical lever according to these principles up to seven reflections. Tests made with the fifth-order reflection proved the model to be quite satisfactory.

INTRODUCTION

THE usual form of optical lever makes use of a single reflection of a beam of light from a rotating mirror, which means that the reflected beam is deflected by twice the angle of rotation of the mirror. Another frequently used form consists of a fixed plane mirror placed opposite the moving mirror, with the beam of light reflected back and forth between the two. The deflection of the emergent beam is that for the single mirror, multiplied by the number of reflections from the moving mirror. The main disadvantage of this latter type of mirror system is that the moving mirror must be large enough so that the successive intersections of the beam fall at different positions; if they overlap, the complete beam cannot escape from the ends of the system. This requirement makes the system unsuitable for use where small mass or size of the moving mirror is important.

The multiple-reflection optical lever described here is designed to remove this objection, while retaining the multiplied sensitivity. The optical system is such that light leaving the rotating mirror in one direction is returned to the same place on the mirror, but from a different direction. The mirror may therefore be made very small.

BASIC PRINCIPLES OF THE OPTICAL LEVER

The construction and performance of the optical system are complex, and therefore a step-by-step explanation of the ideas behind them is given.

On Fig. 1, the arc, SS', represents the surface of a spherical mirror of radius r, the center of which is at C. The two blocks, M and M', are two small plane mirrors, the surfaces of which lie in a plane which passes through C, and the midpoints of which lie the same distance, d, from the point C. The line CV is drawn perpendicular to the plane MM'.

---

* Communication No. 1215 from the Kodak Research Laboratories.

Assuming d to be a small fraction of the radius of the spherical mirror, view the two mirrors, M and M', from any point, P, on the surface of the spherical mirror. The surface normal, of course, passes through C, and M and M' subtend approximately the same angle on either side of the normal. The distance PM' exceeds the radius by the same amount that the distance PM is less than the radius (or vice versa, if the point P is on the other side of CV). Therefore, a bundle of rays proceeding to any section of the spherical mirror from the point M will be focused, to a close approximation, at the point M'.

Speaking mathematically, we say that the center of a spherical reflecting surface has a magnification of -1. A line element at this point is imaged on itself, but reversed.

In Fig. 2 is shown the path of the beam which constitutes the optical lever. The path is laid out in the following way: A ray is drawn perpendicular to the mirror M', intersecting the spherical mirror at P_a. The spherical mirror directs the reflected ray to M, which, in turn, sends it back to the spherical mirror at P_b. This means that a ray directed into the system at P_b would retrace its path from the reflection at M', and leave the system again at P_b, having been reflected once at M' and twice at M. To get five reflections from M and M', instead of three, the spherical mirror is extended to reflect the rays once more at P_b. The dashed line indicates how the two rays, entering and emerging, are directed again to the mirror M', and leave the system at P_c. The path as defined in this way will be referred to as the undeviated beam.

Effect of Rotating the Mirrors

In the case of three reflections, as shown by the solid lines in Fig. 2, it will be seen that rotating the mirror M counter-clockwise by a small angle, α, around the axis perpendicular to the plane of the drawing produces a counter-clockwise deviation of approximately 4α in the emergent ray. However, rotating the mirror M' in the same direction by the angle α produces a *clockwise* deviation of 2α in the emergent ray. **Therefore, in order that the deviations shall be additive, it is necessary that the two mirrors, M and M', shall be rotated in opposite sense.**

This requirement is fulfilled if M' is a virtual image of M, produced by placing a long plane mirror on the line CV. When this is done, the actual path of the rays is as shown in Fig. 3. The solid lines indicating three reflections, and the dashed lines indicating two more reflections, correspond to the rays shown in Fig. 2. To avoid confusion, the system will still be shown "open," as in Fig. 2, but it should not be forgotten that CV represents a plane mirror, and that everything shown to the left of CV is a virtual image.

The Collimating Lens

If we consider a complete beam of light traveling through the system, rather than just a single central ray, it is evident that objectives and field lenses are needed. The spherical mirror acts as a field lens at each reflection, but there must be a collimating lens in front of the mirror M. This lens must render parallel a bundle of rays proceeding from the point P_b, focus the reflected rays again at the point P_a, and similarly for the other reflections. The lens should be as close as practicable to M, its axis in the plane of the drawing, and parallel to CV. The mirror M should be placed so that a perpendicular to CV from the point C passes through the virtual image of the mirror, as seen through the collimating lens. From this it is seen that the focal

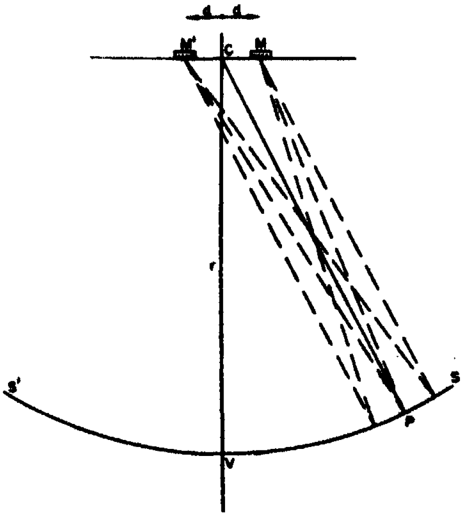

FIG. 1. Diagram of a spherical reflecting surface, showing how a point lying a small distance from the center is imaged to a close approximation on a point diametrically opposite.

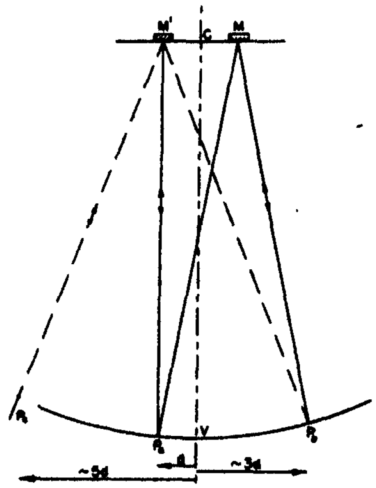

FIG. 2. Schematic view of the path of the light beam in the optical lever.

length of the lens must be slightly less than the radius of the spherical mirror.

Preferably, the collimating lens is corrected for chromatic and spherical aberration, and its field is curved on a radius approximately equal to its focal length. Coma and color magnification are corrected automatically, since the lens and its virtual image form a completely symmetrical objective, with the mirror M as the stop. In the working model described below, an ordinary telescope objective has proved to be quite adequate for the purpose.

The collimating lens, L, is shown in Fig. 3. Because the drawings are of a schematic, rather than pictorial, nature, the lens is not shown in Figs. 4–7, but it should be understood that it is necessary in the actual construction. The proper converging power could be obtained by using a concave mirror at M instead of the lens, but the field of such a concave mirror is curved in the opposite direction from that of the lens, and therefore will not match the curvature of the fixed concave mirror.

Position of the Deviated Images

In Fig. 4(a) is shown the system with three reflections, as explained in Fig. 2. The solid lines represent the path of the rays when the deflection mirror is perpendicular to the plane mirror, CV, while the dashed and dotted lines are the path of the deviated ray, when the mirror is rotated by an angle, α. The first reflected ray is deviated by the angle 2α, and strikes the spherical mirror at P_a', from where it is sent to M'. The distance between P_a and P_a', which will be called δs, is approximately equal to $2r\alpha$. After reflection at M', the returning ray, now indicated by the dotted lines, intersects the spherical mirror again at P_a'', is reflected once more by the mirror M, and emerges at the point P_b''. Since 2α is added to the deviation of the ray at each reflection by M or M', it may be seen that the distance P_aP_a'' is approximately $2\delta s$, and the distance P_bP_b'' is approximately $3\delta s$, or $6r\alpha$.

A similar drawing for a system with five reflections is shown in Fig. 5(a), indicating that the resultant deviation of the ray is approximately $10r\alpha$.

In actual practice, the deviated emerging ray falls on a scale having the same curvature as the spherical mirror. The beginning point for the fixed entering ray is a reference line in the focal plane of an eyepiece, or an index mark or slit illuminated by a condensing lens. In the first case, the exit pupil of the eyepiece is the image of the moving mirror; in the second case, the condensing lens images the light source on the moving mirror.

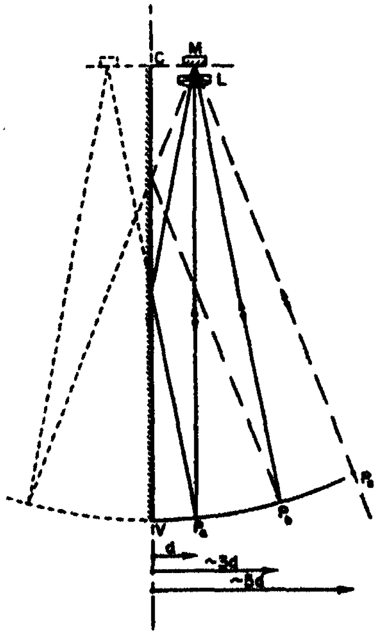

FIG. 3. The actual path of the beam when a plane mirror is placed along the vertical center line, CV.

This means that the emerging ray should not follow exactly the path of the entering ray. The two may be separated by directing the entering ray toward M from a point slightly below the plane of the drawing of Fig. 4(a). In Fig. 4(b) is shown what happens in that case. Figure 4(b) is a view in elevation of the same rays shown in plan in Fig. 4(a). The two squares are the mirrors M and M', viewed normally, and the line MM' is the plane of the drawing of Fig. 4(a). The solid line indicates again the path of the undeviated ray, and the solid dots the intersections of this ray with the spherical mirror. The intersections of the deviated ray are indicated by the small circles.

The ray enters the system at the point P_0, directly under P_b. The successive intersections with the spherical mirror are then P_1, which is above P_a, P_2 below P_a, and the final point P_3 above P_b. Separation between entering and emerging rays in the vertical direction is thus achieved. The points of intersection with the spherical mirror of the deviated ray are then, successively, P_1' above P_a', P_2' below P_a'', and the emergent point P_3' above P_b''.

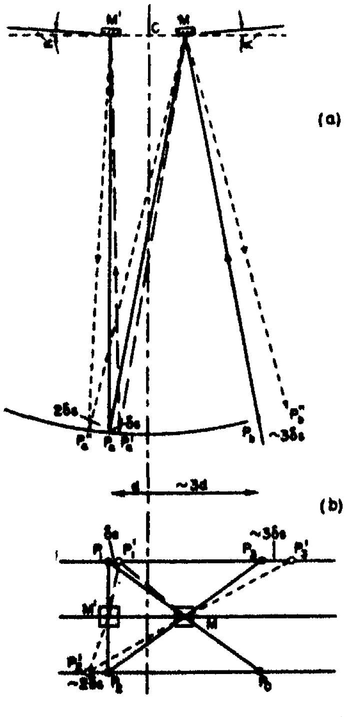

FIG. 4. The deviation in the beam caused by rotation of the mirror, M, for a system of three reflections: (a) a plan view; (b) the elevation.

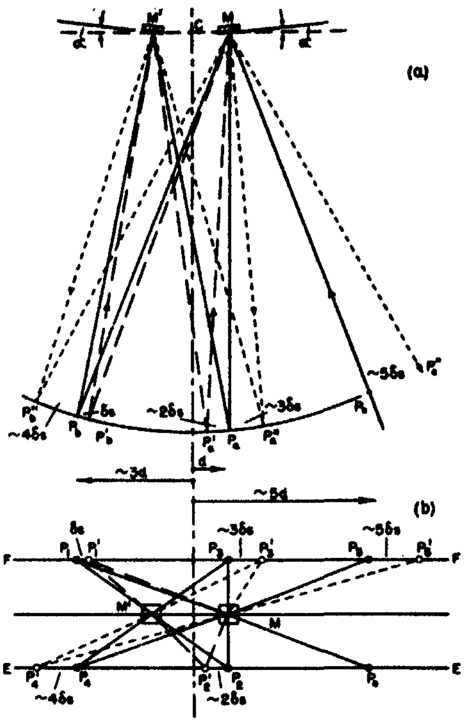

FIG. 5. The deviation in the beam for a system of five reflections.

A similar plan view for the case of five reflections is shown in Fig. 5(b).

In Fig. 6, the drawings of Figs. 4(b) and 5(b) have been reproduced, but with the virtual images to the left of the fixed plane mirror, indicated by dotted lines, and the intersection points shown where they actually occur to the right of that mirror, as in Fig. 3. The path of the deviated ray has not been drawn, but its intersection points are shown.

Limitations on the Measurable Angle

From Fig. 6 may now be seen how the total deviation of the ray is limited by the dimensions of the system. Referring first to the case of three reflections (Fig. 6(a)), we see that the distance between the points P_2 and P_0 is approximately $2d$. Since P_0 is the entering point, and P_2' must fall on the reflecting surface, the maximum possible deviation is reached when P_2' reaches the position of P_0, which means that $2\delta s = 2d$. It was shown earlier that $\delta a = 2r\alpha$, and therefore the largest measurable angular deviation of the mirror M *in this direction* is $\alpha = d/2r$, and the largest scale deflection produced is $3\delta s = 3d$. If

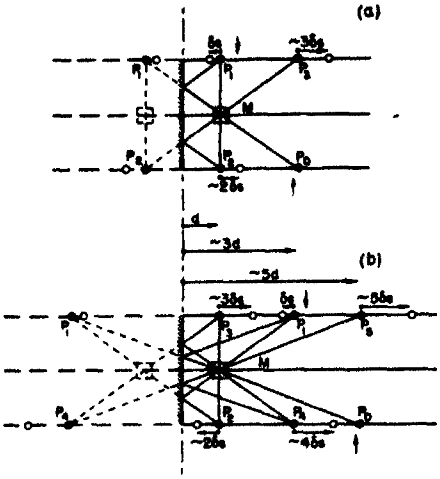

FIG. 6. Plan views for systems of (a) three reflections, and (b) five reflections. These are Figs. 4(b) and 5(b) replotted to show the actual path of the beam with the plane mirror along the center line.

the mirror M is rotated in the opposite direction, the limiting position is reached when the point P_2' meets P_1'. For this position, $4\delta s=2d$; the maximum angle is $\alpha=d/4r$; and the maximum scale reading $1.5d$.

It should be noted that, in order to take full advantage of both directions for the deflection, it is necessary that the spherical mirror have different lengths above and below the center plane, as indicated by the vertical arrows in Fig. 6. Although the beam returning to a position directly above the entrance aperture has been called the "undeviated" beam, there is no reason why the zero of the moving mirror should not be adjusted to lie at some other part of the scale. The concept has been used only for convenience in the explanation.

For the system of five reflections (Fig. 6(b)), the deviation in the direction shown in the drawing is limited by the point P_4' reaching P_0. Then, $4\delta s=2d$, the maximum angle is $\alpha=(1/4)(d/r)$, and the maximum scale reflection is $5\delta s=2.5d$. In the opposite direction, the limiting position is that where P_1' and P_4' meet, which means that $6\delta s=2d$. The corresponding angle and scale deflection are, respectively, $\alpha=(1/6)(d/r)$ and $5\delta s=(5/3)d$.

The total maximum measurable angles and maximum scale deflections will be the sum of those in both directions, as follows:

	Max. angle	Max. scale
$3x$:	$0.75(d/r)$	$4.5d$
$5x$:	$0.41(d/r)$	$4.1d$

It may be seen from this that the maximum measurable angle for a given number of reflections is directly proportional to d. However, the larger the value of (d/r), the less closely the actual dimensions of the system approach the approximate values given above, and the greater the departure from linearity of the scale reading as a function of the mirror deflection, α. No calculations have been made as to the amount of non-linearity that might be expected in such a system.

The non-linear errors will, of course, be greater, and the maximum measurable angle smaller, when the "mechanical advantage" of the system is increased by using more than five reflections from the moving mirror. The approximate dimensions of such a system may be found by using the same arguments as given above for systems of three and five reflections.

Systems with an Even Number of Reflections

The system as illustrated in Fig. 2 always results in an odd number of reflections from the

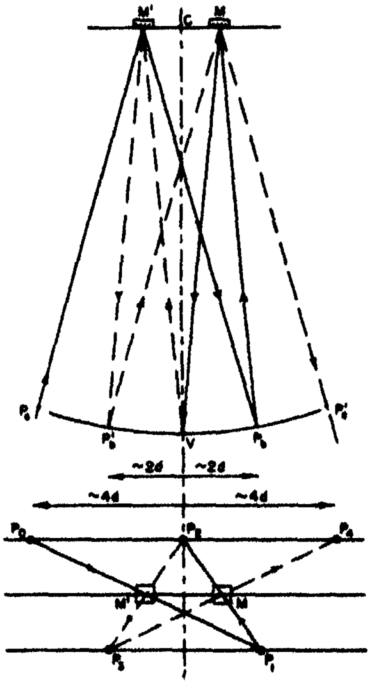

FIG. 7. The path of the beam for an even number (4) of reflections.

moving mirror. Systems with an even number of reflections may be developed by starting the ray from the point *V* toward the moving mirror, as shown in Fig. 7. The elevation view of the system indicates that the emerging ray always follows the path of the entering ray, and cannot be separated from it in the vertical direction. Another disadvantage of such a system is that the undeviated ray falls exactly on the joint between the spherical mirror and the fixed plane mirror.

DESCRIPTION OF THE MODEL

A simple model of the optical lever was constructed, and a photograph of it is shown in Fig. 8. The spherical mirror and the fixed plane mirror should be easily identified in the photograph. The former was cut from a lens element having a surface of the desired curvature, and the latter is a strip from a piece of good-quality plate glass. The moving mirror is attached to the galvanometer movement, and the collimating lens is mounted in a simple focusing mount which replaces the window originally furnished on the galvanometer. The galvanometer mirror is only 3×4 mm. This particular model was intended to detect a yes-or-no deflection, so the slit was extended both above and below the meridian plane, and the small rectangular mirror with a vertical knife-edge placed next to the slit to reflect the emerging beam into a photo-cell.

The vertical entrance slit is 22 mm long, and the height of the mirrors is 25 mm. The collimating lens is a telescope doublet, with an aperture of 18 mm. The radius of the spherical mirror is about 20 cm, *d* is 1 cm, and the distance of the slit from the fixed plane mirror is 5.5 cm, so that the beam undergoes five reflections from the galvanometer mirror when it is perpendicular to the fixed mirror. Accordingly, the model shown has a sensitivity equal to that of a single-reflection optical lever one meter long.

The galvanometer-adjusting knob may be turned counter-clockwise until the first-order reflected image of the slit falls back on the entrance slit. As the knob is turned clockwise from this position, the first-order image moves across the spherical mirror. When it reaches the joint between the mirrors, the second-order image starts across. When these two images coincide, the third-order image may be found at the entrance slit. With further rotation of the knob, the successive orders follow across the mirror. Seven orders are easily visible, even though the system was laid out to use only five. The optical image quality of all visible orders is good. Of course, in this particular application the even orders might be used as well as the odd, since the emerging beam does not have to be imaged on the entrance slit, nor separated vertically from it.

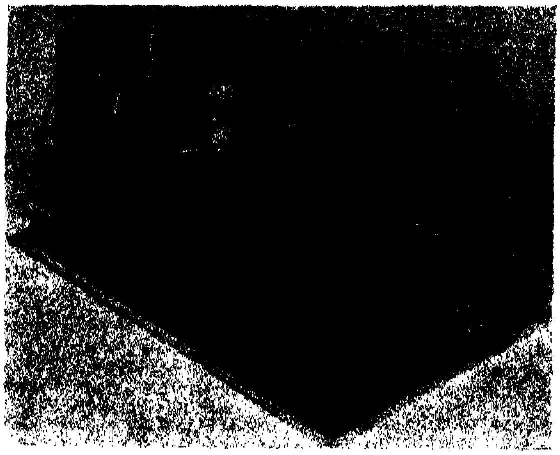

FIG. 8. A working model of the multiple-reflection optical lever.

One other limiting factor of this type of optical lever became apparent in the model: the loss of light in the high order reflections. Each additional reflection from the galvanometer mirror requires two other reflections from the fixed mirrors and two passages through the collimating lens. Although the two fixed mirrors have good evaporated aluminum first-surface coatings, and the lens has an antireflection coating on both surfaces, still each reflected image of the slit looks about half as bright as the image of the next lower order.

Geometrically, the model demonstrates very nicely the principles of the system, and no special mechanical difficulties were encountered in its construction.

THE REVIEW OF SCIENTIFIC INSTRUMENTS VOLUME 20, NUMBER 1 JANUARY, 1949

Improved Magnetic Focusing of Charged Particles

LARKIN KERWIN
Department of Physics, Laval University, Quebec, Canada

(Received September 20, 1948)

A general theory of geometric magnetic focusing of charged particles is developed. Some special cases are discussed. One proves to be the type of focusing in general use; another, equally simple, eliminates second-order aberrations.

I. INTRODUCTION

THE majority of experimental mass spectrometers constructed during the last decade have utilized the second-order focusing properties of wedge-shaped magnetic fields as described by Barber[1] and Stephens.[2] The general appearance of the ion beam trajectory is shown in Fig. 1A. In undertaking the construction of such an instrument in this laboratory, some thought was given as to how the edges of the magnetic field might be reshaped so as to improve the focusing, and possibly reduce the size of the magnet.

II. PERFECT FOCUSING

It is of interest to consider what symmetrically shaped uniform magnetic field would give theoretically perfect focusing of an ion beam of wide divergence. In Fig. 2, where OY is the axis of symmetry, it is desired that all rays leaving a source A should refocus through a point B, such that $AO=OB=a$. We shall here only consider rays in the plane AYB, which is the median plane (midway between and parallel to the pole pieces).

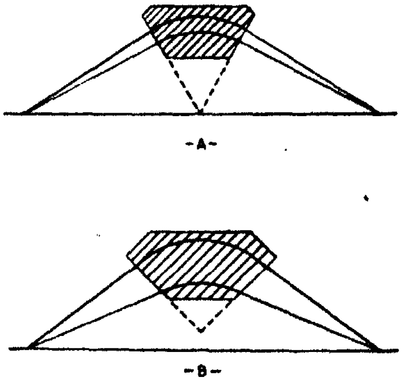

FIG. 1. Typical mechanical appearance of normal and inflection type magnetic fields.

Symmetry imposes the condition that all beams should cross OY at right angles and, therefore, that the center of curvature of the ion beam while in the magnetic field should lie on OY. For a beam leaving A at any angle θ with AB, it is a simple problem in geometry to obtain the point (x, y) where it must enter the magnetic field in order to cross OY at right angles with a given radius of curvature R centered on OY. From Fig. 2 we then have

$$\begin{aligned} y/(a-x) &= \tan\theta \\ &= x/(R^2-x^2)^{\frac{1}{2}}, \end{aligned}$$

whence

$$y = x(a-x)/(R^2-x^2)^{\frac{1}{2}}. \qquad (1)$$

Tracing the points (x, y) for various values of θ gives a symmetrical field as shown by the shading in the figure. This field will give perfect focusing at B of any ions coming from A.[3] Various values of the ratio R/a give the field shapes as shown in Fig. 3.

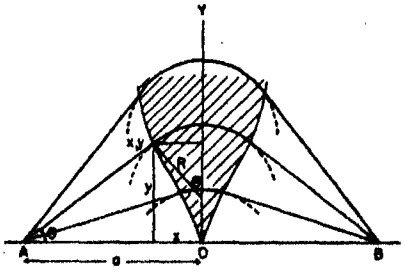

FIG. 2. Geometric composition of perfectly focusing magnetic field.

[2] William E. Stephens, Phys. Rev. 45, 513 (1934).

[3] It has been brought to our attention that H. Hintenberger has recently published an article [Zeits. f. Naturforschung 3a, 125 (1948)] in which similar considerations are presented, and our Eq. (1) is developed. To date, we have not been able to obtain copies of his paper.

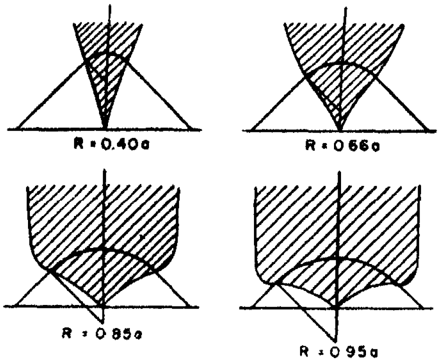

FIG. 3. Variation of ideal field shape with ratio R/a.

III. GENERAL EQUATION

Should the theoretically ideal field as given by Eq. (1) be changed in some way, then an ion leaving A in a given direction would not pass through B, but would have its point of intersection with the line AB displaced. As will be discussed later, aberration, dispersion, image width, etc. may all be considered as being caused by the ideal field's being approximated by some other. Therefore, we shall develop the general equation giving the displacement of the point of intersection with the base line AB produced by any approximation to the ideal magnetic field shape.

In Fig. 4 is shown the path traversed by a charged particle leaving a source O and recrossing the base at L after being deflected by a uniform magnetic field of arbitrary shape. Using the notation as shown and putting $\theta=(\phi+\epsilon)$ where ϵ is small, it may be shown that

$$OL=2x_1-2a+2R\sin\theta-\frac{(x_1-a)(x_2-x_1)}{R\cos^2\theta\sin\theta}+\frac{2(x_1-a)}{\cos^2\theta}. \qquad (2)$$

If we use a uniform magnetic field of the shape as determined by Eq. (1), then the above expression gives the focusing point of the various ion beams. If the ideal magnetic field boundaries are then changed, as indicated in Fig. 5, there will be a displacement dL of the point of intersection as given by Eq. (2). This may be shown to be

$$dL=\frac{2\eta}{[\tan\theta+f'(x)]^2}\left[\tan\theta+f'(x)+\frac{\tan\theta(a-x)f'(x)}{R\cos\theta\sin^2\theta}\right]. \qquad (3)$$

In this expression, $f(x)$ is given by Eq. (1).

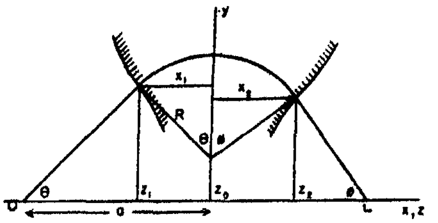

FIG. 4. Path of a charged particle leaving O and being deflected by an arbitrary field.

IV. STRAIGHT LINE APPROXIMATIONS—ABERRATION

Equation (3) gives the displacement dL of the intersection point due to the displacement of the magnetic field boundaries by an amount whose y component is η. In general, η is also a function of x, and it is convenient to express dL in terms of this function. More particularly, it is useful to obtain the expression for straight line approximations, as these are the simplest to use in practice. Thus, in Fig. 6, we see that if the ideal boundary is approximated by a straight line crossing the ideal boundary at a point P, then a ray entering the field at an angle ω with the ray through P has, in effect, the field boundary displaced a certain distance from the ideal. Its point of intersection with the line AB will therefore be displaced an amount dL, which is the aberration due to the approximation. We may now conveniently rewrite Eq. (3) in terms of ω. We see that $\eta=F(\Delta x)$, and since it may be shown that

$$\Delta x=(a-x)\omega/[\tan\theta+f'(x)]\cos^2\theta,$$

we may finally write for a beam divergence of 2ω (ω on either side of the central ray):

$$dL=\frac{2}{[\tan\theta+f'(x)]^2}F\left[\frac{(a-x)\omega}{[\tan\theta+f'(x)]\cos^2\theta}\right]\times\left[\tan\theta+f'(x)+\frac{\tan\theta(a-x)f'(x)}{R\cos\theta\sin^2\theta}\right]. \qquad (4)$$

Equation (4) gives the aberration produced by any straight line approximation to the theoretically perfect curve in terms of the half-divergence ω of the incident beam. It is now necessary to find straight line approximations for which $\eta=F(\Delta x)$ is small if the aberration is to be small.

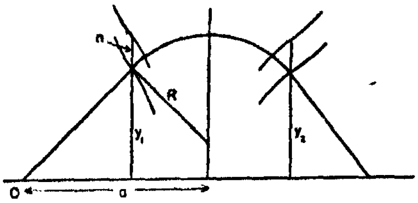

FIG. 5. η is the y component of a displacement of the magnetic field boundary.

V. NORMAL CASE

In Fig. 7, the point P is such that the distance AP is a minimum, i.e., AP is normal to the curve. In finding this point by expressing AP as a function of x and equating the derivative to zero, it is found that for this condition $R=a\sin\theta$. In other words, the tangent to the curve at P passes through O, and $PO=R$. This tangent is a good approximation to the curve at P, and if we expand the ideal boundary equation in a Taylor series at the point P, then the tangent equation will differ from it only in terms of the second degree and higher. That is,

$$\eta=\tfrac{1}{2}f''(x)dx^2+\cdots. \quad (5)$$

By substituting this expression in (4), along with the relations established from Fig. 7, we obtain for the aberration in this case,

$$dL=a\omega^2.$$

If the aberration is measured at the image point normal to the central ion trajectory, it becomes

$$dL=a\omega^2\sin\theta. \quad (6)$$

We note that this case is exactly that developed by Barber, Stephens, and others. In other words, the type of magnetic focusing currently in use is that operating on this tangent to the ideal boundary as shown in Fig. 7. It will hereafter be referred to as *normal focusing*.

VI. INFLECTION CASE

From Eq. (1) it may be shown that the ideal curve has an inflection point given by

$$x_f=3a+(9a^2-8R^2)^{\frac{1}{2}}/2. \quad (7)$$

Therefore, we may closely approximate the ideal curve by a straight line tangent to the curve through the inflection point, as shown in Fig. 8.

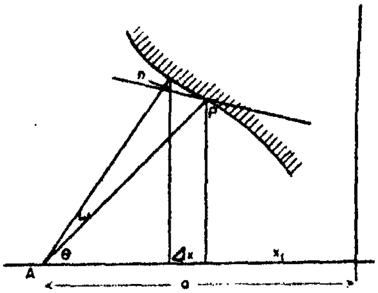

FIG. 6. General case of straight line approximation to ideal curve.

In this case we see that the straight line equation differs from the Taylor expansion of Fig. (1) at the point P only in terms of the third degree and higher. That is,

$$\eta=1/6f'''(x)dx^3+\cdots. \quad (8)$$

Ignoring higher orders and substituting this expression in (4), together with the relations established in Fig. 8, we obtain for the aberration, measured as before,

$$dL=2/3\omega^3[(3a-x)(3a-2x)\sin\theta/6x(a-x)^{\frac{1}{2}}]. \quad (9)$$

This type of focusing will hereafter be referred to as *inflection focusing*. We see that for small values of ω, the aberration produced by this approximation to the ideal field will be smaller than that due to normal focusing.

VII. OTHER CASES

Any other straight lines approximating the ideal curve will be either tangents at some point, or will cut it at an angle. In all cases they will differ from the ideal curve by at least the second degree in the Taylor series, and will produce aberrations of the second order. Theoretically, fields bounded by curved edges will approach the ideal even more closely than the inflection field. For example, third-order aberration will result from the use of magnetic fields whose edges are in the shape of circles. The centers of these circles are located on the extended lines of the central ion beam's initial and final directions, and their radii are given by[4]

$$R_m=R\cot^3\theta.$$

---

[4] This radius is obtained by finding the radius of curvature of the function given by Eq. (1) at the "tangent" point as defined in Section V. In a paper currently in press, K. T. Bainbridge reveals that he is constructing a

Application of Eq. (3) gives the aberration produced by this shape of field as

$$dL = R\omega^3.$$

Obviously, the ideal field may be approximated closely by the arc of a circle at any other point as well. A limiting case is the circle of infinite radius at the inflection point, a case discussed as inflection focusing.

Similarly, field edges in the shape of two arcs of circles centered on the normal to the ideal curve at the inflection point, and tangent to it from opposite directions, would give a better approximation than the tangent line at this point. If the length of field edge to be used extends a distance k on either side of the inflection point, then the radii of the circles to be used are given by

$$1/R = f''(x) + [f'''(x)/4]k,$$

where $f(x)$ is given by Eq. (1). In this case, the *average* of the third-order aberrations of a beam width extending over the distance k is equal to zero.

VIII. DISPERSION

The dispersion produced by an inflection field does not differ greatly from that produced by a normal field. It is possible to express the dispersion as a function of η, and so Eq. (4) provides a convenient means for evaluating it exactly. It may be shown that the dispersion for the general case is given by

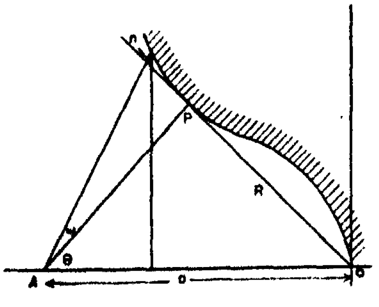

FIG. 7. Normal approximation to ideal curve. Point P is such that AP is normal to tangent.

$$D = 2\Delta R \sin\theta + \frac{\eta}{[\tan\theta + f'(x)]^2}\left[\tan\theta + f'(x) + \frac{\tan\theta(a-x)f'(x)}{R\cos\theta\sin^2\theta}\right]. \quad (10)$$

When the conditions for the normal field are substituted and measurement is made normal to the central ion beam at the image, this becomes

$$D_n = 2a\Delta R/R \sin\theta. \quad (11)$$

This is the familiar case[3] and verifies the correctness of the theory. For the inflection field, substituting the proper expressions gives

$$D_f = 2\Delta R/R(a - x/3) \sin\theta. \quad (12)$$

D_f will therefore have a value between D_n and $2/3D_n$. In the usual case, as discussed later, D_f is approximately $0.9D_n$.

IX. WIDE SOURCES

The theory developed in the previous paragraphs has treated only point sources. If the source section in the median plane is a straight line of width s perpendicular to the central ion trajectory, then it is possible to use Eq. (4) to calculate the image produced by the various approximations. It has thus been verified that the image in both normal and inflection cases is a straight line equal to the source in width, but is inverted.

X. PRACTICAL CONSIDERATIONS

It has been shown that magnetic focusing devices such as mass spectrometers may be designed so as to utilize inflection focusing. This will eliminate second-order aberrations, yet re-

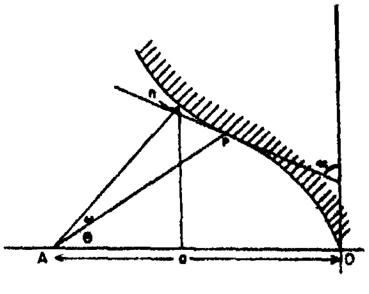

FIG. 8. Inflection approximation to ideal curve. Point P is inflection point of curve.

---

spectrometer in which the aberration is reduced by curving the edges of the magnetic field. He gives as the expression for the radius of curvature $R_m = R\cot^3\theta(\cot\theta - \alpha)$ where α is the half-divergence. This is practically identical with our own. Dr. Bainbridge also gives the expression for correcting the shape of the pole pieces when only one side is available for the purpose.

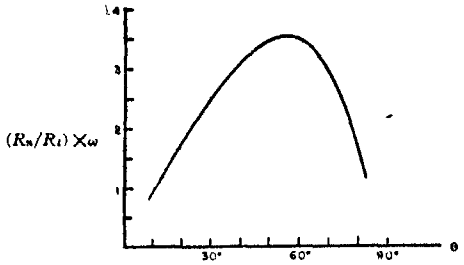

FIG. 9. Ratio of resolving powers of inflection and normal type magnetic fields as a function of θ.

tain simple, straight line field boundaries. The appearance of such a device is suggested by Fig. 1B, where it is seen to bear close mechanical resemblance to the normal focusing device of Fig. 1A. Of some interest is the ratio of the resolving powers of the two fields for various values of θ and a point source. Considering the resolving power as being proportional to the dispersion divided by the aberration, this ratio of resolving powers becomes

$$R_f/R_n = 6x(a-x)^{\frac{1}{2}}/2(3a-2x)\omega. \qquad (12)$$

This has been calculated for various values of θ, and is shown graphically in Fig. 9. We see that there is an optimum ratio near 60°, in which case the usual divergence of 2ω equal to about 4° would give the inflection instrument a resolving power about 10 times higher than that of the normal instrument. It is interesting to note that the optimum case corresponds to a value of α (see Fig. 8) of 90°, in which case the magnetic field profile becomes a single straight line, like those used for 180° deflection in normal spectrometers. In Table I are set down some pertinent data which may be of interest to designers.

The discussion presented here, however, deals with geometric focusing in the median plane, whereas many other factors enter into the design of actual instruments. Rays whose trajectories are not in the median plane are subject to other aberrations. Those whose paths lie at an angle to this plane will experience a dispersion due to the shortening of their velocity component parallel to the median plane. If we include this effect, then the total aberration for a line source becomes in the normal case

$$A = R\omega^2 + R\beta^2,$$

where ω is half the angle of divergence in the xy plane as discussed before and β is the angle of divergence in the z direction permitted by a source of length h. β is given by[6]

$$\beta = h/[2R(\cot\theta + \theta)].$$

In the usual instrument, β^2 is less than $0.1\omega^2$, so that the aberration due to this effect may be neglected. A similar divergence is produced by a variation in the energies of the ions furnished by the source. It is usually made small by using high accelerating voltages. These effects will be somewhat diminished by inflection fields whose dispersion is less than that of normal fields.

For the inflection case, where the rays do not enter the magnetic field normal to its boundaries, rays not in the median plane suffer another defocusing effect due to the fringing magnetic field. Since the field lines at the fringe are curved, the non-median rays will not cross them at 90° and, because of their angle of entry, there will be a small component of the fringing field normal to both the ion trajectory and the main field. This will defocus the beam in the z direction. Therefore, the image of the source will be longer than the source and, unless the exit slit is as long as the image, there will be a loss of current intensity to the collector.

It may be shown from geometric considerations that the resolving power of the direction focusing instrument is given by

$$RP = R/I + F + A,$$

where R is the radius of curvature of the ion path in the magnetic field, I is the image width (equal to the object width), A is the total aberration due to various causes, and F is the exit slit width. Whether or not the total aberration has much effect on the resolving power

TABLE I.

θ	R	x	D_f/D_n	A_f/A_n	R_f/R_n	α(Fig. 8)

depends, therefore, on the particular design. For the inflection field, the aberration due to the geometric shape of the field is very small, and it would probably be advantageous in most cases to increase the divergence of the beam in order to obtain increased intensity at little cost in resolving power. The aberration $R\beta^2$ is also usually negligible. In the case of 180° spectrometers it is possible to obtain increased intensity for the same resolving power by using longer, narrower sources of greater area, but producing the same total aberration as the usual short wide source.[5] In the general case this is also possible insofar as the effect is not too greatly reduced by the field fringe effect.

It is suggested that the principle of inflection focusing may be applied so some of the problems to which attention has recently been invited by Auld.[6]

ACKNOWLEDGMENTS

Sincere thanks is due the members of the Physics Department for enlightening discussions, and in particular are tendered to Professor Enrico Persico who provided a neat mathematical development of Eq. (4) and guided the theory's development, to Professor Paul Koenig who instigated the investigation and followed it critically, and to Professor Claude Geoffrion. Appreciation is expressed to Professor Kenneth T. Bainbridge of Harvard University, who kindly permitted us to read the manuscript of one of his papers currently in press.

THE REVIEW OF SCIENTIFIC INSTRUMENTS VOLUME 20, NUMBER 1 JANUARY, 1949

A Geiger-Mueller Counting Unit and External Quenching Equipment for the Estimation of C^{14} in Carbon Dioxide

W. B. MANN* AND G. B. PARKINSON**
National Research Council, Atomic Energy Project, Chalk River, Ontario, Canada

(Received August 19, 1948)

A counter unit and external quenching circuit for use with carbon dioxide and carbon disulfide mixtures are described. The counter unit consists of a long and short counter to eliminate end effects. The quenching circuit, which depends on the action of a multivibrator, enables the voltage across the Geiger-Mueller counter to be reduced in a controllable manner by any desired amount and for any desired time.

I. INTRODUCTION

THE internal gas-counting technique developed by Miller,[1,2] using Geiger-Mueller counters filled with carbon dioxide and carbon disulfide mixtures, is especially suitable for the determination of the activity of C^{14} samples that can readily be converted into carbon dioxide. For accurate measurements, however, it is necessary to use an external quenching circuit for the Geiger-Mueller counter that is consistent and stable in operation and can be adjusted to suit the characteristics of the counter. It is also necessary to make corrections for, or eliminate errors caused by, the end effects of the Geiger-Mueller counter. These two requirements have been met by the use of a compensated Geiger-Mueller counter, described in Section II, and a multivibrator quenching circuit described in Section III. By these means it has been possible to obtain highly reproducible measurements.

II. COMPENSATED GEIGER-MUELLER COUNTER

In using gas counters for the assay of C^{14} it is necessary to be assured that the end corrections are either small, or are eliminated, and that there is no appreciable correction for beta-particles originating near the wall and entering the material of the wall without giving rise to an electron avalanche.

Calculations based on the probable number of ion pairs produced per millimeter in carbon dioxide show that any wall effect of the type referred to is likely to cause only a small error. Calculations for the end effect, however, show that counts arising from beta-particles entering the cathode volume from the ends may amount to as much as 25 percent for a two-inch-long counter of half-an-inch diameter, with ends one-inch long.

Such a calculation for the end effect takes into account, however, only one element of possible error, namely, that due to beta-particles entering the cathode volume. A further possibility of error arises in the distortion of the electric field at each end and its penetration into the region of space beyond each end of the cathode volume. The magnitude of the error arising from this is difficult to estimate.

The total end effect may, however, be completely eliminated by taking a pair of counters of suitably different length but having the same cross-sectional dimensions and similar end geometries. Such a unit constructed from half-inch-diameter platinum tubes, 0.004-inch tungsten wire, and soft glass is shown in Fig. 1. If the short counter is long enough to provide a small length in the middle having only a radial component of electric intensity, the divergence of electric field at the ends should be identical for both counters. The difference in the counts will, therefore, correspond to an amount of radioactive gas contained in a cylindrical volume equal to the difference in volume of the long and short cathodes. This idealized cylindrical volume will have an electric intensity which is normal to tne wire everywhere along its length (the difference in length of the long and short cathodes), and no correction is required for particles entering the open ends of the cathodes provided the end geometries are approximately similar. The need to use very long counters to reduce the correction caused by the ends is thus obviated.

Fig. 1. Compensated counting unit.

III. MULTIVIBRATOR QUENCH CIRCUIT

It is well known that in a non-self-quenching Geiger-Mueller counter the discharge can be quenched by reducing externally the voltage across the counter, by a sufficient amount and for a sufficient period, following each discharge. Various circuits devised for this purpose have appeared in the literature.[3–9] Miller used a Neher-Pickering circuit to provide external quenching for his counters filled with carbon dioxide and carbon disulfide. The circuit described here, shown in Fig. 2, is believed to be superior to the circuits previously used, and in particular to the Neher-Pickering or Neher-Harper type of circuit, the reason being that in this circuit the voltage is quickly lowered below the threshold of the counter, held there for a predetermined period, and then promptly restored to the operating value. The counter is thus never operating at an intermediate voltage for more than an infinitesimal part of the time. It is also different from most simple multivibrator circuits in that the multivibrator itself is not used to apply the quenching voltage directly to the counter.

In the circuit of Fig. 2, a discharge in the counter causes the grid of V_1 to be driven negative, and this in turn causes the circuit to operate, generating a large negative square pulse which is applied to the anode of the counter through C_2. At the end of this pulse the voltage on the counter anode is restored to its original value, at which it remains until the next discharge occurs. For a short period immediately following the square pulse the circuit is inoperative, and it is a necessary condition for satisfactory operation that, should a count occur during this period, the discharge current of the counter must not be so great as to cause a substantial drop in its anode potential through charging C_2.

R9-QUENCH PERIOD CONTROL
R34-SENSITIVITY CONTROL

NOTE
ALL RESISTORS ARE ½ WATT UNLESS OTHERWISE STATED

FIG. 2. Multivibrator quench circuit.

A detailed description of the circuit operation follows.

When a discharge occurs in the Geiger-Mueller counter it causes a negative voltage pulse to appear at the grid of V_1; this causes a positive pulse to appear at the plate of V_1, and at the suppressor of V_3 through R_5, C_3. The suppressor of V_3, which is a dual-control tube, is normally biased beyond cut-off, so that no plate current flows. When the voltage on this suppressor is raised sufficiently, by the positive pulse, to allow plate current to flow through R_8, the grid of V_4 is driven negative, causing the plate and screen currents of V_4 to be interrupted. Consequently, the screen potential of V_4 rises sharply, and so does the grid potential of V_5, which is normally biased beyond cut-off. As the grid potential of V_5 rises, plate current begins to flow through R_{20}, causing a negative square wave—the quenching pulse—to be applied to the Geiger-Mueller anode, and the grid of V_1, through C_2. This process is shown diagrammatically in Fig. 3.

The circuit remains in this state, with V_1, V_4 cut off, and V_3, V_5 conducting, until C_4 has discharged sufficiently, through R_{10}, R_9, to allow the grid potential of V_4 to recover far enough for V_4 to conduct again. When this happens the process is reversed; V_5 is cut off, the voltage on the Geiger-Mueller anode is restored, and V_1 becomes conducting; this drives the suppressor of V_3 negative so that the plate current of V_3 is cut off, allowing C_4 to recharge, through R_8 and V_{2B}.

The duration of the negative square wave applied to the Geiger-Mueller anode—the quench period Q—is then determined by the time constant of C_4 and R_{10} in series with R_9. R_9 is made variable, so that the quench period can be adjusted.

At the end of the quench period, V_4 conducts, plate current flows through R_{14}, and the grid of V_3 is driven negative, so that V_3 becomes completely cut off. V_3 remains cut off until C_5 has discharged sufficiently, through R_{13}, to allow its grid potential to recover, at which point V_3 begins to draw screen current again, but not plate current, since its suppressor is now negative. C_5 recharges during the next quench period.

While the grid of V_3 is thus driven negative, this tube cannot draw plate current, so that the circuit is insensitive to further operation until the grid potential of V_3 has recovered. The time required for this recovery—the delay time δ—is determined by the time constant of C_5 and R_{13}. The purpose of this delay time is to allow C_4 to recharge, and to allow the other capacitors—the "speed-up" capacitors C_3, C_6, and the coupling capacitor C_2—to regain their normal potentials before the circuit is retriggered. In this way the operation of the circuit is made independent of the counting rate and of the random time distribution of the pulses from the Geiger-Mueller counter.

Should a count occur in the Geiger-Mueller counter during the delay time, it is not ignored, even though the circuit cannot operate immediately to produce a quenching pulse. In this event the Geiger-Mueller counter continues to discharge, drawing current through R_1 and so biasing off V_1, so that the plate voltage of V_1, and the suppressor voltage of V_3 rise until the suppressor can no longer prevent the flow of plate current in V_3. At the end of the delay time the grid potential of V_3 has recovered to approximately ground level, and V_3 becomes conducting; plate current will now flow through R_8 since the suppressor is no longer biased off. The grid of V_4 is thus driven negative, and the cycle of operation, as described above, is repeated, so that a quench pulse is again produced and applied to the Geiger-Mueller anode. Thus a count occurring during the delay time is quenched at the end of this time.

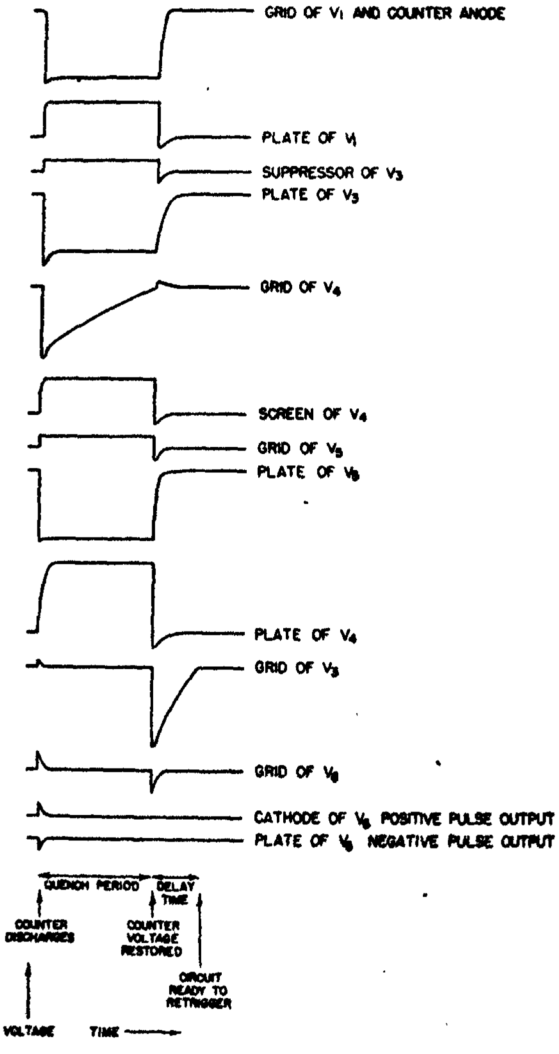

FIG. 3. Wave forms illustrating quench-circuit operation.

The output is obtained by differentiating, through C_7 and R_{21}, the positive square pulse appearing at the screen of V_4 during the quench period. A sharp positive pulse is thus applied to the grid of V_6 at the beginning of the quench period and a sharp negative pulse at the end. Since V_6 is biased beyond cut-off, only the positive pulse causes this tube to conduct, producing a positive output pulse at the cathode and a negative output pulse at the plate. These output pulses are suitable for operating a scaler, oscilloscope, or other auxiliary apparatus. V_6 acts as a buffer, preventing the output loading from having any effect on the operation of the circuit.

The duration of the quench period is variable from approximately 180 to 1800 microseconds. This range has been found sufficient for most applications, but it can be extended, in either direction, by altering the value of C_4. The delay time is approximately 50 microseconds; this also can be changed if required by altering the value of C_5. The magnitude of the quench pulse applied to the Geiger-Mueller anode is determined by the voltage drop across R_{20} when V_5 is conducting; since R_{20} is large, this is substantially equal to the $B+$ voltage supplied to the plate of this tube. For Geiger-Mueller counters operating below 1500 volts, a quench pulse of 250- to 300-volts amplitude is generally quite sufficient; for counters operating above 2000 volts a 500-volt quench pulse is found to be more suitable.

The variable resistor R_{34} controls the bias voltage on the suppressor of V_3, and therefore the triggering level of the circuit. At minimum sensitivity (with R_{34} adjusted to zero resistance), the circuit will be triggered by a pulse of approximately 1- to 2-volts amplitude at the grid of V_1; this is sufficient sensitivity for most counters, but with certain special types it may be desirable to increase the sensitivity somewhat. As the sensitivity is increased a point may be reached beyond which the circuit becomes unstable and goes into self-oscillation, whether a counter is connected to it or not. For this reason it is not advisable to work with the sensitivity control set too close to the point of instability, since this may give rise to spurious and repetitive counts.

The peak amplitude of the output pulses is approximately 30 volts and their width 5 microseconds. This has been found satisfactory for most purposes.

It will be seen (Fig. 2) that it is necessary to apply the high potential to the counter as a negative voltage on the cathode, the anode resting at approximately ground level. The stray capacitance of the wiring connecting the grid of V_1, R_2, R_1, C_2, and the input terminal should be kept as low as possible—so also should that of the lead from the counter anode to the input terminal. If possible, this lead should be short and unshielded. In cases where the counter capacitance is high, or where a shielded lead is necessary, so that the stray capacitance to ground at the input terminal is unavoidably high, a further point arises in connection with the circuit operation, as follows: At the end of the quench period V_5 is cut off and its plate potential rises towards the $B+$ level, with time constant determined by R_{20} and the stray capacitance at the input, simultaneously restoring the counter anode to its operating potential. If this time constant is too long the voltage at the grid of V_1 will not have recovered sufficiently for V_1 to become conducting by the end of the delay time. In this event the suppressor of V_3 will not be biased off, so that V_3 will draw plate current and the circuit will be retriggered, whether a discharge has occurred in the counter or not. The circuit will go into self-oscillation, which will cease as soon as the excessive stray capacitance is removed. To overcome this difficulty, it is merely necessary to increase the delay time to a safe value, by increasing C_5.

In constructing this circuit it is advisable to use accurate resistors (±1 percent) for R_4, R_5, R_6, R_{16}, R_{17}, R_{25}, R_{28}, R_{29}, R_{30}, R_{31}; the rest of the components can be of normal tolerance (±10 percent). R_{26}, R_{27}, R_{32} should be adjusted if necessary, with the circuit in its quiescent state, to correct the +120-, +60-, and −100-volt supplies to within ±2 percent; the $B+$ voltage should be between 260 and 310, but is otherwise not critical; C_4, C_5 can now be adjusted, using an oscilloscope, to give the desired range of quench period and delay time. This procedure will take care of the normal nonuniformity of tube characteristics and will minimize the work involved in setting up.

When operating with a 500-volt quench pulse, it is preferable to replace V_5 by a 6AG5, since it has a higher plate voltage rating than the 6AK5; the auxiliary 500-volt $B+$ supply necessary for this operation (for the plate supply to V_5) is not shown in the diagram. A 6AS6 (made by Western Electric) was chosen for V_3, since it appeared to have a sharper control characteristic on the suppressor than any other available tube. A 6SJ7 was chosen for V_1 because of its low grid current characteristic, although there are doubtless other suitable tubes. It appeared desirable to make R_1 large, so that if the counter should go into continuous discharge the voltage developed across R_1 would be sufficient to operate the circuit and quench the counter. The large negative quench pulses, which are applied to the grid of V_1, certainly exceed the peak voltage rating of this tube by a considerable margin, especially with 500-volt operation. However, there appears to be no satisfactory remedy for this since the only tubes rated for these voltages have otherwise unsuitable characteristics. So far no trouble has been experienced with the 6SJ7 in this respect, but it remains a point to be watched.

IV. RESULTS

Plateaux were obtained using the multivibrator quenching circuit with a four-inch long platinum cathode of half-an-inch diameter, comprising one limb of a compensating counting unit, and varying mixtures of carbon dioxide and carbon disulfide. These mixtures were varied over a wide range—the carbon disulfide from approximately 0.001-cm Hg up to 2-cm Hg pressure, and the carbon dioxide in approximately 5-cm steps from 5 to 20 cm Hg. A typical set of plateaux, using an external gamma-ray source and a quench period Q of 780 microseconds, is shown in Fig. 4. Good working plateaux were obtained even with approximately

0.01-cm Hg pressure of carbon disulfide—an amount which is small enough to neglect in measuring the pressures of carbon dioxide (say 10 to 20 cm Hg) to determine the quantity of carbon dioxide in the effective counting volume.

The effect of changing the quench period Q is shown in Fig. 5 where plateaux are plotted for a number of quench periods between 100 and 780 microseconds.

V. DEAD TIME CORRECTION

In order to obtain absolute counting rates it is necessary to know the correction for counts lost during the dead time of the quenching circuit.

The recorded counts consist of those which occur during delay intervals and those which occur during the quiescent intervals that follow the delay intervals. When a pulse occurs during a quiescent interval, the dead time that follows, during which pulses cannot be recorded, is Q. If a pulse occurs during a delay interval, the dead time consists of the remainder of the delay time δ in addition to the quench period Q, since the circuit cannot record more than one pulse occurring in the delay time. The dead time for such a pulse is $Q+f\delta$, where $f\delta$ is some fraction of δ (e.g., pulse C in Fig. 6).

Let C_A be the recorded counting rate, C_T be the true counting rate, and τ be the effective dead time of the circuit. Further, let us consider the state of affairs existing at the end of a quench period following a count, e.g., as X following count B in Fig. 6. The probability of no further counts occurring in the subsequent delay time δ is then equal to $\exp(-\delta C_T)$.

The probability of one or more counts occurring during this delay time is, on the other hand, equal to $1-\exp(-\delta C_T)$.

In other words, if we consider events occurring immediately after a time corresponding to X in Fig. 6, the probability of the *next* count occurring after the delay time δ, i.e., in a quiescent period, is $\exp(-\delta C_T)$, while that of its occurring during the delay time δ is $1-\exp(-\delta C_T)$.

The number of counts which occur per second during quiescent periods, and are recorded, is $C_A \exp(-\delta C_T)$. Each of these is followed by a dead time Q.

The number of recorded counts which occur per second during delay times is $C_A(1-\exp(-\delta C_T))$. Each of these is followed by a dead time $Q+\eta$ where η is the average value of $f\delta$ for all recorded pulses occurring per second in a delay time.

But for an effective dead time τ the counting system is unable to record counts for a total time of $C_A\tau$ per second. We have, therefore, that

$$C_A\tau = C_A \exp(-\delta C_T)Q + C_A(1-\exp(-\delta C_T))(Q+\eta),$$

i.e.,

$$\tau = Q+\eta(1-\exp(-\delta C_T)). \qquad (1)$$

It is now necessary to determine η.

Consider times t and $t+dt$ after X and *during* the immediately subsequent delay time δ.

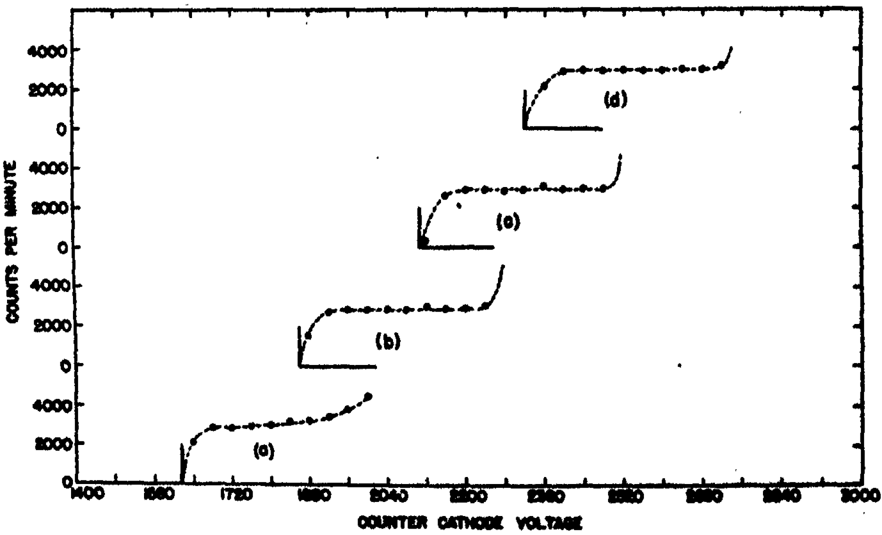

Fig. 4. Plateaux obtained with carbon disulfide at 2.12-cm Hg pressure and carbon dioxide at pressures of (a) 4.84 cm Hg, (b) 9.63 cm Hg, and (d) 19.63 cm Hg.

Then the chance of no counts occurring during t is $\exp(-tC_T)$, while that of a count occurring in dt is $C_T dt$.

The chance, therefore, of the first pulse after X occurring in the interval t to $t+dt$ is $C_T\exp(-tC_T)dt$.

The average value of t for all counts recorded in delay times is thus given by

$$\bar{t}=\frac{\int_0^\delta C_T\exp(-tC_T)tdt}{\int_0^\delta C_T\exp(-tC_T)dt},$$

which is equal to

$$\frac{1-\exp(-\delta C_T)(1+\delta C_T)}{C_T(1-\exp(-\delta C_T))}.$$

The time required is, however, the average time remaining in the delay time δ *after* a pulse.

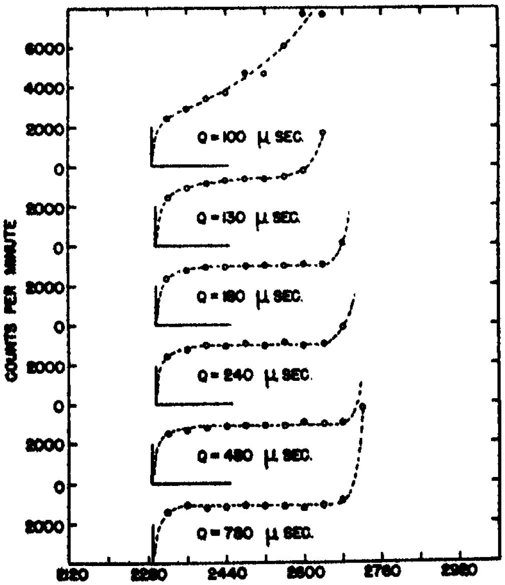

FIG. 5. Effect on plateaux of altering quench period.

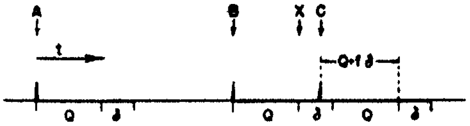

FIG. 6.

This is

$$\eta=\delta-\bar{t}=\delta-\frac{1-\exp(-\delta C_T)(1+\delta C_T)}{C_T(1-\exp(-\delta C_T))}. \quad (2)$$

Substituting this in (1) gives

$$\tau=Q+\delta-\frac{1}{C_T}(1-\exp(-\delta C_T)). \quad (3)$$

If the exponential term in (3) be expanded, we obtain the rapidly converging expression

$$\tau=Q+\tfrac{1}{2}C_T\delta^2-\tfrac{1}{6}C_T^2\delta^3+\cdots. \quad (4)$$

The time $Q+\delta$ can be measured by increasing R_9 until the multivibrator becomes unstable and goes into self-oscillation. When this happens a scaler connected to the output will register pulses, the number of which per second is equal to the reciprocal of $Q+\delta$. The value of Q may be deduced from the setting of the quench-period control which, in turn, is calibrated by connecting a cathode-ray oscilloscope, having a calibrated sweep, to the grid of V_8.

Alternatively, τ can be measured experimentally by, say, the two-source method.

VI. CONCLUSION

Further experiments using the type of counter described, with radioactive C^{14}, have been carried out by one of us in collaboration with Mr. R. C. Hawkings and Mr. R. F. Hunter, to whom our thanks are due for extensive testing of the quenching unit. We also wish gratefully to acknowledge the help of Mr. F. N. MacGillivray, who measured the quench periods for various settings of R_9 using a cathode-ray oscilloscope.

THE REVIEW OF SCIENTIFIC INSTRUMENTS VOLUME 20, NUMBER 1 JANUARY, 1949

Apparatus for Cloud-Chamber Investigations with Free Balloons

E. J. Lofgren, E. P. Ney, and F. Oppenheimer
University of Minnesota, Minneapolis, Minnesota

(Received August 19, 1948)

Apparatus for taking cloud-chamber pictures in free balloon flights is described. The twelve-inch cloud chamber is photographed once per minute by stereo cameras. The complete equipment for a six-hour operation at 90,000 to 100,000 feet weighs 65 pounds and is housed in a 30-inch diameter gondola equipped with temperature control.

INTRODUCTION

Balloons have been developed by the General Mills Company which are capable of carrying 60 or 70 pounds to altitudes of 90,000 to 100,000 feet and remaining there for periods of hours. These balloons are of the open appendix constant volume type and are pear shaped, 70 feet in diameter by 100 feet long. They are made of poly-ethelene one one-thousandth inch thick. The load is carried by strips of tape which also seal the seams. The balloons were used in cloud-chamber and photographic emulsion investigations of cosmic rays. They were flown at Camp Ripley, Minnesota by the Aeronautical Research Group of General Mills.

DESCRIPTION OF APPARATUS

The cloud chamber and associated equipment are housed in a 30-inch diameter spherical gondola spun from 0.020 inch aluminum. The gondola is sealed and has 15 p.s.i. absolute pressure maintained in it at all times. Since gas is supplied for chamber expansion, it is necessary to have a pressure relief valve to hold the pressure constant. Although the expansion ratio of the chamber is temperature compensated in a manner to be described later, the gondola temperature is maintained near room temperature by regulating the amount of solar heating of the section of the sphere containing the cloud chamber. The arrangement is shown in Fig. 1. An insulating wall of Styrafoam[1] separates the sphere into two sections, the lower of which contains the apparatus; this section is internally insulated with fiberglass and is covered on the outside with aluminum foil. A small polar zone on the outside of the upper hemisphere is painted black. With this arrangement, the lower section would reach a temperature below 21°C and the upper section a temperature well above it. When the section containing the apparatus cools below 21°C, a thermostat turns on a blower which circulates warm air from the upper section. Figure 2 is a graph of the temperatures in the two sections of the gondola during a winter flight. Because of the great variation in the angle of the sun in Minnesota throughout the year, it is necessary to make an adjustment in the fraction of the sphere which is painted black. The reason for this is that the insulating barrier between the top and bottom allows some heat to flow when the blower is not on. The black polar zone was 35 inches in diameter on the February flight whose record is shown. The adjustment of

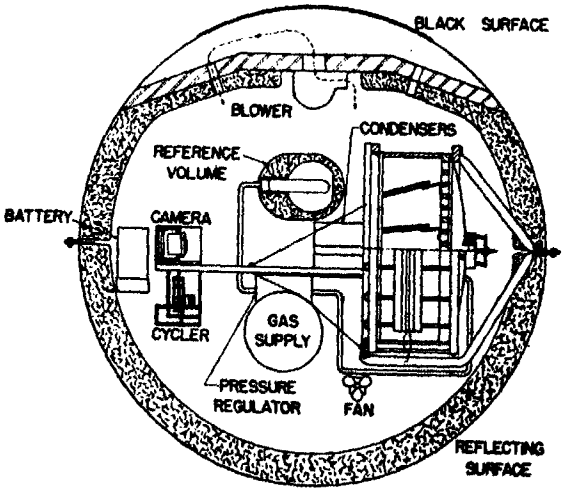

Fig. 1. The sphere and major components are shown. Air is blown through the upper hot compartment by a thermostat-controlled blower to provide temperature regulation.

---

[1] Styrafoam is a form of polystyrene for insulating purposes. It is made by the Dow Chemical Company, Midland, Michigan.

the size of the black zone has not been correctly made on all flights, and temperatures have become as high as 30°C at the end of some flights. During the first hour in which the balloon ascends to 60,000 feet, there is a larger heat loss than at the equilibrium high altitude conditions. This is clearly evident in the initial dip of the temperature curve. Batteries which could be jettisoned at 50,000 feet were used to make up this loss on some flights, but their weight was excessive and they were later replaced by a candle and oxygen supply sufficient for 1½ hours.

Figure 1 also shows the main components of equipment. The twelve-inch diameter cloud chamber is of the rubber diaphragm type whose expansion ratio is determined by compression to a fixed pressure. Most of the experiments have been carried out with either four or five quarter-inch thick lead plates in the chamber. The clearing field is applied between the plates. The chamber is fabricated from aluminum and magnesium and weighs 12 pounds without plates. The aluminum is anodized wherever it is in contact with the sensitive volume of the cloud chamber. The photographs are taken by two cameras between whose optic axes there is an angle of 27°. The lenses are 26-mm focal length and $f/4$ aperture and cover a frame 15/16 inch square on 35-mm film. The film is driven continuously by the motor which drives the cycling cams. The camera bodies are one-piece magnesium castings. The cameras weigh 1 pound each. The chamber is illuminated by a pair of flash lamps with immersion lens systems which have been previously described.[2] The flash lamps[3] are designed to operate at 1000 volts and can be triggered at voltages as low as 400 volts. The lamps are operated by applying a voltage pulse to a model airplane spark coil connected to the aluminized reflector on the lamps. The flash lamp condensers are Mallory Electrolytics with etched plate cathodes, type W.P. There have been no failures of these condensers. They weigh ⅓ as much as oil filled condensers for the same stored energy. Each light has three 350-volt 120-microfarad condensers in series which are charged successively from a 400-volt battery made of sections of Mini-Max Battery No. 493. The cyclic charging is accomplished by a switch on the timing motor. The illumination system complete with a battery to last seven hours weighs 5½ pounds. The clearing field for the chamber is obtained from the voltage across one condenser.

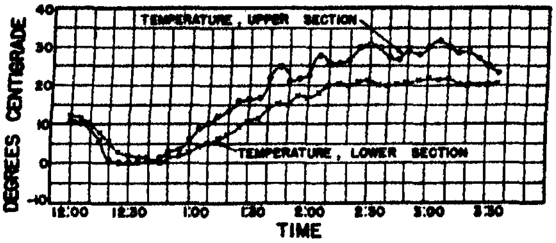

FIG. 2. Observed gondola temperatures in the two sections of the sphere during a February flight.

The cycling is carried out by a constant speed d.c. motor with a cam arrangement.[3] This is shown in Fig. 3. The motor consumes one watt at six volts. Doubling the voltage changes the speed less than ½ percent. Cam set *A* consists of cams for short circuiting the clearing field, expanding the chamber and flashing the lights. In order to achieve accuracy in setting these cams, the shaft which operates them turns approximately 36 r.p.m. The chamber is expanded once per minute so Cam *B*, which actuates a micro switch, functions as a permissive switch, allowing cam set *A* to operate the chamber only when *B* is actuated. Figure 3 also shows the switch, *C*, which cycles the condenser charg-

ing battery. This motor, the blower, and the fan are powered by Vitamite[4] storage batteries.

The gas for chamber expansion is supplied from a 500-cu in. Air Forces oxygen tank which is filled to 800 p.s.i. The gas supply is sufficient for a six-hour flight. The pressure is reduced and regulated by means of a modified Air Corps two-stage regulator valve. The second stage is constructed in such a way that gas is allowed to flow to compress the chamber until the pressure is equal to the pressure in a reference volume (see Fig. 4). The pressure in the reference volume then determines the compressed pressure and volume of the cloud chamber. If Δp is the difference between expanded and compressed pressures and p is the expanded pressure, then with our chamber to get the best tracks at any temperature, $\Delta p/p$ must increase with temperature about 1 percent per degree C. This can be accomplished if the pressure in the reference volume increases faster with temperature than the expanded cloud-chamber pressure. With argon and a mixture of 70 percent ethyl alcohol and 30 percent water by volume in the cloud chamber, and with a permanent gas and pure alcohol in the reference volume, the desired compensation was obtained over a temperature range of at least 15°C. In order to have the system operate while the temperature was changing, it was also necessary to make the thermal time constant of the reference volume the same as that of the chamber. This was approximated by adjusting the quantity of alcohol and the insulation of the reference chamber. A rubber diaphragm in the reference volume keeps the alcohol from distilling out of the volume. This is a modification of a system used by Leighton.[5]

The entire assembled system weighs about 65 pounds. Figure 5 shows the complete apparatus with the top hemisphere removed.

OPERATION

Eight cloud-chamber flights have been made. Six were recovered and of these five have yielded about 500 useful photographs. Some of the

results have already been published.[6] One photograph, Fig. 6, is included here as an example. It shows a nuclear disintegration produced at 83,000 feet by a fast penetrating particle. The disintegration contains fast penetrating and slow highly ionizing fragments.

We wish to express our appreciation for the ONR support which made this work possible and to Dr. Urner Liddel for his continued interest. These flights would not have been possible without the full cooperation of the General Mills Corporation and especially of T. R. James and Henry Stinger. The recovery was made possible in most cases because of the assistance of Captain Swenson and other pilots at Wold Chamberlain Field. We wish to thank J. T. Tate for his encouragement, and Rudolph Thorness and George DeWitt for help in the design and construction of the apparatus.

THE REVIEW OF SCIENTIFIC INSTRUMENTS VOLUME 20, NUMBER 1 JANUARY, 1949

The Statistical Theory of the Dead Time Losses of a Counter

C. E. CLARK
Mathematics Department, Emory University, Emory University, Georgia

(Received April 9, 1948)

In the case of events at random times, the number of events must be estimated from the number of counts recorded by a counter. In this article we study the statistical distribution of the unknown number of events. We show that this distribution is approximately normal, and we approximate the standard deviation.

A COUNTER such as a Geiger counter misses some counts because parts of the instrument have dead time intervals following any one of the impulses that are being counted. Let μ-impulses occur, and let ν be the number of these impulses recorded by the counter. For the case in which the impulses occur at random times, there have appeared in the literature methods of approximating $E(\mu)$, the expected value of μ, assuming ν is known.[1] In this article we extend these results by studying the statistical distribution of μ. We show that μ is approximately normally distributed with standard deviation

$$(E(\mu)[E(\mu)-\nu]/\nu)^{\frac{1}{2}}. \tag{1}$$

This information is needed before we can infer that a small difference between $E(\mu)$ and ν implies a small difference between μ and ν. Moreover we can use a counter when $E(\mu)-\nu$ is large because we have fiducial limits for μ, and we know how many counts we must have for $E(\mu)$ to be an adequate estimate of μ.

To derive the distribution of μ we note that μ could theoretically be any integer not less than ν. The probability $P(\mu)$ that given ν-counts, the unknown number of impulses is μ, is proportional to the probability that ν-counts would be recorded in a run of μ-impulses. Since the probability that an impulse is counted is $p=[\nu/E(\mu)]$, we obtain from the theory of probability that

$$P(\mu)=(k\mu!/\nu!(\mu-\nu)!)p^{\nu}q^{\mu-\nu},$$

where k is the constant of proportionality mentioned above, and $q=1-p$. To determine k we note that, summing from $\mu=\nu$ to $\mu=\infty$,

$$\sum P(\mu)=k\left\{p^{\nu}+\frac{\nu+1}{1!}p^{\nu}q+\frac{(\nu+1)(\nu+2)}{2!}p^{\nu}q^{2}+\cdots\right\}.$$

---

[1] See, for example, L. Alaoglu and N. M. Smith, Jr., Phys. Rev. **53**, 832 (1938).

Since $q<1$, this expression reduces to a convergent binomial series expansion, and we have that

$$\sum P(\mu)=kp^{\nu}(1-q)^{-\nu-1}=(k/p).$$

Since probability theory gives $\sum P(\mu)=1$, we have $k=p$ and

$$P(\mu)=(\mu!/\nu!(\mu-\nu)!)p^{\nu+1}q^{\mu-\nu}.$$

Relations between the binomial and normal distributions imply that approximately

$$P(\mu)=\frac{p}{\sigma(2\pi)^{\frac{1}{2}}}\exp\left\{-\frac{(\nu-p\mu)^2}{2\sigma^2}\right\},$$

where

$$\sigma^2=\mu pq.$$

Setting $\rho^2=q/p$ and rearranging we see that

$$P(\mu)=\frac{1}{\rho(2\pi\mu)^{\frac{1}{2}}}\exp\left[-\frac{\left(\mu-\frac{\nu}{p}\right)^2}{2\mu\rho^2}\right].$$

Setting

$$\mu=\frac{\nu}{p}+(\nu)^{\frac{1}{2}}y \tag{2}$$

and multiplying $P(\mu)$ by $d\mu/dy=(\nu)^{\frac{1}{2}}$ we obtain the probability distribution of y as

$$P(y)=\frac{(\nu)^{\frac{1}{2}}}{\rho\left[2\pi\left(\frac{\nu}{p}+(\nu)^{\frac{1}{2}}y\right)\right]^{\frac{1}{2}}}\times\exp\left\{-\frac{\nu y^2}{2\rho^2\left(\frac{\nu}{p}+(\nu)^{\frac{1}{2}}y\right)}\right\}.$$

We see that for large ν, approximately

$$P(y)=\frac{(p)^{\frac{1}{2}}}{\rho(2\pi)^{\frac{1}{2}}}\exp\left\{-\frac{py^2}{2\rho^2}\right\}.$$

Hence y is approximately normally distributed with mean zero and standard deviation $\rho/(p)^{\frac{1}{2}}=(q)^{\frac{1}{2}}/p$. This with (2) shows that μ is approximately normally distributed with mean $\nu/p=E(\mu)$ and standard deviation $(\nu q)^{\frac{1}{2}}/p$. Since $p=[\nu/E(\mu)]$, the standard deviation of μ can be reduced to (1).

THE REVIEW OF SCIENTIFIC INSTRUMENTS VOLUME 20, NUMBER 1 JANUARY, 1949

An Apparatus for Determining the Effect of Centrifugal Force on the Potentials of Galvanic Cells

B. ROGER RAY* AND D. A. MACINNES
Laboratories of The Rockefeller Institute for Medical Research, New York, New York

(Received October 7, 1948)

An apparatus is described with which electric potentials, developed as a result of phenomena occurring in the rotor of a centrifuge, can be measured within one microvolt, and radial temperature differences in the rotor can be determined and controlled within 0.01°. Rotation in a vacuum minimizes the rise of temperature of the rotor, which can also be measured. The speed of rotation is controlled by a friction drive within 0.01 percent and maintained at definite values, between 400 to 7200 r.p.m., corresponding to stroboscopic patterns. The instrument was designed to measure the effect of centrifugal fields on simple galvanic cells.

THE effect of centrifugal fields on simple galvanic cells has been studied by des Coudres[1] and by Tolman.[2] Some preliminary measurements have also been reported by MacInnes.[3] In the investigations by Tolman, and by MacInnes, the galvanic cells were of the type

$$(\mathrm{Pt}) : \underset{r_2}{\mathrm{I_3}}, \mathrm{KI}, \underset{r_1}{\mathrm{I_2}} : (\mathrm{Pt})$$

in which two, otherwise identical, iodide-iodine electrodes were placed at radii r_1 and r_2 in a centrifugal field. The limiting form of the thermodynamic equation for the resulting potential, E, is

---

$$EF = 2\pi^2 n^2 (r_2^2 - r_1^2)[t_K(M_{KI} - \bar{V}_{KI}\rho) - (M_I - \bar{V}_I\rho)], \quad (1)$$

in which F is the faraday, n is the number of rotations per second, t_K is the transference number of the cation constituent, ρ the density of the solution, M_{KI} and $\bar{V}_{KI}$ are the molecular weight and partial molal volume of potassium iodide, and M_I and V_I are the atomic weight and partial atomic volume of iodine. Since all the other terms are known or can be measured, this furnished a method for determining the transference number, t_K. The method provides a means for investigation of salts in non-aqueous solvents, for which other procedures have proved inadequate.

The apparatus to be described is the result of a long research undertaken with the purpose of making the centrifugal method an accurate means of obtaining transference numbers and ionic mobilities in solutions. The method involves (a) precise measurement of the potential of the cell; (b) adequate speed control and measurement; (c) control of the temperature gradient across the rotor; (d) measurement of the temperature of the rotor; and (e) control of the atmosphere surrounding the galvanic cell. In addition the constants r_1 and r_2 of Eq. (1) must be very accurately known.

The apparatus and the electrical connections are shown diagrammatically in Fig. 1. the rotor $R-R$ is turned by means of the pressure of the disk D on the plate P, which is rotated by the synchronous motor M. The rotor speed can be varied by changing the position of the disk D with relation to the plate P. The potential between the electrodes E_1 and E_2 of the cell C is measured, during the rotation, by electrical contacts through the mercury commutators G_3 and G_4. The difference of temperature at radii corresponding to the positions of E_1 and E_2 is obtained by means of the thermojunctions $J-J$ (actually arranged around the cell C), the thermopotential being measured between the commutators G_3 and G_4. Finally, the temperature of the rotor is found, using a single junction in the rotor, the commutators G_1 and G_2, and the external ice bath K.

THE CELLS

Two forms of galvanic cells are used. For the type shown in Fig. 2A the cylindrical vessel A was machined from the plastic CR 39, kindly furnished by the American Plate Glass Company. This plastic is chemically resistant and is not readily deformed. One of the electrodes, E_2, rests on the bottom of vessel A and the other, E_1, on a shoulder of the vessel. The closing cap consists of two parts, B and K, the first made of CR 39, and the other of Lucite. The two materials are necessary since the CR 39 is too brittle to support the screw threads of the nuts used in sealing the cell, as described below. Three holes pass through the cap B, two of which are used for the leads L_1 and L_2 to the two electrodes, and another for filling the cell. The cap K carries three Lucite nuts, D_1, D_2, and D_3, which exert pressure on Lucite washers, F, and the Neoprene gaskets, N. The filling hole is closed by the use of a Neoprene gasket and a CR 39 plug R with an attached circular disk replacing the washer. The vessel A and the caps are enclosed in a silver plated brass shell H. Four longitudinal slots (not shown) are cut into the cylindrical wall of this shell, so that the filling process can be observed through the transparent walls of vessel A. A threaded brass ring M provides pressure through a Pliofilm gasket P holding the caps against the vessel A.

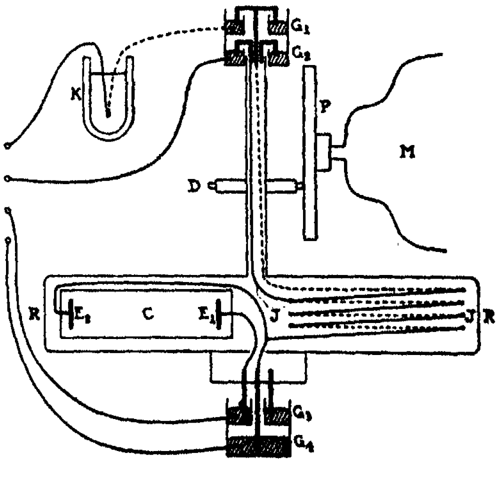

FIG. 1. Diagram of apparatus.

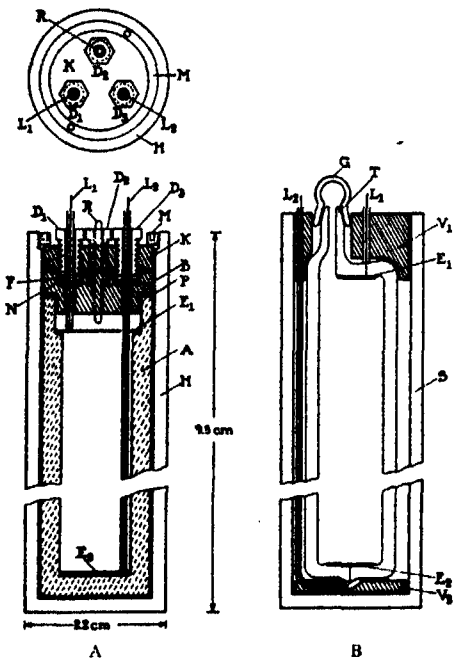

FIG. 2. The galvanic cells.

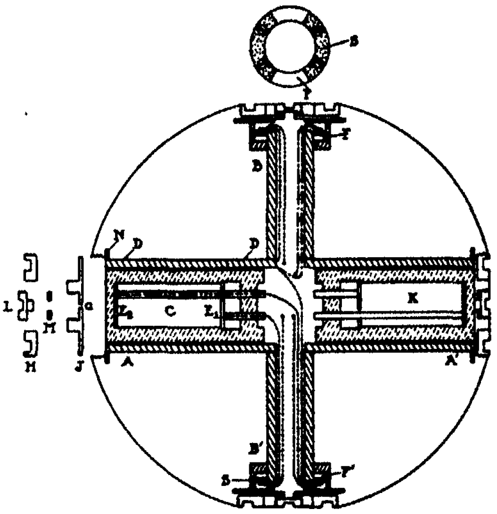

FIG. 3. Horizontal cross section of rotor.

The electrodes E_1 and E_2 are made of disks of platinum, respectively 13 mm and 11 mm in diameter, and 0.2 mm thick, to which No. 24 platinum wire is welded. These wires are enclosed in soft glass tubing, which, at the point of contact with the electrode, is sealed to the wire with lead glass.

These cells have the advantages that they are not fragile and that the dimensions, from which values of r_1 and r_2 of Eq. (1) can be obtained, can be measured accurately with a depth gauge. As a result of their complexity they are somewhat hard to keep clean. Glass parts replacing the plastic vessel A and the cap B have been constructed but have not yet been fully tested.

A simpler cell which has also been used is shown in Fig. 2B. In this design the electrodes E_1 and E_2 are sealed into the Jena 16 III glass wall of the cell. The platinum wire leads, L_1 and L_2 are enclosed in flexible plastic tubing. Filling and removal of solution are carried out through the tube T which is closed with a ground glass cap G. The whole glass cell is enclosed in the brass shell S, the space between the shell and cell being filled with vaseline. This semifluid material helps to equalize the pressure on the two sides of the glass walls and bottom of the cell when in a centrifugal field. Two Bakelite spacers, V_1 and V_2, hold the glass cell in a fixed position in the shell S. Though the dimensions of this cell cannot be obtained with the accuracy of the plastic cell described above, it is more readily cleaned and manipulated. It can also be calibrated with the aid of data obtained with the other cell.

THE ROTOR

The rotor, which is shown in horizontal cross section in Fig. 3, and in vertical cross section in Fig. 4, is constructed from a disk of magnesium 23 cm in diameter, and 5 cm thick. Two cylindrical channels, A–A' and B–B', of 25-mm and 13-mm diameter, respectively, are bored at right angles through the disk. In order to show details of construction clearly, the diameters of these channels and their constants relative to their lengths have been doubled in Fig. 3 but are in the correct proportions in Fig. 4. In the channel A–A' of Fig. 3 is placed the cell C and the counterpoise K. This counterpoise is made to resemble the cell closely, since a precise balance has been found necessary to eliminate vibration, for the speed control, and to be sure that the rotor turns around its geometrical center. The channel B–B' provides readily accessible electrical connections to the cell and the thermojunctions. The channel is lined with an insulating tubing. Bakelite rings, F and F', at each end of the channel carry metal insulated sectors S, which are fitted with screws for fastening the ends of wire leads. One of these rings is shown at the top of the figure. At the ring F' the two leads from the cell C pass to the metal sectors, which are, in turn, connected by wires to the commutators G_3 and G_4, as shown in Figs. 1 and 4.[4]

The cell C is enclosed by a thin cylindrical Bakelite shell D–D in which are embedded the copper-constantan wires which form 22 junctions, 11 of which are at a radius corresponding to electrode E_2 and 11 corresponding to E_1. The terminal leads of these junctions are connected to metal sectors on the insulating rings F and F' from which copper wires pass to the commutators G_2 and G_4, and a constantan wire connects through a sector on ring F to G_1. It is possible to remove this cylindrical shell without disturbing the leads to G_1 and G_2 which pass through the hollow shaft on which the rotor is suspended. As explained above, the purpose of the multiple junctions is to determine the difference of temperature existing between the electrodes E_2 and E_1.

In order to control the atmosphere surrounding the cell C arrangements are made for sweeping out the free spaces in the channels A–A' and B–B' with a gas, such as nitrogen, and to keep the gas from escaping while the measurements are being made. For this purpose the end of each channel is furnished with a closing device, the separate parts of which are shown on the left hand side of channel A–A'. The threaded annular ring H presses against a disk J which in turn compresses the Neoprene gasket N which is recessed into the wall of the channel, thus forming a gas-tight seal. A cylindrical projection from the disk J is fitted with a threaded plug L.

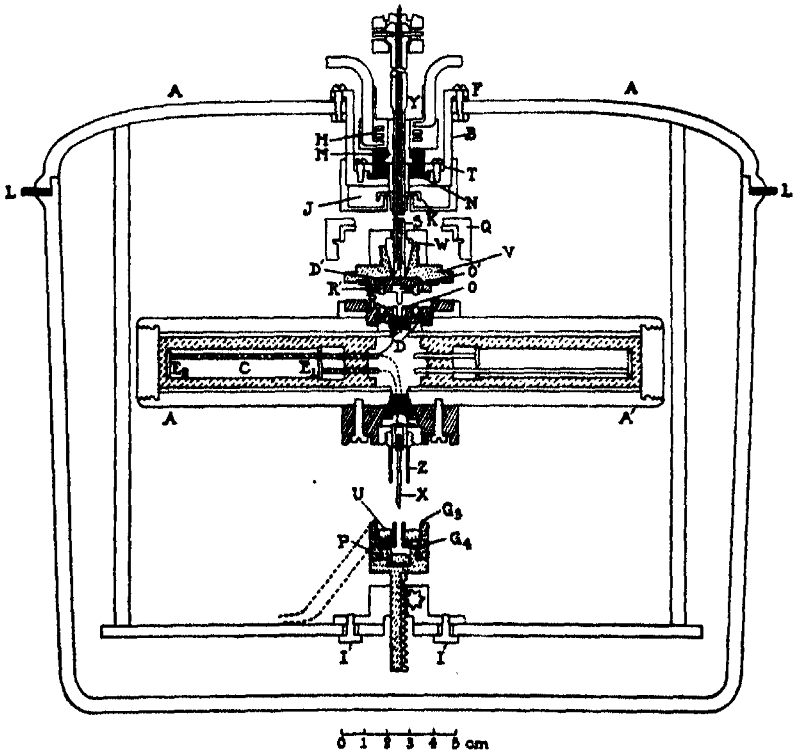

FIG. 4. Vertical cross section of rotor and vacuum chamber.

---

[4] It is necessary to connect the wires from the cell C to the sectors S on the ring F' before inserting the cell into the channel $A-A'$. The lead wires must therefore be long enough to extend out of the open end of this channel. On inserting the cell the extra lengths of the wires (not shown) are looped into the channel $B-B'$ and toward the ring F. To pull the wires in this direction as the cell C is slid into place, there is a cord attached to a small slip ring passing around both wires. This cord is detached after use. For the lead wires a light, many-stranded insulated cable, such as is used with hearing aids, is serviceable. For connecting to the cell C these wires are soldered to tiny screw clamps which grip the platinum leads from the electrodes. An annoying tendency of the leads to break at the soldered joint has been overcome by the use of a low melting alloy, Cerrolow 117, made by the Cerro di Pasco Company.

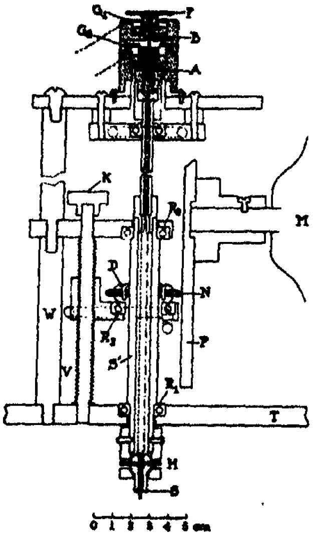

Fig. 5. Speed regulation mechanism.

This, with the washer *M*, is used to close the small hole, *a*, which is used for the entrance and exit of gas. In order to sweep out the channels with nitrogen the plug *L* is replaced with a threaded brass tube connected to the source of the gas. Similar tubes are placed at the ends of the other channels, and bubble tubes are attached to indicate the rate at which the gas is passing. After the channels are fully swept out the threaded plugs *L* are replaced, one at a time, while the gas continues flowing. It is quite essential that the channels should be gas-tight since during a determination the rotor is surrounded by a vacuum and leakage would reduce the vacuum and might also result in disturbance of the solution in the cell.

Further details of construction of the rotor are shown in vertical cross section in Fig. 4. Since it is convenient to be able to remove the rotor without disturbing the copper and constantan leads that pass through the hollow shaft *S*, a special connector for these leads has been provided. The constantan wire from the rotor passes to a small cylinder *O* of that material and the copper wire is connected to a copper ring *R*, the two being fitted into a Bakelite disk *D*. This disk holds a small rubber stopper through which both wires pass and which forms a gas-tight seal. A rubber ring under the disk completes the seal. The wires passing down through the shaft *S* terminate in a constantan pin *O'* and a copper ring *R'*. These are set into a Bakelite disk *D'* which is fastened into the steel member *V* which, with the aid of the chuck *W*, is firmly attached to the flexible shaft *S*. To fasten the rotor to the member *V* and thus to the shaft *S* the collar *Q* is brought into place so that its screw threads engage those on the rotor, with the result that the electrical connections are also made. A rubber washer under the copper ring *R* assures a firm contact with *R'*. During this process the rotor is held by four clamps, one of which can be seen on a supporting post in Fig. 6.

The bottom surface of the rotor carries the leads to the commutators G_3 and G_4 which will be described below.

The vacuum chamber in which the rotor turns has been made by modifying a commercial aluminum pressure vessel, a cross section of which is indicated in Fig. 4. The rim of the vessel has been turned down so that the gasket *L* is on the outside edge. As can be seen in Fig. 6 the cover of this vessel is supported by the framework. From this cover *A–A* of Fig. 4 are suspended the stationary parts of the commutators G_3 and G_4.

In this cover is also mounted a vacuum-tight, water cooled bearing through which passes the flexible shaft *S*. To obtain correct values of the centrifugal potential of the galvanic cells *C*, it is necessary to prevent the development of a radial temperature gradient across the rotor, and it is further desirable that the rotor temperature should not rise during a determination. Rotation in a vacuum of 1μ or less prevents the production of appreciable heat through gas friction. The temperature at the bearing can be controlled by appropriate cooling. In practice the radial temperature differences have been reduced to less than 0.01° by empirically choosing the temperature of the water circulating around the bearing. This cooling water comes from a small thermostat, and is driven through the coils *H* with the aid of a "Marco" diaphragm pump. The coils are joined to the bronze bearing *M*, which is, in turn, fitted into the Neoprene mounting *N*, which gives additional flexibility to the rotating system. An annular projection of this mounting is fastened to the brass cup *B* by means of the ring *T*, the cup itself being joined solidly to the cover with the gas-tight seal *F*. The space *Y* holds vacuum pump oil, which lubricates the bronze bearing *M*. Since there is a pressure difference of one atmosphere across this bearing the oil is slowly forced along the shaft. It is, however, thrown into the chamber *J* by the disk *K* which is attached to the shaft.

THE SPEED CONTROL

Details of the arrangement for speed control are shown in Fig. 5. The hollow shaft S' turns on the ball bearings R_1 and R_2. At the lower end of this shaft is a universal joint which supports and rotates the flexible hollow shaft, *S*, of Fig. 4, to which the rotor is attached. Around the shaft S' and running on the ball bearing R_3 is the disk *D* carrying a ring of Neoprene *N*. This presses lightly on the flat circular aluminum plate *P* which is rotated 1800 r.p.m. by the ⅛ h.p., G.E., synchronous motor, *M*. This motor is mounted on an extension of the supporting plate *T*, and is furnished with an adjusting screw and bolts (not shown) so that the pressure of the Neoprene ring *N* on the rotating plate *P* can be adjusted and held at a definite value. The disk *D* is keyed into a vertical slot on the shaft S' so that disk and shaft turn together. The position of the contact point of the ring and the plate can be shifted by use of the knurled knob *K* which operates the threaded rod *V*. With this arrangement the rotational speed can be adjusted with high accuracy from 400 to 7200 r.p.m. The top end of the shaft S' carries a stroboscopic disk *F* with one white radial band on a black background. With a stroboscopic lamp illuminating this disk with pulses of light at a constant frequency a series of symmetrical patterns are observed as the rotational speed is varied. The use of these patterns to establish speeds with high precision is described in a paper from this laboratory.[8] Since this method requires a rough preliminary knowledge of the speed a pointer moving with the disk *D* passes over a scale attached to the post *W*. This is shown in Fig. 6. With occasional slight manual adjustments it has been found that the speeds can be readily held within 0.01 percent at any desired value within the range of the apparatus.

THE MERCURY COMMUTATORS

The detail that probably contributed most to the success of the apparatus is the design of the mercury commutators, G_1 and G_2 of Fig. 5 and G_3 and G_4 of Fig. 4. It was possible, with these connections from the stationary to the rotating parts of the apparatus, to make measurements of potentials within 1 microvolt. This precision is necessary because the highest potentials determined are of the order of a millivolt. As shown in Fig. 4 the leads from the electrodes E_1 and E_2 of the cell *C* pass through a small rubber stopper, and then to supports for the copper needle *X* and the hollow copper tube *Z*. Below these is shown a Lucite cylinder in which there is a small pool of mercury *P* and an annular ring of mercury *U*. By a rack and pinion motion the Lucite cylinder can be raised so that the copper pin is inserted into the pool of mercury and the hollow tube into the annular ring. Adjusting screws *I–I* make an accurate centering possible. The contactors *X* and *Z* must not rub against the Lucite walls or potentials will be developed. Repeated tests of this pair of commutators have been made in which the leads to the cell have been shorted

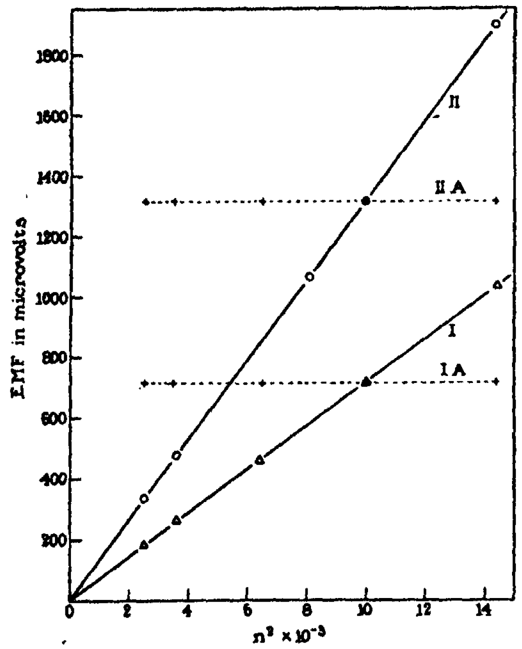

FIG. 7. Typical results. E.M.F. of cell in microvolts *vs.* square of revolutions per second.

and the speed of rotation increased to its highest value. In no case has the observed potential been over 1 microvolt, and it is usually less than this. It has been found desirable to have the tube *Z* of small diameter (8 mm) to reduce peripheral speed and with a smooth, well amalgamated surface. The mercury reservoirs should not be too small otherwise potentials will develop, probably due to heat effects.

Because of their position the design of the commutators G_1 and G_2 of Fig. 5 is slightly different from those just described. The copper and constantan wires which pass up through the shaft *S′* end respectively in a copper tube *A* and a constantan pin *B* which are insulated from each other. Connection from this pin to the annular ring of mercury in the commutator G_1 is made with the overhang sleeve of constantan attached to the lower side of the stroboscopic disk *F*. A similar sleeve joins the copper tube *A* with the mercury in commutator G_2.

SOME TYPICAL RESULTS

The results of two typical experiments are shown in Fig. 7, in which values of the potentials, *E*, in microvolts, are plotted as functions of the square, n^2, of the speed of rotation in seconds. In this plot line *I* refers to data obtained with an aqueous solution of 0.2-normal potassium iodide and 0.01 iodine, using the plastic cell shown in Fig. 2A. Line II is the corresponding plot for a solution of 0.2 N KI and 0.07 N I_2 in pure methanol, in the glass cell of Fig. 2B. According to Eq. (1) these relations should be linear. That they are straight lines to very high accuracy is shown by plotting the slopes, E/n^2, against values of n^2 as shown in I A and II A. These slopes are seen to be constant within a very small limit of error.

To anticipate conclusions which will be published in full elsewhere, the interpretation of the results on a series of measurements on the aqueous solutions of potassium iodide and iodine leads to values of the transference number, t_K, in very close accord with those found by Longsworth[6] by the quite independent moving boundary method for determining these constants. The data, and a modification of Eq. (1), based on a more complete understanding of the cell process, have also yielded a quite new method for demonstrating the presence of the complex ion I_3^- in these solutions.

Up to the present it has not been possible to obtain transference numbers in non-aqueous solutions by the Hittorf and moving boundary procedures. This is due to disturbances arising from Joule heat effects. The results obtained with this centrifugal method for solutions in methanol indicate that transference numbers can now be obtained in many non-aqueous solvents. Together with conductance determinations these constants can be used to obtain ion constituent mobilities, and with e.m.f. measurements on simple galvanic cells they will serve for the computation of activity coefficients in solvents other than water.

ACKNOWLEDGMENT

The authors wish to express their indebtedness to the Institute instrument maker, Mr. Josef Blum. His skill and ingenuity have been invaluable in the development of the apparatus described in this paper.

Circuits for Minimizing Transient Effects on Energy Measurements in Calorimetry

HAROLD J. HOGE
National Bureau of Standards, Washington, D. C.

(Received September 20, 1948)

Transient effects on electrical energy measurements in calorimetry will be minimized if P, the power developed in the heater, satisfies the condition $dP/dR=0$, where R is the resistance in which the power is developed. It is shown that this condition is satisfied if the resistance U between the two points of the supply network to which R is connected is kept equal to R. Circuits for maintaining this condition are described.

THE electrical energy supplied to a calorimeter in a heating period of length t is $Q=\int_0^t EIdt$, where E is the e.m.f. across the heater and I is the current through it. A series of suitably timed readings of both E and I is ordinarily made, from which the power $P=EI$ may be computed as a function of time. This permits the integral to be evaluated accurately even though, as is usually found, both E and I show small, more or less uniform upward or downward trends. There may, however, be rapid changes at the very beginning of a heating period which cannot be conveniently followed in the measurements of E and I. These are caused by a change in the resistance of the heater which results from its rapid rise in temperature. If it is assumed that the power during the period of rapid change is the same as that observed later in the heating period, an error may be introduced. In many calorimeters this error is negligible. Osborne, Stimson, and Ginnings[1] found this to be the case, using a ballistic galvanometer to integrate the effect. The possibilities of error become larger, however, (1) if the heating period is short, (2) if the heater is in poor thermal contact with the calorimeter, or (3) if the heater has a relatively high temperature coefficient of resistance. All three of these conditions occasionally arise in practice.

Calorimetric workers do not seem to be generally aware that errors due to transient effects can be greatly reduced by an approximate matching of the resistance of the supply circuit to the resistance of the calorimeter heater. If the resistance U of the supply circuit is made equal to the resistance R of the calorimeter heater, the power developed in the latter satisfies the condition $dP/dR=0$. Probably the most widely used power-control circuit for calorimetry is the simple series circuit of Fig. 1a. It is commonly used either with $A<(1/10 \text{ to } 1/5R)$ or with $A>(5 \text{ to } 10R)$. The first condition tends to keep E constant as R changes, throwing the variation into I; for the second condition the converse is true. Either of these arrangements is satisfactory where transient errors are unimportant, which is normally the case. However, if there is reason to expect transient effects to be appreciable, it is preferable to operate in the matched condition ($U=R$, $dP/dR=0$). Matching might be more often adopted if it did not mean that the resistor A (Fig. 1a) is no longer available as a means of adjusting the power.

It is not difficult to design control circuits which permit the power to be adjusted by means of resistors, and which may still be kept matched at all times. One of the simplest of such circuits is that of Fig. 1b. It consists of a potential divider D connected across a bank of cells, with an adjustable resistor A in series with the movable tap. The required range of adjustment of A is generally only a small fraction of its maximum resistance. In addition there are a standard resistor in which I is measured and a milliammeter for convenience in adjusting the current. In both the circuits of Fig. 1 the condition of matching is properly met if the resistance from point 1 to point 2 is equal to R by either the right-hand or left-hand path. For circuit *a* this is evident from first principles. Letting the resistance from 1 to 2 via the right-hand path be U and letting the e.m.f. of the battery on open circuit be $E\infty$, it is easily shown that the power developed in R is $P=RI^2=R\{E\infty/(R+U)\}^2$ and that $(R/P)(dP/dR)=(1-R/U)/(1+R/U)$. Hence, $dP/dR=0$ when $R=U$, $P_{\max}=E^2\infty/4U$ and $P/P_{\max}=4/(1+R/U)(1+U/R)$. The expressions for $P/P_{\max}$ and for the logarithmic derivative $(R/P)(dP/dR)$ are particularly useful because they depend only on the ratio of R to U.

By properly defining $E\infty$ and U, these results may be made to apply to any resistance in any network of resistances and batteries. According to Thévenin's[2,3,4] theorem, any two points on such a network may be considered to be the terminals of an equivalent cell. The current which may be drawn from the two points by connecting them with an additional conductor is the same as that which could be drawn from a cell of e.m.f. $E\infty$ and internal resistance U, when $E\infty$ and U are the e.m.f. and resistance between the two points of the network before the additional conductor is attached. In applying the theorem to circuit b, the two points chosen are 1 and 2, *before* either R or the dummy is connected. Since the entire right-hand side of the circuit is equivalent to a cell of e.m.f. $E\infty$ and internal resistance U, the current which will flow when R is connected is $I=E\infty/(R+U)$. But this expression is the same as that for the simple series circuit a, and hence all the results found above for it apply to this circuit also. They apply in fact to any network of resistances and batteries which may be devised to supply power to the calorimeter.

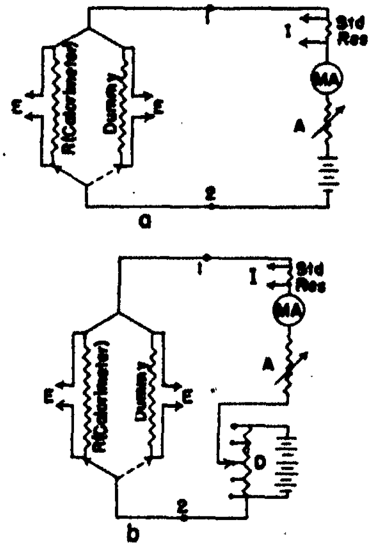

FIG. 1. Two circuits for controlling the power supplied to a calorimeter. Circuit a is the one most commonly used. Circuit b is preferable when the resistances of calorimeter and supply network are to be kept matched.

The author has used circuit b in calorimetric work and found it to be satisfactory. The potential divider D is composed of several fixed resistors in series, as a single resistor with a sliding contact was found to be too unsteady. The condition of matching $(U=R)$ is maintained by adjusting A (between heating periods) to compensate for changes in R caused by changes in temperature. A convenient method of making the adjustment makes use of the fact that when $R=U$, $E=E\infty/2$. First the dummy is made equal to R by means of readings of E. Then resistances A and D are adjusted as desired until, when the resistance of the dummy is made infinite, the e.m.f. across it is doubled. If it is preferred not to interrupt the current long enough for $E\infty$ to be measured, the dummy may be arranged so that its resistance can be changed by several percent. The power is then measured for two values of the dummy resistor, $\Delta P/\Delta R$ computed, and the circuit adjusted to make this quantity zero.

Fortunately $P/P_{\max}$ plotted *versus* R/U has a fairly broad maximum. Hence, the adjustment to make $R=U$ does not need to be made with very great accuracy, and it may in some cases be permissible to use a fixed resistor for A. Assuming the battery to have zero resistance, the combined contribution of D and the battery to U varies from 0 to $D/4$, having its minimum value when the tap is at either end and its maximum value when the tap is in the middle. If A is properly chosen U will never differ from R by more than $D/8$ as a result of adjustment of D. Hence if D is a relatively low resistance and the changes in R are not large the circuit will never be very far from the matched condition.

[4] William Littell Everitt, *Communication Engineering*, 2d ed., p. 47 (McGraw-Hill Book Company, Inc., New York, 1937). A very satisfactory discussion of the application of the theorem to a.c. circuits.

If for any reason it is desired actually to measure the power during a transient period it is generally best to observe either E or I but not both. This greatly increases the speed with which observations may be made and it does not require the matched condition to be given up. Whether the supply circuit is complicated or simple, $E_\infty = (R+U)I = E+UI$. Hence if E_∞, U, and E are known I can be calculated or if I is known E can be calculated. This calculation is made of course only for the transient period. During the period of steady heating both E and I are measured in the usual way. To determine E_∞ and U, auxiliary measurements are made in which E and I are observed for a widely different value of R (in this case R is the dummy resistor). These, together with any pair of corresponding values of E and I observed during the period of steady heating, permit both E_∞ and U to be calculated. Since E_∞ and U may change slowly with time, the auxiliary measurements should be made just before or just after the heating period in question.

An Accurate Gas Metering System for Laminar Flow Studies[*]

J. W. ANDERSEN AND R. FRIEDMAN[**]
University of Wisconsin, Naval Research Laboratory, Madison, Wisconsin

(Received October 18, 1948)

The design and performance of an accurate flow system utilizing critical velocity orifices is described. Results indicate that an absolute accuracy of three parts in a thousand is realized over a flow range of 0.002 to 2 cubic feet per minute. Calibration of the flow system was accomplished by means of a specially modified and carefully standardized wet test gas meter. Descriptions of the components of the flow system and of subsidiary calibrating equipment are presented.

Critical flow orifice discharge coefficients are found to be independent of the type of gas; however, because of gas impurities, prediction of relative rates of flow of various gases through an orifice by use of theoretical relationships is uncertain, and experimental data are given to illustrate this.

INTRODUCTION

As the prerequisite for a variety of scheduled studies with laminar flames and flowing gases, it was required to design, construct, and calibrate a gas flow system of unusual accuracy. This system was designed to meet the following specifications:

a. be able to handle three separate streams of gas;
b. each stream to have a range from 0.002 to 2 cubic feet per minute;
c. each stream adjustable independent of the others;
d. fluctation-free flow.

Essentially the system includes the following features: sensitive pressure regulators, interchangeable critical flow orifices coupled with ten-foot mercury manometers, and accompanying specially modified calibration equipment.

CONTROL AND INDICATION OF GAS FLOW

A diagrammatic sketch of the flow system is presented in Fig. 1. It is seen that there are three independent and identical lines which converge in a mixing chamber. One of these lines will be discussed in detail.

Gas is reduced to a 100-p.s.i. gauge from a high pressure cylinder by a conventional two-stage regulator. Because of the Joule-Thomson effect, it is necessary to bring the gas back up to room temperature. This is accomplished by an electrical gas heater which utilizes porous bronze disks for efficient heat transfer, the disks also serving as gas filters. A sensitive regulator[1] to

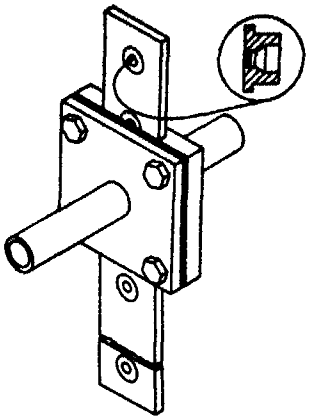

FIG. 2. Orifice assembly and orifice sizes. Jewel sizes (mm): 6/120, 8/120, 12/200, 17/230, 24/230/, 32/230, 44/200, 64/230, 94/260, 110/230. Flow ranges for oxygen (c.f.m.): 0.0023–0.0065, 0.0055–0.016, 0.0080–0.021, 0.016–0.044, 0.032–0.085, 0.057–0.15, 0.10–0.28, 0.22–0.60, 0.27–0.73, 0.50–1.4.

control the upstream pressure to the critical flow orifice[2] is next. The delivery pressure from this regulator is varied from 15 to 56 p.s.i. gauge. Since the flow through a critical flow orifice is directly proportional to the upstream pressure and independent of downstream pressure, as long as the pressure ratio is below the critical (because of sonic velocity at the throat), it follows that the flow rate may be varied 2.8-fold for any one orifice. In order to cover a 1000-fold flow range, a series of ten orifices mounted in a movable steel strip are clamped between rubber-faced flanges, as shown in Fig. 2. The orifice sizes are chosen so as to provide overlapping of ranges. Sapphire cap bearing jewels[3] are used as orifices because they are extremely durable; their contour approximates that of a convergent nozzle, and their use avoids the problem of making extremely small orifices. Diameters of the jewel holes ranged from 6 MM to 110 MM (1 MM = 0.01 millimeter, jewelers' notation).

The pressure on the upstream side of the orifice is measured relative to the atmosphere by means of a ten-foot mercury manometer, the critical portions of which are precision-bore tubing.[4] This permits calculation of pressure from measurement of the lower leg only. The manometer tubes are mounted in a four-inch standard steel channel, the upper and lower ends of the tubes being supported in steel blocks with rubber gaskets, shown in Fig. 3. There is a constriction with a by-pass in the line to the manometer, which guards against blowing out the manometer. A manometer level indicator is shown in Fig. 4. This device may be moved up or down on a 48-inch steel scale and includes a cross-hair with which the mercury level may be measured to 0.01 inch.

Although flow rate is independent of pressure downstream from the orifice, a butyl phthalate manometer is provided to measure this pressure.

To allow for mixing, a heavy-walled cylindrical tube packed with steel wool is provided.

CALIBRATION OF FLOW SYSTEM

1. The Wet Test Meter

An accurate as well as convenient standard was required for the calibration of the thirty orifices in the complete flow system; a wet test meter rated at 50 cubic feet per hour was selected as the most satisfactory device. However, usual operation of the wet test meter does not insure accuracies much better than two percent because of calibration difficulties and maintenance of constant water level. Consequently, the meter was modified in two ways:

a. A method which is capable of measuring the water level to within 0.001″ was installed (Fig. 5). Essentially, an electric circuit was completed when a depth micrometer contacted the water surface in the meter side-arm. The side-arm diameter was increased to 1.5 inches to minimize capillarity. In actual operation the original water level indicator supplied with the meter was lowered approximately $\frac{1}{8}''$ below the surface. Thus, indication of contact with the water by the micrometer was readily accomplished by use of an ohmmeter, the reading dropping sharply from "infinity" to about 10,000 ohms when contact was established.

To insure reproducibility, the meter was rotated at least one complete revolution, always terminating at the zero point on the meter face, and then allowed to drain for five minutes before determining water level. Following this procedure, successive readings were checked to within 0.001 inch. Care must be taken so that the micrometer tip is dry before the determination is made.

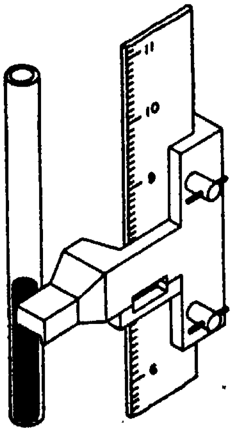

Fig. 4. Manometer level indicator.

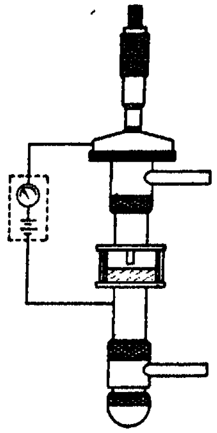

Fig. 5. Wet test meter level indicator.

b. It is obvious that the precautions discussed above must be supplemented by an accurate plumbing of the meter. The spirit level supplied was not sufficiently sensitive, and was replaced by a 12-inch plumb line permanently installed and shielded from drafts by a glass cylinder.

Since the readings of the wet test meter may be affected by the method of calibration, it was decided to calibrate the meter under conditions identical to those used in subsequent orifice calibrations. Thus, while the usual practice of meter calibration is to pass a measured volume of gas slowly through the meter, the initial and final readings being taken with the meter at rest, the system which was constructed is capable of passing through the meter a measured volume of gas at controllable rates of flow up to 0.8 c.f.m., the meter revolving at a constant rate *throughout* the test.

Figure 6 illustrates the system for the calibration of the meter. The sequence of operations is as follows:

a. Saturated air is drawn into the entire system through line *H*.

b. With valves *I* and *J* closed, pressure is applied above distilled water in the fifteen-gallon vessel *B*. Approximately 20 p.s.i. were applied at the higher rates of flow (0.8 c.f.m.).

c. Valve *I* is opened. Water then flows into a four-liter, heavy-walled filter flask. This serves to act as an induction period for the establishment of the rate of flow and elimination of entrained air. During this period the meter reaches a constant rate of rotation.

d. From vessel *C* the water then operates float switch *D*, actuating an electric circuit, thus indicating the instant at which the measured volume begins passing through the meter. This instant is recorded by means of an idler needle which follows the meter pointer until stopped by a solenoid. The circuit is then broken and the idler needle re-engaged.

The needle is stopped again after the water fills the calibrated five-gallon bottle *F* and contacts float switch *E*. After this point the flow may be stopped. By coupling the float switches to a solenoid operated stopwatch, the interval of the run is timed.

It is seen that the primary standard for the entire calibration depends on precise knowledge of the volume of bottle *F*. This volume was determined by weighing the quantity of distilled water required to fill the bottle with the special brass closure clamped in place. Weighings were made on a large analytical balance, and temperature and buoyancy corrections were applied. A drainage correction to account for water left in the bottle from each previous run was made.

Results of the meter calibration showed that there was no detectable change in the calibration factor for rates between 0.1 and 0.8 c.f.m. Therefore it was possible to use the same meter factor "*F*" (ratio of true volume to meter reading) for all flow rates up to 0.8 c.f.m., keeping the water level always constant.

2. Calibration of the Critical Flow Orifices

After the establishment of the wet test meter factor it was possible to calibrate the thirty critical flow orifices with various gases. The theoretical equation governing the behavior of critical flow orifices[2] may be expressed in the following form:

$$w = CA_2p_1[(gMk/RT)(2/k+1)^s]^{\frac{1}{2}}, \tag{1}$$

where w = mass flow rate, C = discharge coefficient, A_2 = orifice cross section, p_1 = upstream pressure, k = specific heat ratio, g = gravitational constant, M = molecular weight, R = gas constant, T = absolute upstream temperature, and $s = (k+1/k-1)$. Upon reduction of Eq. (1) to a convenient set of units, the following result is obtained:

$$V = 3.617CA_2p_1(K/d)^{\frac{1}{2}}, \tag{2}$$

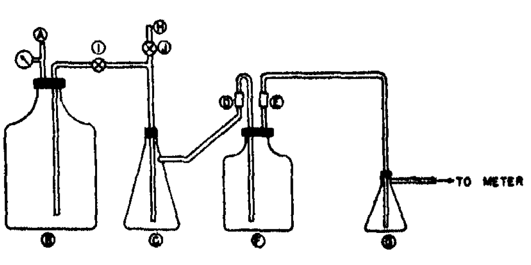

Fig. 6. Calibration system for wet test meter.

where V = volumetric flow rate, cubic feet per minute at 25°C and one atmosphere, A_2 = orifice cross section, square inches; p_1 = upstream pressure, inches of mercury (25°C); d = gas density, pounds per cubic foot at 25°C and one atmosphere; $K = k(2/k+1)^s$.

It may be seen from Eqs. (1) or (2) that the discharge rate is theoretically independent of downstream pressure and varies directly with the absolute upstream pressure. This assumes that the orifice has the proper contour. Independence of downstream pressure was checked experimentally at a pressure ratio of about three to one, and it was found that the rate of discharge did not vary measurably when the downstream pressure was varied ten percent, holding upstream pressure constant. Linear dependence of flow upon upstream pressure was found to hold to within experimental error for all gases over the entire range of orifices.

Since it is difficult to measure with sufficient accuracy the diameter of very small orifices, the product CA_2 should be considered instead of C alone when comparing flows of different gases through the same orifice. Discharge coefficients for the various orifices varied from about 0.8 to 0.95, as calculated from approximate measurements of A_2.

The general plan for the calibration of the thirty orifices with various gases included two phases: the calibration of each orifice with nitrogen, thus obtaining CA_2, and establishment of the ratio of flow of the test gas to that of nitrogen. It will be shown later that C is independent of the gas and that the theoretical formula when properly modified for gas impurities describes relative rates of flow of different gases through a given orifice. Adoption of this procedure materially reduces the labor of the calibration and results in a more flexible flow system.

In actual calibration, discharge rates were corrected to 25°C and one atmosphere by the following formula:

$$V = (rF/\theta)(T_1/T_2)(p_B - p_W/p_B)(p_B/760) \times (298.16/T_1)(T_3/298.16)^{\frac{1}{2}},$$

where V = volumetric flow rate, cubic feet per minute at 25°C and one atmosphere; r = meter reading, cubic feet; θ = time of test, minutes;

F = meter factor = ratio of true volume to meter reading; T_1 = temperature of gas entering meter, degrees Kelvin; T_2 = temperature of meter, degrees Kelvin; T_3 = temperature of gas entering orifice, degrees Kelvin; p_B = barometric pressure, millimeters of mercury (25°C); and p_W = vapor pressure of water at T_1, in millimeters of mercury.

The calibrations were performed by saturating with water vapor just before the gas passes through the meter; hence the formula corrects back to dry gas.

CRITICAL DISCUSSION OF PERFORMANCE

The limiting accuracy of each of the steps in the calibration is as follows:

1. *Calibrated bottle.* The volume was measured four times, the mean deviation from the average value being 2.5 parts in 10,000.

2. *Meter calibration.* (a) Precision of calibration. Sixteen runs were made under nearly identical conditions. The mean deviation from the average value of the meter factor was 2.0 parts per thousand. (b) Water level. The water level could be reproduced to within 0.001 inch. This variation causes a change in the calibration factor of 1.5 part in 10,000.

3. *Orifice calibration with nitrogen.* A given orifice was tested seven times with nitrogen, the mean deviation from the best straight line through the data and the origin being one part in a thousand, when flow rate is plotted against pressure. This includes errors caused by meter reading, meter timing, pressure fluctuation, and pressure measurement. (All runs were made of such length that the number of meter revolutions was an integer.) In order to illustrate the caliber of data which may be obtained, a calibration run is given in Table I.

TABLE II.

Test gas	Av exp. ratio: flow rate of test gas / flow rate of nitrogen	Theoretical ratio: flow rate of test gas / flow rate of nitrogen	Difference rel. to exp. (%)
Nitrogen	1.0000	1.0000	—
Oxygen	0.9349	0.9344	−0.05
Air	0.9908	0.9852	−0.57
Hydrogen	3.666	3.736	+1.91
Helium	2.616	2.806	+7.27
Argon	0.8770	0.8883	+1.29
Carbon dioxide	0.7960	—	—

4. *Orifice calibration with different gases.* Flow rates of seven different gases were measured through each of six orifices varying in diameter from 0.06 to 0.64 millimeter. For nitrogen, oxygen, hydrogen, and argon, each of the results presented in the table below is an average of about thirty independent runs with that gas. For air, helium, and carbon dioxide, each of the values is an average of ten independent runs. The value which best represents the mean deviations of these sets of data is three parts per 1000. No trends in the ratio of flow rate of any given gas to the flow rate of nitrogen (through the same orifice) were observed. It follows that the flow rate ratio is independent of orifice size within the limits studied (see Table II).

The theoretical values were calculated with Eq. (2), assuming that the discharge coefficient C is independent of the type of gas, and using molecular weight M and heat capacity ratio k on the assumption that the gases were perfectly pure. It will be observed from the above table that there are discrepancies between theoretical and experimental values. In the cases of helium and hydrogen, these discrepancies can be explained by a consideration of the reported purity of the gases:

Nitrogen	99.7=0.1%
Oxygen	99.5=0.1%
Hydrogen	99.5=0.1%
Helium	98.2% min.
Argon	99.8% min.
Carbon dioxide	99.5% min.

Assuming that the impurity is always nitrogen, the theoretical ratios may be corrected by computing molal averages of M and k. It is to be noted that the mixture molecular weight of hydrogen or helium would be particularly sensitive to a relatively high molecular weight impurity, such as nitrogen. Unfortunately, since exact analyses of the gases are not available, and vigorous averaging procedures are not thoroughly understood, detailed correction calculations are not presented, but preliminary calculations indicate that application of such corrections would probably make the theoretical and experimental ratios indentical.

It may be concluded that the discharge coefficients are in actuality independent of the type of gas, and that the theoretical equation (2) would correctly describe the dependence of flow rate upon molecular weight and heat capacity ratio for pure gases.

THE REVIEW OF SCIENTIFIC INSTRUMENTS VOLUME 20, NUMBER 1 JANUARY, 1949

Optical Properties of Surface Films. II[*]

ALEXANDRE ROTHEN AND MARJORIE HANSON
Laboratories of The Rockefeller Institute for Medical Research, New York, New York

(Received July 9, 1948)

Measurements of ellipticity of light reflected from a film-coated metal surface have been made for films varying in thickness from 25 to 40,000A. It was found that the approximate formulas of Drude which express as a function of the film thickness the ratio and phase difference of the components vibrating in the plane of incidence and perpendicular to it are valid for thin films. The general formula of Drude expressing the phase shift as a function of the film thickness represents with a fair approximation the experimental results obtained with metallic slides coated with films of Ba stearate whose thickness is up to the order of the wave-length of light. Thus, for the first time, Drude's theoretical formulation has been verified experimentally. For films whose thickness is many times the wave-length of the light used, there is a progressive divergence from Drude's general formula, the cause of which can possibly be due to the birefringence of the films which has been neglected in this work.

Thin Films

THE first attempt to correlate the change in ellipticity of reflected light with the thickness of thin films was made by Drude more than fifty years ago.[1] Since then various formulas have been developed, but the only ones which can be submitted to a practical test are those derived by Drude himself and some of the subsequent modifications of his original formulas.[2,3] In the form in which they are given, Drude's formulas are first approximations, valid only for films whose thickness is small compared to the wave-length of light. When the technique for the deposition of thin films of known thickness was developed, mainly by Langmuir and Blodgett,[4] these formulas could be checked with experimental data. Tronstad[2] was the first to verify them using monomolecular films of fatty acids deposited on a mercury surface. He found close agreement between calculated values and the length of the fatty acid chains.

When a beam of light is linearly polarized at 45° to the plane of incidence it becomes ellipitically polarized on reflection from a metallic surface, and the presence of a film on the metal alters the ratio ψ of the electric vectors vibrating in the plane of incidence and perpendicular to it, as well as their difference of phase Δ. Drude's formulas correlate the parameters ψ and Δ, with the optical thickness of the layer, the angle of incidence ϕ, and the optical constants of the metal. Since these optical constants depend to some extent on the condition of the metallic surface, it was desirable to determine the optical constants of the same stainless steel slides that were used for the deposition of the layers in our experiments.

DETERMINATION OF THE OPTICAL CONSTANTS OF STAINLESS STEEL SLIDES

The optical constants ν and κ correlated to the complex index of refraction $n=\nu(1-i\kappa)$ can be calculated from the equations

$$\nu=\sin\bar{\phi}\tan\bar{\phi}\cos 2\bar{\psi} \quad\text{and}\quad \kappa=\tan 2\bar{\psi}.$$

---

TABLE I.

Angle of incidence	49.2°	69.2°	74.2°
ψ'	38.6_5°	32°	29.3°
Δ'	160.5°	127°	109.8°
$\psi-\psi'(l=24.4\text{A})$	0.00°	0.34°	0.61°
$\Delta-\Delta'(l=24.4\text{A})$	1.37°	3.6°	3.55°

In these equations $\bar{\phi}$ is the angle of principal incidence, i.e., the angle at which metallic reflection brings about a phase shift of 90° between the components vibrating in the plane of incidence and perpendicular to it. The principal azimuth $\bar{\psi}$ is the ratio of the two components after reflection at this angle.

To determine $\bar{\phi}$ the $\lambda/4$ plate of the ellipsometer is set in the two positions in which its principal directions are perpendicular and parallel to the plane of incidence, and in each position the angle of incidence is found for which the light is again linearly polarized after compensation. If the plate is exactly $\lambda/4$, this angle is the same for both positions. With most plates, however, two different values are obtained, and the true angle of principal incidence may be taken as halfway between these values if the $\lambda/4$ plate is not too far from 90°.

To determine $\bar{\psi}$, the light is reflected at the true angle of principal incidence and the resulting ellipse analyzed by adjusting the $\lambda/4$ plate and analyzer simultaneously to produce complete compensation. From the experimental value of θ thus obtained and the known value of δ, the ellipticity ϵ can be calculated according to Eqs. (1) and (3) of the previous section.* The ellipticity in this case is identical to the principal azimuth $\bar{\psi}$.

For the stainless steel slides used, the following values were found:

$$\bar{\phi}=77.5°, \quad \bar{\psi}=28°,$$

from which

$$\nu=2.46, \quad \kappa=1.48.$$

Drude's Formulas

Drude's formulas express as a function of the film thickness the ratio and phase difference of the components vibrating in the plane of incidence and perpendicular to it. They are

$$2\psi-2\psi'=\sin 2\psi'\frac{4\pi}{\lambda}\frac{\cos\phi\sin^2\phi\,\alpha'}{(\cos^2\phi-\alpha)^2+\alpha'^2}\times(1-n_1^2\cos^2\phi)\left(1-\frac{1}{n_1^2}\right)l,$$

$$\Delta-\Delta'=\frac{4\pi}{\lambda}\frac{\cos\phi\sin^2\phi(\cos^2\phi-\alpha)}{(\cos^2\phi-\alpha)^2+\alpha'^2}\left(1-\frac{1}{n_1^2}\right)l,$$

where ψ' and Δ' are the values of ψ and Δ where there is no film, ϕ is the angle of incidence, n_1 the index of refraction of the film of thickness l, and α and α' two constants obtained from ν and κ by

$$\alpha=\frac{1-\kappa^2}{\nu^2(1+\kappa^2)^2}, \quad \alpha'=\frac{2\kappa}{\nu^2(1+\kappa^2)^2}.$$

From the above given values of ν and κ for the metal used, $\alpha=-0.0193$, $\alpha'=0.0479$.

The simplest way to test Drude's formulas would be to determine the position (β) and ellipticity (ϵ) of the ellipse characterizing the reflected light for one given film thickness and from these two parameters to calculate the values ψ and Δ to be compared with the theoretical ψ and Δ. This procedure would not make the best use of the ellipsometer which is most sensitive as a differential instrument with a half-shadow arrangement. Therefore, the experimental procedure was as follows. The light before reflection vibrated linearly at 45° in the second and fourth quadrant for an observer looking toward the light. The $\lambda/4$ plate was placed so as to compensate with its fast axis in the first and third quadrant. The positions of the analyzer and the $\lambda/4$ plate for maximum

TABLE II. Ellipticity of light reflected from slides coated with 1, 3, 5, and 7 monolayers of Ba stearate. (Calculated from Drude's formulas.)

Monolayers Ba stearate	Incidence	ϵ	β	$\lambda/4$	ϵ'	β'

7	74.2	33.5	−6.2	9.9	−3.8	−35.3

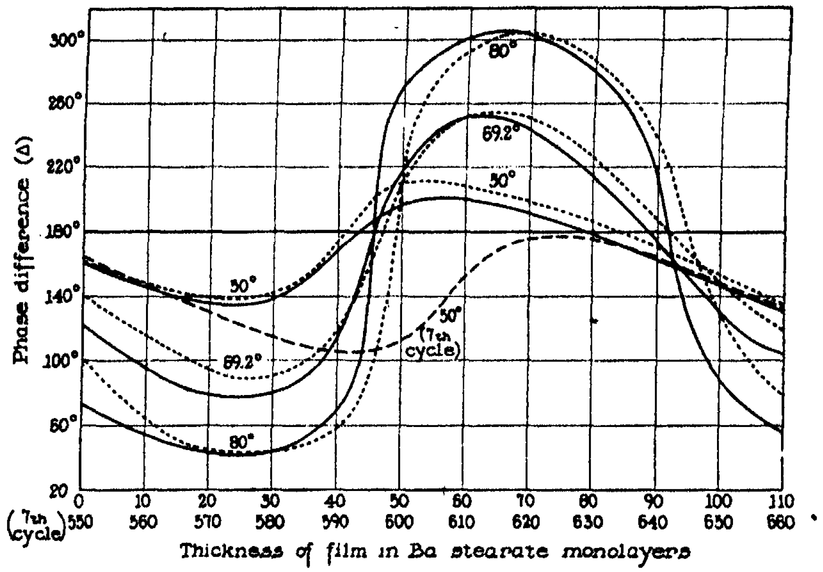

FIG. 1. Phase shift produced by films of Ba stearate at 50°, 69.2° and 80° incidence. The dotted curves are theoretical, and the solid lines and the dashed line are experimental.

extinction were determined for reflection from clean uncoated metal slides at incidence of 49.2°, 69.2°, and 74.2°. The values of ψ' and Δ' determined from these positions are given in Table I. The error involved in a reading of this kind can be neglected here, as ψ' and Δ' are to be used as references to obtain differential values. Then slides were covered with one and three monolayers of Ba stearate as previously described, and the position of the analyzer read for which both half-fields appeared of the same intensity, the position of the $\lambda/4$ plate being so chosen to produce good compensation of both ellipses. Additional layers of Ba stearate were successively deposited on the slide and the corresponding analyzer positions for matching half-fields were read, the $\lambda/4$ plate position remaining unchanged. It remained to check these analyzer positions with those that should be obtained if the reflected light obeys the theoretical formulas. For the above angles of incidence the values of $\Delta-\Delta'$ and $\psi-\psi'$ were calculated from Drude's formulas for one monolayer of Ba stearate ($l=24.4$A, $n=1.495$) and are given in Table I. The values for more than one monolayer are the corresponding multiples of these. From these theoretical values the corresponding ellipses of orientation β and ellipticity ϵ were calculated as well as the theoretical ellipses of small ellipticity resulting when the light goes through the $\lambda/4$ plate of known position and phase retardation. The results have been summarized in Table II. ϵ and ϵ' are the ellipticities of the reflected light before and after going through the $\lambda/4$ plate (85.3° retardation), respectively. The angles from the fast direction of the plate to the perpendicular to the plane of incidence are tabulated under the heading $\lambda/4$. The value of β corresponds to the angle from the major axis of the ellipse of ellipticity ϵ to the perpendicular to the plane of incidence. The values of β' are the angles from the major axis of the ellipses ϵ' to the fast direction of the $\lambda/4$ plate.

These two ellipses of small ellipticity resulting from the compensation of the light reflected from the half-fields which differ in thickness by 49A can be made of equal ellipticities and of opposite sign by proper adjustment of the $\lambda/4$ plate. In this case, the direction transmitted by the analyzer, when both half-fields appear of the same intensity, would be the bisector of the angle made by the minor axis of the ellipses. However, since for successively thicker films the $\lambda/4$ position remains unchanged in actual practice, the direction indicated by the analyzer for equal illumination does not bisect the angle made by the axis but is nearer to the minor axis of the ellipse with the greater ellipticity. The position of optical equilibrium can be calculated from

$$\sin^2\epsilon_1\cos^2\alpha_1+\cos^2\epsilon_1\sin^2\alpha_1=\sin^2\epsilon_2\cos^2\alpha_2+\cos^2\epsilon\sin^2\alpha_2$$

with the condition $\alpha_1+\alpha_2=\alpha$, where α is the angle made by the axes of the two ellipses with ellipticities ϵ_1 and ϵ_2; α_1 and α_2 are the angles from position of equilibrium to the respective axis of the ellipses. This formula reduces to $\sin^2\epsilon_1+\sin^2\alpha_1=\sin^2\epsilon_2+\sin^2\alpha_2$ for small values of α.

Using the calculated values of ϵ' and α' for the theoretical ellipses the positions of the analyzer corresponding to equal illumination for half-fields covered with one and three, three and five, five and seven monolayers were calculated to be 25.9°, 29.3°, and 33.2° for an angle of incidence of 69.2°. Therefore, the calculated angle by which the analyzer should be rotated when one double layer of Ba stearate is deposited on an optical gauge of one and three monolayers is 3.4°. The experimental value is 3.2°. However, it was also found experimentally that the ratio $\Delta\alpha/\Delta N$, N being the number of layers of Ba stearate deposited on an optical gauge, diminishes linearly with the increase in N for the $\lambda/4$ position used and the value $\Delta\alpha/\Delta N$ extrapolated for $N=0$ was 3.4° in perfect agreement with the theoretical value calculated from Drude's formulas. For a film thickness of 50A the experimental value $\Delta\alpha/\Delta N$ is 7 percent smaller than the calculated one, and this difference increases for thicker films.

At an angle of incidence of 49.2°, $\Delta\alpha/\Delta N = 1.3_5°$ (calculated) compared to $\Delta\alpha/\Delta N = 1.4°$ to 1.25° (experimental) depending on whether the double layer was deposited on an optical gauge of one to three layers or seven to nine layers. In other words, at this angle of incidence the experimental values $\Delta\alpha/\Delta N$ vary much less with N than at higher angles of incidence. At 74.2° incidence the following values were obtained for a double layer deposited on a gauge of one to three layers. $\Delta\alpha/\Delta N = 4.9$ (calculated); $\Delta\alpha/\Delta N = 4.5$ (experimental). These results show that Drude's formulas represent the experimental data well. The formulas not only give the right values for the ellipticity at one particular angle of incidence but also describe correctly the variations of the ellipticity as a function of the angle of incidence. At 49° incidence the experimental values remain in good agreement with the theoretical ones up to film thicknesses of about 250A.

Thick Films

Thus, Drude's formulas fit remarkably well the experimental values of the change in ellipticity of reflected light produced by thin films of known thickness. On the other hand, these formulas are first approximations and cannot be expected to hold when the thickness of the film is not small compared to the dimension of the wave-length used. Calibration curves[5] show that the angle $\Delta\alpha/\Delta N$ by which the analyzer has to be turned when a few successive double layers of Ba stearate are deposited, decreases with the number of double layers N, thus showing the beginning of a deviation from Drude's formulas. It was, therefore, of interest to determine the ellipses resulting from reflection when the thickness of the film varied from a few hundred angstroms up to several times the wave-length of the light used.

Experiments were carried out in which successive double layers of Ba stearate were deposited on an optical gauge of one and three monolayers. The ellipses characterizing the light reflected from these films were determined at three different angles of incidence, the readings being made by adjusting both the $\lambda/4$ plate and the analyzer to obtain a position of maximum uniform darkness. Each value obtained with this method is intermediate between those which would be found if accurate readings could be made of each half-field separately.

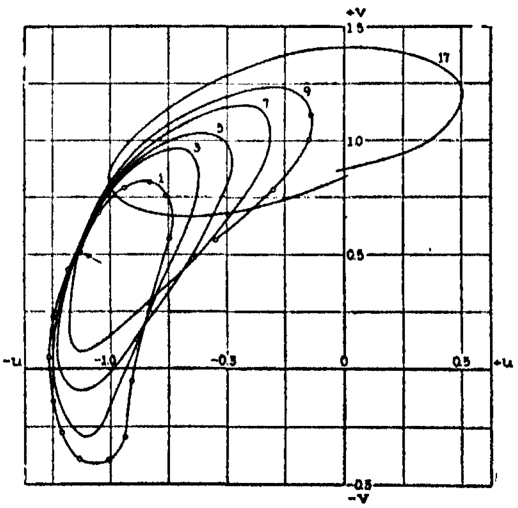

FIG. 2. Ellipticity of reflected light at 50° incidence produced by films of Ba stearate from 0 A up to the equivalent of 17 wave-lengths of light (λ5893). Arrow indicates beginning of the first cycle. All cycles are described clockwise.

---

[5] A. Rothen, Rev. Sci. Inst. **16**, 26 (1945).

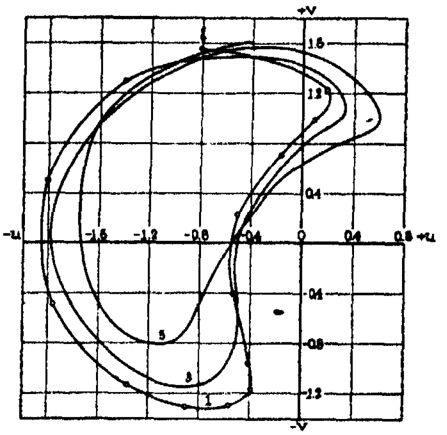

FIG. 3. Ellipticity of reflected light at 69.2° incidence, produced by films of Ba stearate from 0 A up to 5 wave-lengths of light. Arrow indicates beginning of first cycle.

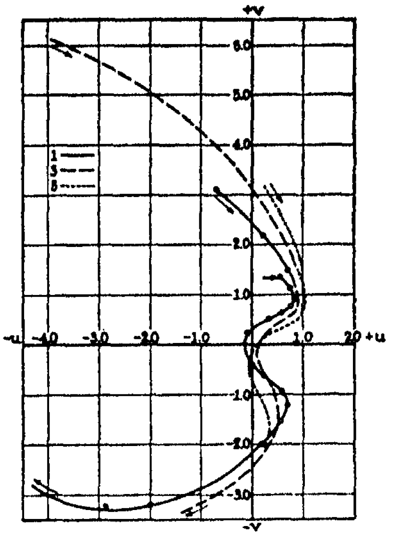

FIG. 4. Ellipticity of light at 80° incidence, produced by Ba stearate films from 0 A up to 5 wave-lengths of light. The described cycles are not closed on account of the rapid change of phase for certain critical thicknesses (45 monolayers for the first cycle) where half of the cycle is described *in a few monolayers of Ba stearate.*

The experimental values of the phase shift Δ between the components parallel and perpendicular to the plane of incidence as a function of the thickness of the film are represented in Fig. 1. The calculated number of monolayers of Ba stearate which produce a path difference of one wave-length of Na D light at the angles of incidence of 50°, 69.2°, and 80° are 93.3, 102.5, and 105, respectively. These figures compare favorably with the experimental values which show that the periods are completed at thicknesses of 92.5, 102.2, and 105 monolayers. Two curves have been plotted to represent the results at 50° incidence. The lower curve was obtained when the slide was coated with 550 to 650 monolayers of Ba stearate, thus representing the seventh complete period. It is to be noticed that this curve is displaced laterally and vertically, a fact which will be discussed later on.

In looking for a theoretical basis for the above experimental curves, it can be noted that Drude's approximate formulas for the light reflected from these films can be obtained from a general equation which should apply to films of any thickness on a reflecting surface. Drude showed that the ratio of the components before (I) and after reflection (R) of the light vibrating either in the plane of incidence (OP) or perpendicular to it (OS) can be quite generally expressed by

$$\frac{R}{I}e^{i\delta}=\frac{r_f+r_m e^{-(4\pi itn\cos\phi/\lambda)}}{1+r_f r_m e^{-(4\pi itn\cos\phi/\lambda)}},$$

where δ is the phase shift, r_f and r_m the Fresnel coefficients representing the amplitudes and phase shift of the components after reflection from the film (r_f) and the metal (r_m), t the thickness of the film, n its index of refraction, and ϕ the angle of refraction in the film. In the case dealt with in our experiments, that of a transparent film deposited on a metal slide, r_m is complex but both r_f and n are real. It also results from the experimental conditions that the incident components perpendicular (OS) and parallel (OP) to the plane of incidence are equal and in phase. Thus, the determined ratio ψ or OP/OS as well as the phase difference Δ produced by reflection from the coated slide is given by

$$tg\psi e^{i\Delta}=\frac{(r^p{}_f+r^p{}_m e^{-ix})(1+r^s{}_f r^s{}_m e^{-ix})}{(1+r^p{}_f r^p{}_m e^{-ix})(r^s{}_f+r^s{}_m e^{-ix})} \qquad (1)$$

when x stands for $(4\pi t/\lambda)n\cos\phi$.

Formula (1) shows that the change of phase is a periodical function of x, a period being completed when the film thickness is such that the optical path difference between the rays reflected from the film and from the metal is equal to one wave-length of light. This formula can be developed as was done by Vasicek[6] in the case of glass reflection. The only difference is that the coefficients r_m are complex and can be represented by $r^{p,s}=X^{p,s}+iY^{p,s}$.

---

[6] A. Vasicek, J. Opt. Soc. Am. 37, 145 (1947).

After separating the imaginary from the real quantities one obtains for the phase difference brought about by film coated metal slides

$$tg\Delta=\frac{AB'+A'B}{AA'-BB'} \tag{2}$$

where

$$A=r_f^p[1+X^{p^2}+Y^{p^2}]+X^p[1+r_f^{p^2}]\cos x + Y^p[1+r_f^{p^2}]\sin x$$

$$A'=r_f^s[1+X^{s^2}+Y^{s^2}]+X^s[1+r_f^{s^2}]\cos x + Y^s[1+r_f^{s^2}]\sin x$$

$$B=-X^p[1-r_f^{p^2}]\sin x+Y^p[1-r_f^{p^2}]\cos x$$

$$B'=X^s[1-r_f^{s^2}]\sin x-Y^s[1-r_f^{s^2}]\cos x.$$

The coefficients $r_f^{p,s}$ are calculated from the Fresnel equations. The quantities $X^{p,s}$, $Y^{p,s}$ are related to the phase shifts δ^p and δ^s (abbreviated $\delta^{p,s}$) and the corresponding amplitudes ρ^p and ρ^s (abbreviated $\rho^{p,s}$) of the components after reflection from an uncoated metal surface by the following formulas

$$tg\delta^{p,s}=(Y^{p,s}/X^{p,s}),\quad \rho^{p,s}=(X^{p,s^2}+Y^{p,s^2})^{\frac{1}{2}}.$$

The quantities $\delta^{p,s}$ and their difference $\delta^p-\delta^s$ as well as $\rho^{p,s}$ can be computed from the optical constants of the clean metal surface by means of equations which can be found, for instance, in the Handbuch der Physik, Volume 20, page 242. It appears from (2) that the phase change Δ is not a sinusoidal function of x since it involves a ratio of polynomials containing not only $\sin x$ and $\cos x$ but also $\sin x \cos x$, $\sin^2 x$ and $\cos^2 x$ terms, in other words, terms corresponding to a periodicity of $2x$. When the calculations were carried out the calculated $\Delta=f(x)$ was in remarkable agreement with the experimental curves (see Fig. 1). Thus the validity of Eq. (1) has been demonstrated for the first time experimentally for transparent films of known thicknesses from a few A up to a wave-length of light.

Further experimental data was obtained for film thicknesses up to 40,000A. The method of Poincaré was adopted for condensed graphical representation of these series of ellipses. Since an ellipse is completely characterized by the ratio of two components and their phase shift, it can be represented on the complex plane by a single point $u+iv$ of modulus $\cot\psi$ and argument Δ. The rectangular coordinates of each point are therefore

$$u=\cot\psi\cos\Delta,\quad v=\cot\psi\sin\Delta,$$

and $u+iv=\cot\psi e^{i\Delta}$.

With this representation all points on the u axis correspond to linear vibrations whereas all points on the v axis correspond to ellipses whose axis are oriented along OS and OP. The points $u=0$, $v=\pm1$ are two circular vibrations of opposite sense. The results obtained at 50°, 69.2°, and 80° have been summarized in Figs. 2 to 4. The points indicated on the initial cycles correspond to thickness intervals of 146A (six monolayers of Ba stearate). From the positions of these points it can be seen that the rate at which the cycle is described is not uniform. This is another way of saying that $\delta\Delta/\delta N$ and $\delta\alpha/\delta N$ are not constant over the period. According to formula (1) the successive cycles (corresponding to one wave-length of light) should be identical. It is especially evident from the results obtained at 50° incidence that the cycles do not superimpose. Each cycle does correspond to an optical thickness of one wave-length of light but the successive cycles precess clockwise around the origin as the approximate center of rotation. The seventh cycle (corresponding to thicknesses from 558 to 650 monolayers of Ba stearate) has rotated by about 60°. Thus, there is a second periodicity on top of the one which corresponds to an optical path difference of one wave-length

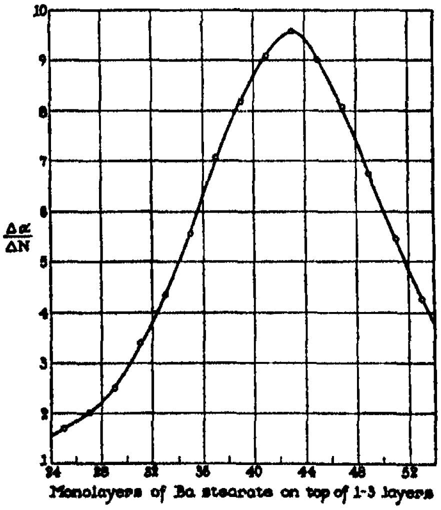

FIG. 5. Calibration curve for 24 to 52 monolayers of Ba stearate, with the fast direction of the λ/4 plate turned 20° counterclockwise from the perpendicular to the plane of incidence.

and this progressive shift affects both ψ and Δ. At 50° incidence the seventh cycle does not cross the u axis (Fig. 2). In other words, the phase shift is never greater than 180°. This can also be observed on the curve of Fig. 1. The precession cannot be predicted from the formula (1). It may be due, however, to the birefringence of the film which has hitherto been neglected. It is known that Ba stearate films are positive uniaxial crystals with indices $n_0=1.491$ and $n_e=1.550$.[3] It was found impossible to build up enough layers to complete the larger period to see whether a cycle would be obtained having the same orientation as that of the first one (0 to 92 layers).

From the practical aspect of the measurement of film thickness, the curves of Fig. 1 exhibit some very interesting facts. A calibration curve[6] is the plot of the position α of the analyzer for equal illumination of both half-fields against the thickness of the film for a fixed position of the $\lambda/4$ plate. In general, the change in phase shift per layer is such as to exert more influence on the orientation of the re-established light than does the change in ψ, so that the analyzer reading shows greatest sensitivity $\delta\alpha/\delta N$ when the change of phase shift $\delta\Delta/\delta N$ is greatest. N is the thickness of the film expressed in double layers of Ba stearate. At 69.2° incidence for a film under 100A thick, $\delta\Delta/\delta N\sim 6°$ and $\delta\alpha/\delta N\sim 3°$. In other words, the analyzer has to be turned 3° for a variation in thickness of 48A. However, $\delta\Delta/\delta N\sim 24°$ and $\delta\alpha/\delta N\sim 9.6°$ when the thickness of the film is about 45 monolayers of Ba stearate. For the same range of thickness at 80° incidence, $\delta\Delta/\delta N\sim 96°$ and $\delta\alpha/\delta N\sim 14°$. It is thus apparent (see Fig. 1) that the range of maximum sensitivity of the apparatus occurs for thicknesses of the order of 45 monolayers of Ba stearate. For thicknesses from 70 to 100 monolayers the sensitivity is still large, although less on account of the skewness of the curve. Finally, there are regions where the sensitivity is very small ($\delta\alpha/\delta N\rightarrow 0$) for thicknesses from 20 to 30 or 55 to 65 monolayers. The plot $\delta\alpha/\delta N$ for N extending from 24 to 55 layers at 69.2 incidence can be seen in Fig. 5. Since with the half-shadow arrangement analyzer positions can be obtained within ±0.02° the maximum sensitivity expressed in terms of thickness of film can then be calculated: $49\times 0.02/9.6=\pm 0.1$A.

Another practical aspect worth considering is the range of thickness which can be determined with a single $\lambda/4$ plate position. Obviously, if the orientation of the ellipses (β) did not change, a single calibration curve could express any range of thicknesses. This condition would be fulfilled if the ratio of the components parallel and perpendicular to the plane of incidence were always one ($tg\psi=1$). All the ellipses would then have their major and minor axis oriented at 45° to the plane of incidence. This condition is approached only as the angle of incidence is decreased. However, on account of the condition $tg2\beta=tg2\psi\cos\Delta$ it can be seen that when $\cos\Delta$ and $tg2\psi$ vary in opposition directions with the increase of the thickness of the film then ($\delta tg2\beta/\delta N$), is small, and the range of the calibration curve is wide.

If the $\lambda/4$ plate does not produce an exact 90° phase shift, some interesting effects are produced. In order to fully compensate an ellipse with such a plate (see part I) its principal directions make an angle β_1 with the axis of the ellipse. In this case even when the orientation remains constant the plate has to be turned if the ellipticity changes, in order to satisfy the equation $\sin 2\beta_1 = (tg2\epsilon/tg\delta_1)(\delta_1=$ phase shift produced by the plate). It may happen that the angle ($\delta\beta_1$) by which the approximate $\lambda/4$ plate should be turned on account of a change in ellipticity may be compensated by the rotation ($\delta\beta$) of the ellipse produced by a change in Δ or ψ or both. In this case the range of thickness covered by a single calibration curve is extended. Because of a combination of this effect and the one described in the preceding paragraph, it was possible to cover a range of thickness from 1500A to 2740A in one calibration curve. The value of the plate used in this case was 76.7°.

SUMMARY

Measurements of ellipticity of light reflected from a film coated metal surface have been made for films varying in thickness from 25 to 40,000A.

It was found that the approximate formulas of Drude are valid for thin films and that the general formula expressing the phase shift as a function of the film thickness represents with a fair approximation the experimental results obtained with films whose thickness is of the order of the wave-length of light.

Sampling Devices for Determining the Bacterial Content of Air

MATTHEW LUCKIESH, A. H. TAYLOR, AND THOMAS KNOWLES
Lighting Research Laboratory, General Electric Company, Nela Park, Cleveland, Ohio

(Received September 20, 1948)

Appraisal of air contamination by micro-organisms which are responsible for infectious diseases or result in spoilage of products requires devices for sampling the air to determine bacterial content. The simplest technique involves the use of open petri dishes containing culture media upon which colonies of the organisms can grow. However, quantitative data require the use of devices which will sample the bacterial content of definite volumes of air.

Air samplers which yield quantitative data may be roughly divided into bubbler and impinger types. In the former type a definite quantity of air, with or without atomization, is bubbled through water, thus collecting a large part of the organisms. In the impinger types the organisms are deposited on the culture medium, either by use of high linear velocity of the air or by application of an electrostatic field.

The authors have developed two types of impinger samplers. One of these, weighing approximately 12 pounds, employs an electrostatic field of about 7000 volts. It can be used wherever 110–120-volt, 60-cycle current is available. The other sampler, called a duplex radial-jet air sampler, uses a high velocity air flow to impinge the organisms on the culture medium. Examples of the use of the latter sampler in important laboratory studies are described and typical experimental results are presented.

MODERN air sanitation has for one of its objectives the reduction of air-borne micro-organisms which may be instrumental in the spread of infectious diseases or the contamination of foodstuffs and other products. The oldest and most commonly used method is ventilation, replacing contaminated indoor air with relatively fresh outdoor air. In the past decade two other methods have been introduced; *viz.*, the use of germicidal vapors and air irradiation with ultraviolet of the wave-length λ2537 which is highly destructive to such organisms.

The appraisal of air contamination and its improvement by air sanitation procedures necessitates the use of some method of air sampling which will indicate the concentration of air-borne micro-organisms. This usually involves the collection of the organisms directly onto a culture medium upon which colonies of the organisms will grow, or else their collection in a liquid by bubbling the air through it and incorporating a portion of this liquid in a culture medium. Since no single culture medium will grow all types of the organisms which may be collected, it is never possible to determine accurately the total concentration of such organisms in the air. By proper choice of the culture medium, the concentration of specific types can be determined.

Many air-sampling methods and devices have been developed and used. The simplest of these is the exposure of open petri dishes, containing a culture medium, in the air to be sampled. Since only the heavier particles in the air will settle out, and since air currents disturb the natural settling due to gravity, this method is selective in its results and is erratic and inefficient. Furthermore, the results cannot be related to a definite quantity of air. Some droplet nuclei may be so small that they will never settle out.[1]

Air sampling devices fall generally into two distinct classes, impinging and washing or

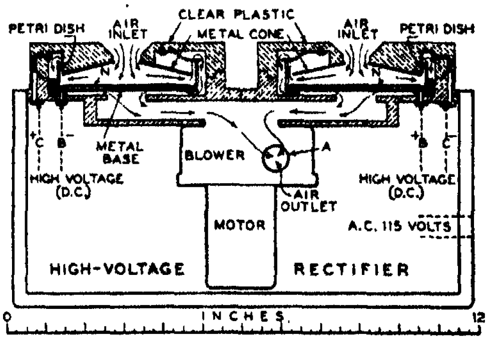

FIG. 1. Diagrammatic sketch of the Luckiesh-Holladay-Taylor electrostatic bacterial air sampler. Air entering the sampler is subjected to an electrostatic field (7000 volts) which increases in intensity towards the edges of the petri dish, as a result of the shorter spacing of the electrodes.

bubbling devices. In the impinging types the air-borne organisms are collected on the culture medium by impingement from air moving at fairly high linear velocity, or by use of an electrostatic field to attract charged particles to the culture medium. In the bubbling devices the air is drawn through water in such a way that fine air bubbles are formed, it being assumed that most of the organisms will be collected by and remain in the water. In one sampler[2] the air passes through an atomizing chamber before passing through water.

One of the earliest samplers operating on the impingement principle was the Wells air centrifuge.[3] It employs a rotating glass cylinder, the inside walls being coated with the nutrient material upon which the organisms grow colonies. The organisms in the air drawn through the sampler are impinged, by centrifugal action, upon the walls of the cylinder which is rotating at high speed.

The United States Public Health Service has made an extensive study of the above two sampling devices and six other types.[4] That study showed that the highest bacterial counts are obtained with the bubbler and atomizer-bubbler types of samplers. The most plausible explanation for this finding is the theory that the micro-organisms are carried in the air in

"clusters." The bubbler-type samplers apparently break up these clusters so that the maximum numbers of colonies develop, whereas the impingement-type samplers do not break up the clusters and only a single colony develops from a cluster.

ELECTROSTATIC BACTERIAL AIR SAMPLER

About three years ago the authors and their colleague, L. L. Holladay, developed a portable air sampler employing an electrostatic impingement principle.[5] It is illustrated in the diagram and photograph of Figs. 1 and 2. It consists of two sampling units, each holding one petri dish. Each dish rests on one electrode of a high voltage d.c. circuit (approximately 7000 volts), one electrode being negative and the other positive. A metal cone above each dish has a polarity opposite to that of the one on which the dish rests. A small blower mounted in the cabinet below the dishes draws air over each dish, through an electrostatic field which increases in intensity as the air approaches the edge of the dish, as a result of shorter spacing between the electrodes. The air is finally expelled at the back of the sampler cabinet. The apertures are adjusted to give an air rate of ½ cubic foot per minute through each unit. The complete sampler weighs approximately 12 pounds; hence it is readily portable. Its operation is very simple and comparative tests with the sampler to be described next show it to be highly efficient. However, it is improbable that it breaks up "clusters" of organisms. It is probable that this could be accomplished with this sampler by collecting the organisms in water and then violently agitating it before incorporating an aliquot part of it in a culture medium.

AN IMPROVED DUPLEX RADIAL-JET AIR SAMPLER

A single-unit radial-jet air-sampler has already been described by the authors.[5] Although developed independently in this laboratory, it is essentially a modification of the slit sampler first developed by Bourdillon, Lidwell, and Thomas.[6] This type of sampler is highly efficient and is very useful in the laboratory.

In the original designs of Bourdillon *et al.* and of the authors, the sampler consisted of a single sampling unit. By means of a vacuum pump, air is drawn into a hollow drum and issues at high velocity through a radial slit onto the culture medium in a petri dish which is rotating slowly underneath and close to the drum. The sampler we described was the result of extensive investigations of the optimum velocity and character of

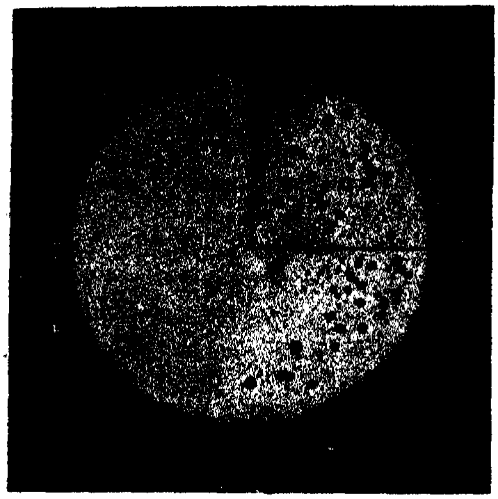

FIG. 7. Typical petri dish illustrating one way in which the sampler can be used to measure the rapid change of bacterial air contamination (see reference 3). It represents periods of 15 seconds before and 45 seconds after exposure of the room air to a 30-watt germicidal lamp. At sampling point the intensity of germicidal energy was 30 microwatts per sq. cm.

the flow of air. The authors later modified this original design to incorporate two identical sampling units, one of which could be used for the control and the other for the test.[7] Used in this way it is a valuable tool in measuring the lethal effect of ultraviolet upon various types of micro-organisms. It can also be used to determine the relative value of different culture media for specific types of organisms or for sampling air in two places in a room simultaneously. The first design of the duplex radial-jet air sampler is illustrated in Figs. 3 and 4. As will be seen, the air flows over the outside of the petri dishes after passing over the culture media, thus allowing possible contamination of the outside of the dishes by bacteria which escape collection. Furthermore, the construction is such that the sampler cannot be autoclaved.

The authors have recently modified the design of the sampler so that the contaminated air does not pass over the outside of the petri dishes. The modified design is illustrated in Figs. 5 and 6. In operation the petri dishes are stationary and are inverted over rotating drums. They are held in place against rubber gaskets by means of a flat spring clamp. Air from the two units after sampling is brought together just ahead of a three-way valve. This valve makes it possible to by-pass air around the sampler while changing petri dishes. Two constant-speed Telechron motors rotate the drums at one revolution per minute. The upper part of the sampler can be removed from the case containing the motors and can be autoclaved without damage. This is an important advantage, especially when sampling pathogenic organisms or molds.

One great advantage of the duplex radial-jet air sampler is that it may be used to measure rapid changes in concentration of air-borne bacteria, such as may occur when a germicidal lamp is turned on in a room. This is illustrated in Fig. 7, a time-indexed photograph of a petri dish after incubation. It shows the concentration of respiratory micro-organisms at a given point in a room 15 seconds before and for 45 seconds after uncovering a 30-watt germicidal unit irradiating the upper air in the room which was 17 feet square and 11 feet high.[7] The test position was in the center of the room, one foot above the mounting height of the lamp. The intensity of the germicidal energy (λ2537) at the sampling position was approximately 30 microwatts per

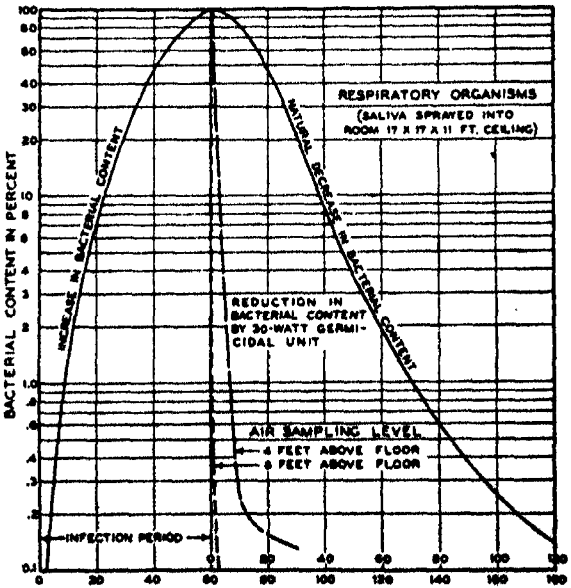

FIG. 8. Some experimental results obtained with the duplex radial-jet air sampler. Saliva was atomized into the air of a closed room for an hour, the air being sampled frequently. At that time the atomizer was stopped and a single 30-watt germicidal lamp unit irradiating the air above the 7-foot level, was turned on. Air samplings at two levels in the center of the room with and without the germicidal unit show its effectiveness in destroying these organisms.

[7] Matthew Luckiesh, A. H. Taylor, and T. Knowles, "Killing air-borne respiratory micro-organisms with germicidal energy," J. Franklin Inst. 224, 267 (1947).

sq. cm. Saliva was nebulized into the room air for approximately 20 minutes before starting the test and ***nebulization continued throughout the sampling period.*** Bourdillon, in a letter to one of the authors, indicated that he has used his sampler in this same way to measure the rate of change in air contamination resulting from the use of a mercury lamp.

The rapid decrease of respiratory organisms in the air of the above room when a single 30-watt germicidal lamp unit was turned on after nebulization of saliva for one hour is also shown graphically by Fig. 8. Data from two tests have been combined to show the natural rate of decrease after nebulization ceased when no lamp was used and the highly accelerated decrease produced by the germicidal energy when the lamp was used in the second test.

The authors have found the duplex radial-jet air sampler very valuable in studying the effect of varying the exposure of specific air-borne organisms to germicidal ultraviolet energy. A simplified diagram of apparatus used for this purpose is shown in Fig. 9. Water containing the organisms is nebulized into an infection chamber, volume approximately 25 cubic feet. Air from this chamber is drawn directly into one unit of the sampler which serves as a control, to indicate the concentration of organisms *before* irradiation. The other unit of the sampler receives air which has passed through an irradiation chamber. This chamber has two quartz windows through which the air is irradiated by 8-watt germicidal lamps. The number of lamps used can be varied from one to fourteen and their distances are also variable over wide ranges. These variations are sufficient to determine lethal curves for organisms varying widely in resistance. Room air entering the infection chamber and air passing out of the sampler is disinfected by passing through glass tubes in which are enclosed 30-watt germicidal lamps.

Instead of using one unit for the control and the other for the test, when determining the lethal effect of ultraviolet, a single unit can be used in the following way. Let the drum make a half revolution with the air being irradiated, then cover the lamps and continue the sampling for the other half of the plate. Possible errors due to changes in concentration during the transition period can be avoided by counting the colonies in 160° rather than 180°. Use of a single plate in this way avoids errors caused by lack of symmetry between the two units.

FIG. 9. Simplified diagram of the arrangement of apparatus used to study the lethal effect of germicidal energy on air-borne organisms of various types.

The electrostatic air sampler is much more easily portable than the radial-jet sampler. The latter requires the use of a vacuum pump which, with motor, weighs nearly 30 pounds. It also requires flow-rate meters in order to maintain the correct air-rates. However, in laboratory studies such as those described above, the jet sampler has distinct advantages.

The sampling efficiency of any air sampler is difficult to appraise, since there is no single method which can be assumed to be 100 percent efficient. Furthermore, as discussed above, some air samplers break up clusters of organisms and produce a larger number of bacterial colonies than those which do not break them up. Also, there is usually no assurance that two samplers operating simultaneously will be sampling homogeneous air. Many tests must be made before valid comparisons are possible. Another factor which may affect sampling efficiency with any particular sampler is the size of the particles carrying the organisms: e.g., dust particles, fine or coarse droplet nuclei, etc. One method of analyzing performance is to put two samplers in series, the second in line to be one known to have a high efficiency. Tested in this way, both of the samplers described above appear to be quite efficient. In many cases reliability and consistency may be more important than the highest possible efficiency. Both of these samplers have proved to be satisfactory in these respects.

THE REVIEW OF SCIENTIFIC INSTRUMENTS VOLUME 20, NUMBER 1 JANUARY, 1949

A Wide-Range Saw-Tooth Generator

PETER G. SULZER
Department of Electrical Engineering, The Pennsylvania State College, State College, Pennsylvania

(Received October 2, 1948)

A new and comparatively simple saw-tooth generator is described. The circuit is capable of operating over the range from 15 cycles to 500 kilocycles with good linearity and rapid flyback.

EVER since the advent of the thyratron saw-tooth generator,[1] various attempts have been made to extend the upper-frequency limit of the linear time base. These have usually taken the form of a modification of Abraham and Bloch's multivibrator.[2] Probably the most successful modification is that due to Puckle,[3] in which one of the multivibrator tubes is used for discharging a condenser, which is subsequently charged through a constant-current device. Although this circuit extended the frequency range by a factor of 10 over the thyratron generator, it has not seen wide application because it requires three tubes. More recently, Keen has described a circuit[4] which performs well with only two tubes.

This paper describes a simple saw-tooth generator that is capable of operating at frequencies as high as 500 kilocycles. Although but a single tube is employed, it appears to function as well as the more complicated circuits mentioned above. The new circuit has been found to be particularly useful as an auxiliary unit for extending the frequency range of already existing oscillographs.

It was thought that a useful time-base generator might be derived from the cathode-coupled multivibrator.[5] Although such a circuit[6] has

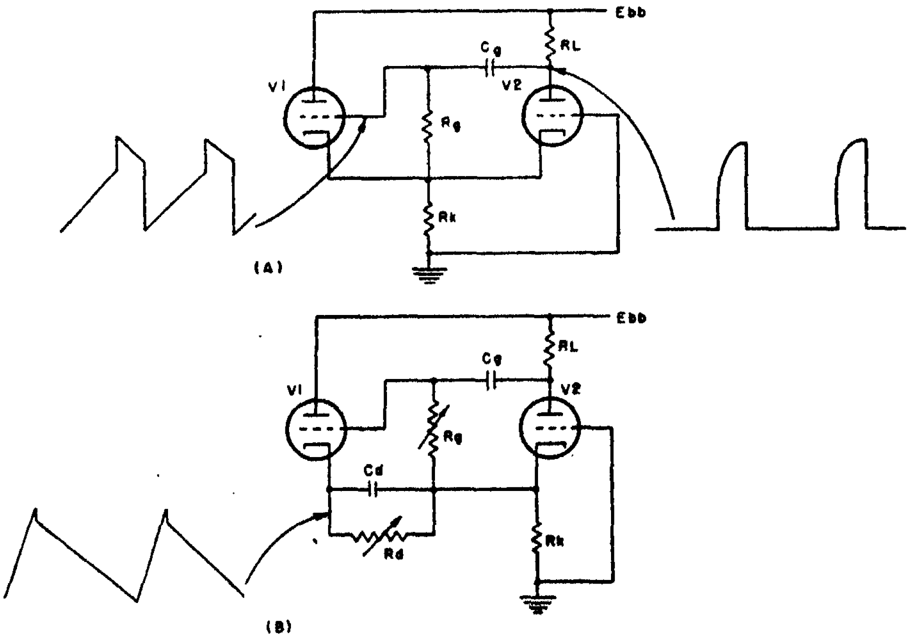

FIG. 1. Cathode-coupled multivibrator.

already been obtained, it does not give constant output with variable frequency, which is so desirable in oscillographic work.

CATHODE-COUPLED MULTIVIBRATOR

In considering the cathode-coupled multivibrator, Fig. 1(A), it is convenient to start with V_1 cut off, and V_2 conducting. Thus the grid of V_1 is negative with respect to its cathode because of the charge on C_g. As C_g discharges through a path containing R_g as the most important element, the bias on the grid of V_1 will fall to a point where the tube starts to conduct. When it does, the cathode current of V_1, flowing through R_k, biases the cathode of V_2, decreasing its plate current, increasing its plate voltage, and thus, through C_g, applying a positive voltage to the grid of V_1. The result of this regenerative process is that V_1 conducts heavily, and V_2 is cut off. During this time, C_g is being charged through a path containing R_L, the grid-cathode resistance of V_1, and R_k. As C_g becomes fully charged, the current through it decreases, reducing the positive bias on the grid of V_1, which starts a reverse regenerative process. By a suitable choice of parameters the charging time-constant, which is roughly R_LC_g, can be made much smaller than the discharging time-constant, which is very nearly R_gC_g. Thus the cathode current of V_1 can be made to flow in a series of short pulses.

CIRCUIT MODIFICATIONS

This fact suggests the placing of a parallel $R-C$ combination in the cathode lead of V_1, as is shown in Fig. 1(B). A saw-tooth voltage would be produced across C_d by charging it for a short time by means of the cathode current pulses, and discharging it for a longer time through R_d. The frequency of the resulting sweep oscillator would be determined by both of the time constants, namely, R_gC_g and R_dC_d. Operation of the circuit would be complicated by the fact that it would be necessary to vary R_g and R_d simultaneously to obtain constant output.

It is possible, however, to avoid this difficulty by using the circuit of Fig. 2(A), which dispenses with R_g and C_g. Thus only one time-constant need be considered. Operation of the device is as follows:

Assume that V_1 is cut-off because of a large voltage across C_d, and V_2 is conducting. With the circuit values of Fig. 2(A), the voltages are as shown at this instant of time. C_d will then

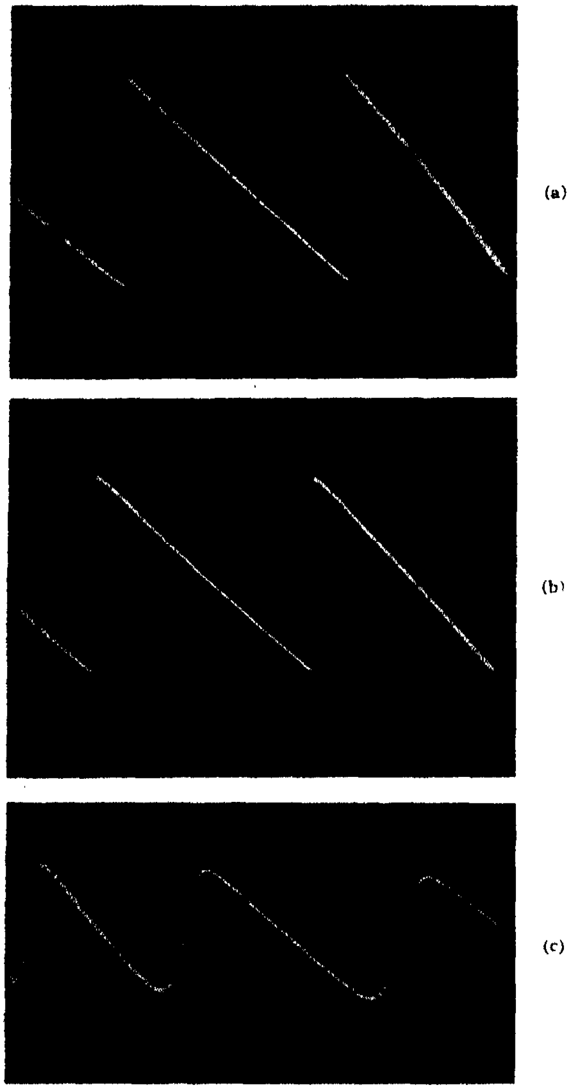

FIG. 3. Oscillograms of the output of the circuit made at (a) 50 cycles, (b) 5 kilocycles, and (c) 500 kilocycles.

discharge through R_d until the cathode voltage of V_1 is lowered sufficiently to allow conduction. The cathode current of V_1 flowing through R_k will place a positive bias on the cathode of V_2, increasing its plate voltage, and making V_1 conduct more heavily. Eventually V_2 will be cut off, as C_d charges through R_k. It is of particular interest to note that V_1 acts as a cathode follower at this time, permitting very rapid charging of C_d through R_k, which is a low resistance. This is desirable for a rapid flyback of the sweep. As C_d becomes fully charged, the current through it decreases, allowing V_2 to conduct, and cutting off V_1. C_d then discharges slowly through R_d, producing the long portion of the saw-tooth, which is used as the active portion of the sweep. Since the saw-tooth is only a small portion of the average voltage between the cathode of V_1 and ground, excellent linearity is obtained without the use of a constant-current device such as a pentode.

It should be noted that the voltage between the cathode of V_1 and ground is not a true saw-tooth because of the small pulse appearing across R_k, which is added to the saw-tooth appearing across C. The amplitude of this pulse is so small, however, that it does not affect the operation of the circuit as a time base.

Figure 2(B) shows a practical circuit using a type 2C51 dual triode. A four-to-one frequency ratio is obtained by varying R_d, while ranges are changed by switching C. The accompanying table shows values of C and the corresponding frequencies covered. With the values shown the circuit produces a 20-volt saw-tooth over the range from 15 cycles to 500 kilocycles. Operation is improved somewhat at the higher frequencies by inserting an inductance in series with R_L.

Synchronization is obtained by applying at least 0.2 volts peak to the grid of V_2, which is normally grounded. Thus synchronizing voltage can be introduced easily without disturbing the other functions of the circuit.

When setting-up the circuit, R_k should be adjusted for a reasonably short flyback with R_g set to a low value and with one of the large condensers switched in for C. Shorter flyback and a higher maximum frequency are obtained with low values of R_k. However, if R_k is set too low, the lower portion of the saw-tooth may be clipped.

Figure 3 contains three oscillograms of the saw-tooth output of the circuit. These were made at frequencies of (a) 50 cycles, (b) 5 kilocycles, and (c) 500 kilocycles. It will be noted that the linearity is good, and that a reasonably short flyback is obtained, even at 500 kilocycles.

CONCLUSION

A new one-tube time-base has been described. It is thought that the circuit could be used to replace the thyratron time base for most oscillograph work.

Laboratory and Shop Notes

Distant Counting of Scintillations*

E. P. Blizard and S. DeBenedetti
Oak Ridge National Laboratory, Oak Ridge, Tennessee
October 7, 1948

TWO limitations to the use of scintillation counters with photo-multipliers are: (a) the photo-multiplier will not operate in strong magnetic fields, and (b) the pulse-height distribution is perturbed by the direct response of the multiplier to radiation. These limitations can be circumvented by separating crystal and photo-multiplier, and focusing or canalizing the scintillation light. To test this point an anthracene sample was mounted at the focus of a hemispherical mirror 1⅝ in. in diameter at one end of an internally reflecting tube of equal diameter and one meter long. A liquid nitrogen cooled 1P21 photo-multiplier was placed at the other end, and the whole assembly made light-tight. With this arrangement we could count with 100 percent efficiency the alpha-particles from a polonium source in contact with the anthracene. With 80 volts per stage the alpha-particle pulses were much larger than those of the photo-multiplier background. Under the same conditions the efficiency for beta-rays of $E_{\max}=0.87$ Mev was also 100 percent within the limits of accuracy of source calibration. Satisfactory results were also obtained with dry ice cooling, and with improved optical techniques it might be possible to dispense with cooling altogether.

A Convenient Method for Checking the Linearity of an Electron Multiplier Circuit

George P. Kirkpatrick
United States Radium Corporation, Almedia, Pennsylvania
October 7, 1948

IN making photometric observations of the brightnesses of phosphors, many workers use electron multipliers and high sensitivity galvanometers. These galvanometers must have a linear response to the output of the multiplier; though this response has been checked initially, very small vibrations do upset the response, and one can do a great deal of work before suspecting the non-linear response. The fact that the suspension of a galvanometer swings freely does not mean that its response to signal strength is linear.

Luminous zinc sulfide deck markers provide a convenient means for checking the linearity of the electron multiplier and galvanometer. The writer uses a set of these markers varying in brightness from 9.0 to 0.30 microlamberts. The set has aged sufficiently so that the breakdown is very slow; weeks are required before a perceptible change in brightness occurs. The markers are also checked (for brightness in microlamberts) against radioactive foil-phosphor light standards. The latter undergo even a slower breakdown than the markers, since the radium exciting source is removed from the phosphor when the standard is not in use.

If the brightest marker is used as a secondary standard, the others may be calibrated in terms of it. First, filters of the proper neutral density are placed between the photocell and the standard marker to give a deflection of approximately 400 mm to 500 mm; the other markers are then observed and their brightnesses computed. The filters are then varied so that the second brightest marker gives the above deflection, and the other markers' brightnesses are computed, assuming the first observed brightness of the second marker. This proceedure may be repeated a number of times using successively fainter markers for the full-scale deflection. The observed brightness of a marker will then be independent of the scale reading, if the response of the circuit is linear.

Method of Linearizing the Voltage Rise of a Relaxation Oscillator*

R. J. Watts
Ohio State University, Columbus, Ohio
August 16, 1948

SOME recently described circuit techniques[1,2] suggest the application of the "bootstrap" generator to the relaxation oscillator in order to obtain a more nearly linear rise voltage. In Fig. 1 is shown a circuit which has been used

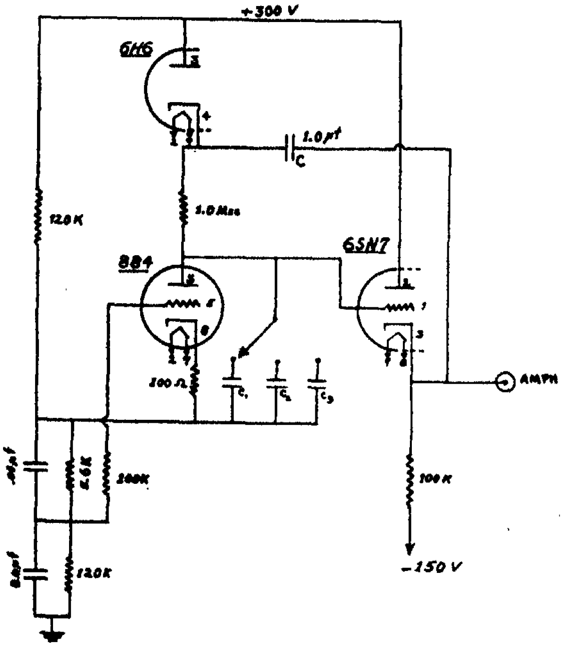

Fig. 1. Circuit for linearizing the voltage rise of a relaxation oscillator.

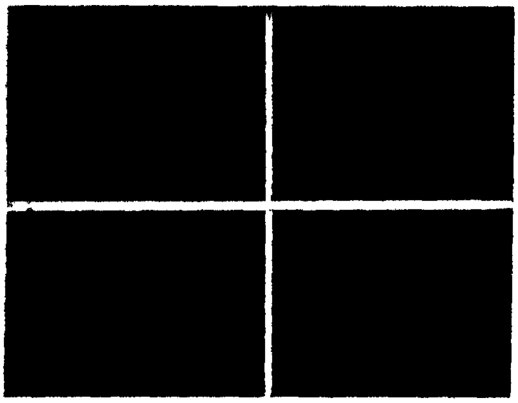

FIG. 2. Oscillograph traces of the voltage wave shapes. *A* is the wave shape of normal relaxation oscillator at 215 cycles/sec.; *A'* is the wave shape observed with circuit described at 215 cycles/sec. *B* is the wave shape of a normal relaxation oscillator at 5.4 kilocycles/sec.; *B'* is the wave shape observed with circuit described at 5.4 kilocycles/sec. (three complete voltage waves are presented in each case).

in this laboratory. In this circuit the "clamp tube" of the usual generator has been replaced by a type 884 thyratron.

The oscillograph pictures shown in Fig. 2 indicate the improvement over the normal relaxation oscillator at two frequencies. Part *A* shows the wave form of the voltage at the output as presented on a Du Mont type 241 oscillograph when the feed-back condenser *C* is disconnected from the cathode of *6H6*. With condenser *C* disconnected, the circuit operation is essentially that of a normal relaxation oscillator. The repetition frequency in this case was 215 cycles/sec.; three complete cycles are shown on the oscillograph trace. No detailed investigation of the linearity of the oscillograph sweep was made, but it was assumed that the central portion of the sweep most nearly approaches linearity. Part *A'* of Fig. 2 shows the wave form observed when feed-back condenser *C* was connected with repetition frequency unchanged. An estimate of the improvement introduced can be obtained by comparison of the central portions of the oscillograph traces. Parts *B* and *B'* show the corresponding results obtained when the repetition frequency was 5.4 kilocycles/sec.

A useful variation of the circuit may be obtained by biasing the thyratron in such a way that the cathode follower 6*SN7* is non-conducting for part of the cycle. In this case, one obtains a saw-tooth voltage with the teeth separated in time from one another by the time during which the cathode follower is non-conducting. The "off period" is useful if one desires to apply keying pulses to some associated circuit, such as those used in television systems.

If, in addition, the thyratron grid is also biased in such a manner that the tube is in a non-repetitive state, a single delayed sweep can be obtained by applying a positive pulse to the grid. The delay time is the time that the cathode follower is non-conducting. This delay time is limited by the useful sweep voltage.

The useful sweep voltage can be increased by the use of a push-pull output. A satisfactory push-pull output can be obtained by using the second triode of the 6*SN7* as a "gain of minus one" amplifier of the type described by Fitch and Titterton.[2]

High Temperature X-Ray Diffraction Techniques

J. J. LANDER
Bell Telephone Laboratories, Murray Hill, New Jersey

November 8, 1948

THREE types of accessories for x-ray studies of materials at high temperatures have been built, and these are sketched in Fig. 1. Accessories (A) and (B) are suitable for the study of materials maintained in high vacuums or controlled atmospheres, and (C) may be adapted for high vacuum but has been used with controlled atmospheres. In either (A) or (B) the incident and diffracted beams pass through strategically placed glass foil sealed to the surrounding glass tube. Since the furnace and containing glass envelope are simply attached to standard equipment (cameras or spectrometer), this technique results in certain simplifications compared with more conventional practice.

The unit (A) can be mounted on an x-ray spectrometer. The glass windows are approximately 1.5 mils thick and are bowed inwards. With CuK_α-radation the ratio of intensities of diffracted feature to background is almost as good as the best obtainable with the glass capillary technique. A range in 2θ of 90° is provided. The powder to be examined is spread on a platinum sheet which is held in the furnace by the thermocouple leads. Temperatures as high

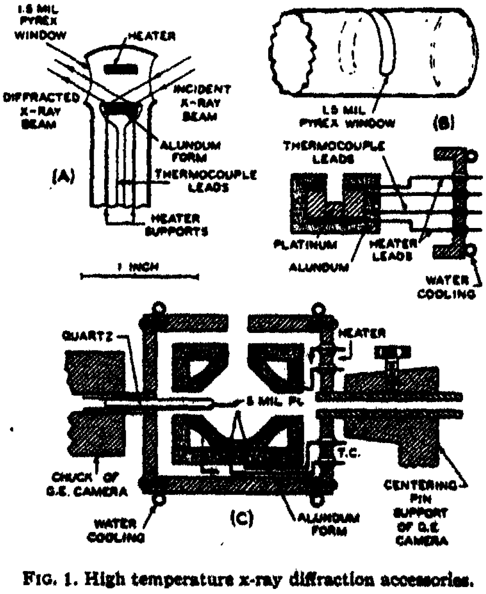

FIG. 1. High temperature x-ray diffraction accessories.

as 1400°C have been maintained and observed with an accuracy of about 5°C, if the coating is thin and adherent. With this accessory and an x-ray spectrometer the time between observations can be reduced to a few seconds. Thus, this technique is ideally suited to the observation of phase transitions and reaction rates, and we have studied the phase transitions of the alkaline earth carbonates in this way.

Materials in test electronic vacuum tubes and cold cathode tubes have been examined by constructing the tubes with opposing glass windows such as are featured in (A). Since the electrical characteristics of the tubes can be measured simultaneously, this technique avoids ambiguity which does result from the use of indirect methods.

Unit (B) is designed to provide a complete powder pattern. It is mounted along the axis of a standard powder camera. The powder to be examined is spread thinly on a wedge filed in a notch in a platinum rod, the ends of which are surrounded by the heater. The temperature of the powder is the more accurately observed, the thinner the powder and the deeper the notch in the rod and the surrounding heater elements. Under favorable conditions the specimen may be held at 1400°C and the temperature observed with an accuracy of about 5°.

Unit (C) is an adaptation of more familiar high temperature equipment.[1] However, the unit is mounted on standard parts of a standard camera. In the design of (C), high vacuums are sacrificed to provide for rotation of the specimen. The furnace design of (C) is also superior since the specimen is almost completely surrounded by heater, and the thermocouple junction is exposed to radiation in a fashion almost identical with that of the sample. Obviously, this feature can be built into (B) and a mechanism provided for rotating the specimen.

New Instruments

W. A. Wildhack: Associate Editor
in Charge of this Section
National Bureau of Standards, Washington, D. C.

These descriptions are based on information supplied by the manufacturer and in some cases from independent sources. The Review *assumes no responsibility for their correctness.*

Regulated Power Supply

A new regulated power supply for an output of 300 volts, 200 milliamperes, has been announced by the Howard Company. Regulation is obtained, within 1 volt, from 0 to full load and line variation from 105 to 125 volts. Ripple is less than 10 millivolts at full load with 115 volts input, and less than 25 millivolts between 0 and full load with line voltage variations from 105 to 125 volts. The supply is stable within 1 volt during long periods of operation at full load.

This power supply is designed to provide a stable source of d.c. for experimental set-ups and is suitable for continuous operation at full load in permanent installations. It is light, compact, and inexpensive, and can be supplied in the cabinet shown or panel mounted for rack installations. The unit measures 17″×10″×9″, weighs 28 pounds, and is priced at $89.00.—Howard Company, *934 Argyle Road, Drexel Hill, Pennsylvania.*

RCA Electron Diffraction Unit

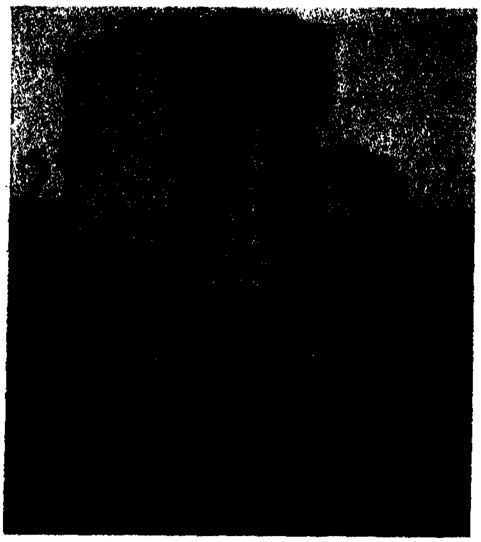
An electron diffraction unit developed by RCA to aid in observing and measuring conditions on surfaces or in thin layers of materials such as metals, ceramics, plastics, organic films, and biological materials, will permit chemical analysis of substances weighing as little as 1/28 millionth of an ounce.

Provisions are included in the instrument for producing electron diffraction patterns by either the reflection or the transmission method. The instrument will also produce shadow micrographs—an essential feature for examining the area of the specimen from which diffraction patterns are obtained.

The new instrument, which resembles RCA's universal model electron microscope in size and shape, consists of an optical system, power supplies, a vacuum system, and a control panel.

The optical system is comprised of an electron gun which produces the electron beam, an anode which accelerates the beam, an electromagnetic lens system to position and focus the beam, an object chamber which allows for introduction and manipulation of the specimen, a viewing screen to make the pattern visible, and a built-in camera to provide for photography of the pattern.

Through the correct choice of apertures and pole pieces, either extremely small illuminating spots may be obtained or wide areas of the specimen may be irradiated. Patterns may be focused by lenses either above or below the specimen.



Five external controls provide for positioning specimens up to 1-inçh square at any desired angle. A transmission specimen holder which takes six specimens on ⅛-inch disks of 200-mesh screen is provided, so that it is possible to carry at all times a calibration sample while unknowns are being studied. A beam stop is provided to reduce undesirable halation. A built-in, rock-steady camera is utilized for photographing the diffraction patterns on 4-in.×5-in. plates.

A power supply similar to that used in the electron microscope provides a 50-kilovolt d.c. supply for the diffraction instrument. The vacuum system evacuates the electron column from atmospheric pressure to an operating pressure below that indicated by 1 micron of mercury in only one and a half minutes. All metal vacuum lines and electromechanical valving are features of this system. A special control panel which provides for complete control of the equipment, a built-in charge neutralizer, and ports for accessories are also included.—Radio Corporation of America, *RCA Victor Division, Camden, New Jersey.*

Precision-Regulated D.C. Power Supply

A d.c. power supply with output voltage regulation better than 0.1 percent, and ripple less than 0.01 percent, is announced by the Hastings Instrument Company.

The precision-regulated power supply is adjusted by the manufacturer for optimum regulation at any specified load from 5 to 30 milliamperes, and for any output voltage from 0 to 100 volts. Regulation is thus obtained within ±0.1 percent for input line voltages varying from 75- to 135-volts a.c. at frequencies from 50 to 400 cycles per second.

Developed for use with instruments requiring highly stable d.c. voltages, the power supply is well suited for resistance thermometers, wire strain gauges, position potentiometers, and many other industrial and laboratory instruments. Because of its unusually low output ripple, it may be used with all types of recording oscillographs.

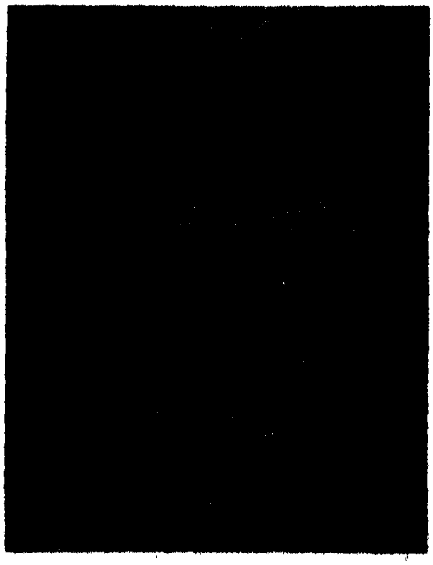
The unit pictured measures 4″×5″×6″ and weighs 6 pounds. It is well designed for laboratory use and is small enough to be readily adapted as a built-in power supply component for large instruments.

Power supplies designed on the same circuit principles for output voltages above 100-volts d.c., units for operation from other current supplies (i.e., 24-volts d.c.), and units having non-standard chassis construction are available on special order. The regular price is $50.00 f.o.b., Hampton, Virginia.—Hastings Instrument Company, Inc., *P. O. Box 1275, Hampton, Virginia.*

Toroidal Coils

Wound toroids ranging from ⅜-inch o.d. up are available from Lenkurt Electric Company, Inc., as an addition to that company's previous line of molded magnetic parts and assemblies. Cores of Permalloy or molded iron powder can be used as required.

Toroidal coils are supplied cased or uncased, impregnated or plain, tapped or not, with an inductance range up to 15 henries and Q as high as 300. Inductance tolerances as close as 0.1 percent can be met. Coils are available with two balanced windings or with a closely coupled secondary superimposed for impedance matching applications.

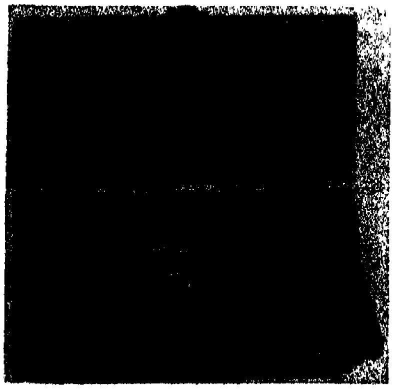


Space savings attained with these toroids range up to 75 percent over helical coils with the same parameters because of improved magnetic efficiency with minimum flux loss.

A few sizes of toroidal cores are molded by Lenkurt as well and are available unwound (up to 3 inches o.d.). Three standard powders are used with applicable frequency ranges: up to 90 kc, up to 5 mc, and up to 200 mc. For special requirements, however, these cores can be molded from any existing ferromagnetic powder.—LENKURT ELECTRIC COMPANY, *1121 County Road, San Carlos, California.*

Multirange Kilovoltmeters

Beta Electronics Company announces the Series 121 multirange kilovoltmeters, with full-scale ranges of 15/30 and 25/50 kv, at 50,000 and 25,000 ohms per volt.

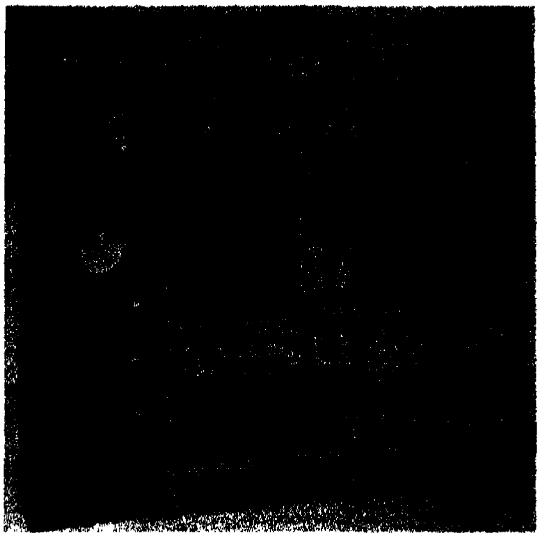


The input resistance on these voltmeters is constant on both ranges, giving a sensitivity of approximately 50,000 ohms per volt on the lower voltage range and 25,000 ohms per volt on the higher voltage range. The meter movement is 20 microamperes full scale and is shunted by proper resistors for the two ranges.

A Lucite safety handle is provided to permit connection of the voltmeter to the source of high voltage.—BETA ELECTRONICS COMPANY, *1762 Third Avenue, New York 29, New York.*

Continuous Hydrogenation Unit

High pressure, high temperature chemical reactions, such as hydrogenations, oxo-syntheses, and general organic syntheses of various sorts require specialized equipment. For general laboratory use, it is necessary that such equipment be compact, simple to operate, and flexible enough for diversified use.



Such a unit has been designed by Autoclave Engineers, Inc., to serve as a research tool or pilot plant for the study of high temperature and high pressure reactions.

The unit as shown consists essentially of two high pressure, high temperature reactors, one high temperature separator, one low temperature separator, two preheaters, feed pumps, valves and fittings, furnace and control equipment for proper operation at pressures to 15,000 p.s.i., and temperatures to 1000°F.

Instruments and control equipment consist of a pressure recorder and controller, multiple-point temperature recorder, two furnaces, temperature indicators and controllers, and six variable transformers for adjusting the flow of current to furnaces and preheaters.—AUTOCLAVE ENGINEERS, INC., *P. O. Box 110, Titusville, Pennsylvania.*

Magnetic Flux Meter

The Model 327 Smith magnetic flux meter provides a new, simple, complete means of measuring a.c., d.c., and transit magnetic flux densities, which eliminates the present search coil errors.

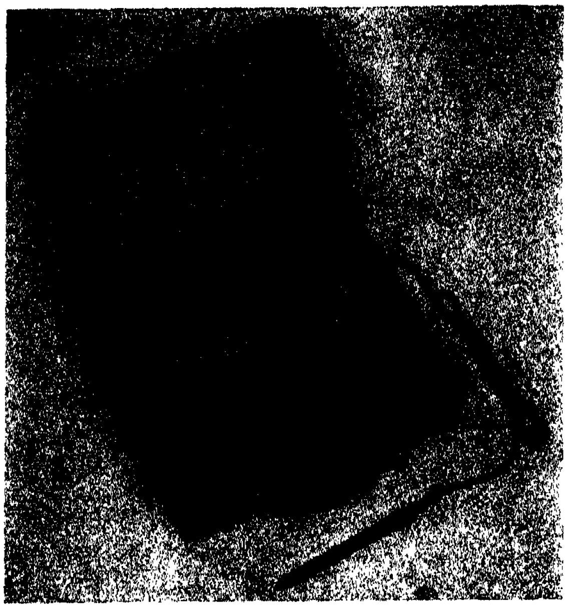
A small probe, thin enough to be readily inserted in the air gap of the average electrical machine, is used for measuring fields approaching a point area.

Probes can be supplied in special thicknesses to suit specific measurement applications.

Simplicity of operation is its outstanding feature.

The interchangeable probe contains a copper constantan thermocouple, and for very accurate results a temperature compensating formula can be applied. Turning the probe in the magnetic field indicates the direction of flux. The maximum reading is obtained when the probe spirals are perpendicular to the field.

Standard range: 0 to 26,000 gauss; special ranges are available. Calibrated accuracy: 1 percent. Connections are provided for oscillographic studies of flux.



A compact, 13½-in.×11-in.×5½-in. portable, its self-contained probes are interchangeable.—Associated Research, Inc., *231 South Green Street, Chicago 7, Illinois.*

Absolute Pressure Gauge

The absolute pressure gauge manufactured by Airplane and Marine Instruments, Inc., is a custom-calibrated instrument intended for use where precise measurements are required in the ultra-low pressure range. It is adaptable to metering in filling electron tubes, indication of pressures in test tanks and distillation chambers, measurement of condenser pressures, and general laboratory use. A and M welcomes inquiries as to its adaptability to other specific applications.

The instrument consists of aneroid-type capsules whose movement is transferred to a needle by suitable linkage. The principle is unique in that the measured medium is introduced into the inside of one capsule, and the movement of this capsule is opposed by an evacuated capsule. The resultant movement is utilized to position the pointer. The interior of the case is not evacuated, so only a dust-proof case is required. Rugged stops are provided to prevent damage should the instrument go off scale.

Accuracy is said to be 1 part in 500, with a sensitivity of 1 part in 1000. The scale diameter is 6 inches, and the scale length is 15 inches.

The following are available as standard ranges: Model 1001-50, 0 to 50 mm Hg; Model 1001-100, 0 to 100 mm Hg; Model 1001-200, 0 to 200 mm Hg. The scales for these ranges may be graduated as requested by the customer. Inquiries for special ranges are invited.—Airplane and Marine Instruments, Inc., *Clearfield, Pennsylvania.*

Pulsed X-Rays

A technique borrowed from wartime radar sets has provided the peak power flashes needed to make super-speed x-ray motion pictures.

Mr. Donald C. Dickson, of the Westinghouse Research Laboratories, recently stated at the National Electronics Conference that a special high voltage, radar-type pulse transformer and an electronic tube are key units in making exposures of 10 millionths of a second on x-ray film moving at 150 frames a second. The tremendous surges of high voltage power necessary to make these exposures are similar to the split-second pulses required to transmit radar signals.

The electronic tube is flashed at 150,000 volts, and the power during pulses exceeds 5 million watts. The tube used for x-ray movie work is a 14-inch long cylinder. This is immersed, along with the radar-type transformer, in an insulating oil bath and is placed 3 feet from the x-ray film.

In order to generate the type of x-radiations needed, it was necessary to heat the tube filament to a temperature where tube life would be limited to 15 minutes. At 150 frames a second, 135,000 individual radiographs could be taken, requiring more than 6 miles of 9½-inch wide film to record them.

For medical and other industrial uses, longer power surges, greater x-ray penetrations, slower exposures, and larger operating fields may be required.—Westinghouse Electric Corporation, *Bloomfield, New Jersey.*

Magnetic Test Set

A new type of test set for magnetic materials in laminar form is announced by the General Radio Company.

Measurements of permeability and core loss are made at 60 cycles and at low levels such as are encountered in inductors and transformers used in communication systems.

Test sample can be a single lamination or a few duplicate strips in parallel. Minimum length of sample is 2¼", maximum width is ⅜".

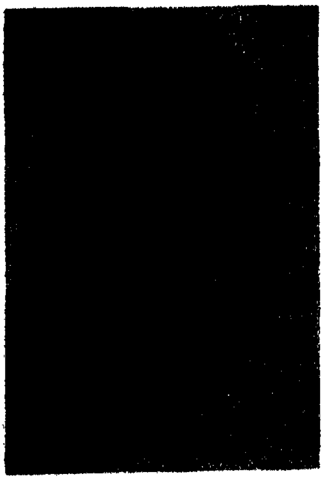
Measurements are made on a Maxwell bridge of the inductance and loss of a solenoid surrounding the sample, which is clamped in test yoke so designed that its reluctance is negligible compared to that of the sample.

The sinusoidal magnetizing force applied to the test sample is adjustable from one millioersted to six oersteds. A d.c. magnetizing force up to 2 oersteds can also be applied for incremental measurements. Permeability range is 25,000 full scale for a specimen cross section of 10 sq. mm, for which the dial reads directly in permeability.

Accuracy of absolute measurements depends upon the precision with which the specimen cross section is known. Similar samples of identical cross section can be compared with an accuracy of 2 percent.—GENERAL RADIO COMPANY, *275 Massachusetts Avenue, Cambridge 39, Massachusetts.*

Midget Meter

International Instruments announces the development of a midget meter, 1 inch in diameter, with a scale arc of 270°. This will provide a scale chord even longer than that obtainable on 3½-inch conventional meters.

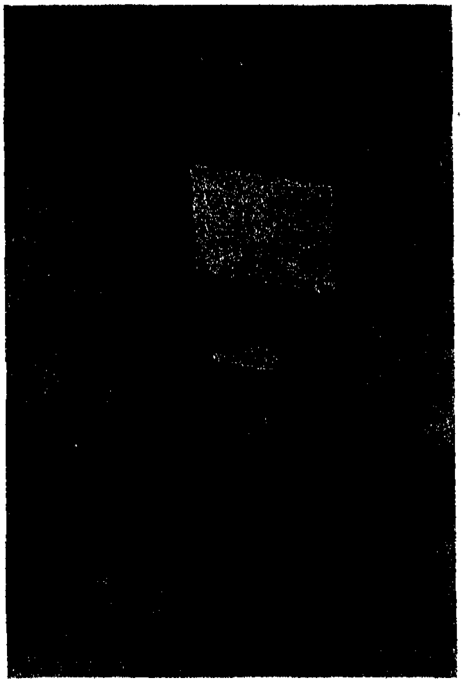


The 1-inch instrument is being developed for special uses in aircraft applications, where size and weight limitations are of prime importance. Other applications are anticipated by the manufacturer, to include radio and television fields, laboratory test equipment installations, and other instances where the use of miniature meters of high accuracy is required. Accuracy is stated by the maker as 2 percent. These midget meters operate on the same general principles as do the conventional D'Arsonval moving-coil types.

The meter is stated to be ruggedly constructed to withstand vibration and shock. The instrument can be made watertight and is designed to mount by means of a threaded ring.—INTERNATIONAL INSTRUMENTS, INC., *331 East Street, New Haven 11, Connecticut.*

Ion Chamber Charger-Reader

A new Model 2050 charger-reader, designed to be used in conjunction with pocket-type ionization chambers, is announced by the Nuclear Instrument and Chemical Corporation. The ionization chambers are used as health monitoring devices in the presence of gamma- or x-ray types of radiation.



The functions of the Model 2050 are twofold. It will charge the ion chamber to a known voltage, and it will measure the residual chamber charge after exposure to radiation. This 110-volt a.c. operated electronic voltmeter and electrometer will charge and read the nuclear Model 3340 diaphragm-type pocket meter, and, by rotation of a selector switch, the non-diaphragm type-pocket ion chamber can also be checked. All "charge" and "read" observations are made on a 3-inch meter with a linear scaler. Accuracy is ±2½ percent of full scale.

Operation of the 2050 is very simple. The regulating circuits will allow stable operation with an a.c. power variation of from 95 volts to 130 volts. The unit is housed in a smooth grey-finish steel cabinet 6″×5″×10½″, and provision is made for storing up to seven pocket ion chambers within the case cover.—Nuclear Instrument and Chemical Corporation, *223 West Erie Street, Chicago, Illinois*

Beta-Gamma-Scaler

The new Kelley-Koett beta-gamma scaler, Model K-280, is 22″×11″×15″ (deep) and weighs only 47 pounds. It was designed and developed for the precise measurement of radioactivity. It may be used for research work, for assaying of metals, and for many other research or routine counting jobs. Incorporated in the scaler are such features as a scale of 256, scale selector, autocount, and autotime. The scaler has a resolving time of 5 microseconds or better. The high voltage supply is continuously variable from 500 to 2000 volts, with regulation of 0.02 percent for 1 percent change in line voltage. The G-M input terminals are located on the front and rear of the scaler. A Highinbotham scaling circuit is incorporated in the Keleket scaler. A detailed bulletin containing a complete description, specifications, and illustrations will be mailed upon request.—Instrument Division, Kelley-Koett Manufacturing Company, Department B, *Covington, Kentucky.*

Vibration Meter

The new Calidyne vibration meter is designed to read vibration levels directly in r.m.s. inches or r.m.s. inches per second when used with the velocity pick-up made by the MB Manufacturing Company.

The vibration meter is a self-contained, battery-operated unit with internal calibration requiring no external power connection—thus offering the utmost convenience for field testing.

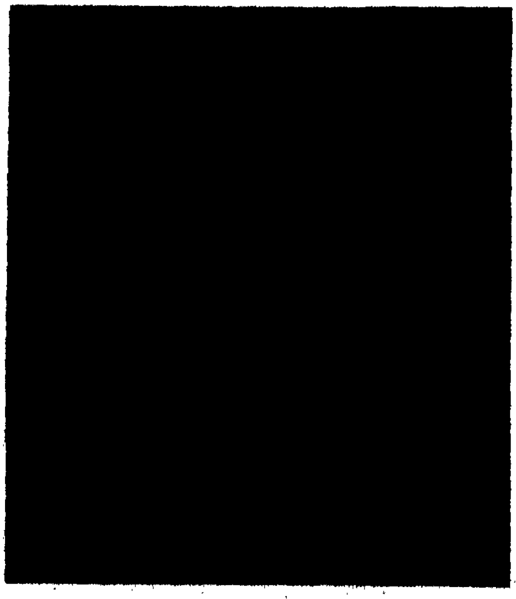
Integration of the velocity pick-up signal to provide displacement measurements directly is effected by throwing a switch. No scale factor or conversion is required.

The instrument is handsomely cased in walnut, is only 7×8¾×11 inches in size, and 14 pounds in weight. Range from 0.001 to 50 inches per second; 0.001 inch up for displacement. Price $350, f.o.b., Winchester, Massachusetts. —The Calidyne Company, *751 Main Street, Winchester, Massachusetts.*

r-f Z-Angle Meter

Another step ahead in speedy, efficient, accurate measurements of complex electronic circuits is announced by the Technology Instrument Corporation engineers with the presentation of the recently developed r-f Z-angle meter. Wherever this new instrument has been shown during the months of testing before its formal announcement to the electronics industry, it has been acclaimed for the way in which it provides direct reading of impedance and phase angle at radio frequencies.

The r-f Z-angle meter has been developed by the engineers who produced the Z-angle meter, which has found wide acceptance for measuring at audiofrequencies, the impedance and phase angle of loudspeakers, transformers, transmission lines, and complex networks without the need of extensive mathematical calculations. The instrument promises to provide the same ease of measurement, at radio frequencies, of broadcast antennas and transmission lines, and for general laboratory measurements which, heretofore, have been avoided because of the cumbersome equipment and calculations involved. The r-f Z-angle meter



is carefully engineered and produced to the exacting specifications which assure users of electronic measuring devices of a highly efficient and practical instrument.

Technical data, prices, and other information are available on request from the TECHNOLOGY INSTRUMENT CORPORATION, *1058 Main Street, Waltham 54, Massachusetts.*

Fatigue Tester

Accelerated fatigue tests by reverse bending at natural or resonant frequencies are obtained with this pneumatically operated fatigue tester. The pneumatic resonant principle is employed, and a relatively small air supply is required.

The fatigue tester consists of an air-operated fatigue motor, a telescope, a pressure regulator, and an air valve.

The test sample, which may be a material specimen or a finished part, is clamped in a holder. The free end is vibrated by air pressure through a tuned air column until the piece fails.

Samples with resonant frequencies between 50 and 300 cycles per second can be tested. Amplitudes of vibration up to 0.5 inch on the free end may be obtained. The specimen is vibrated under conditions which simulate the actual dynamic loading conditions, and, since the specimen is vibrated at its own resonant frequency, test duration is usually short.

The fatigue motor is made up of a holder in which the specimen is clamped, 2 small pistons which are easily attached to the free end of the specimen, and an adjustable air column. This motor operates from a compressed air supply of 20 lb. per square inch minimum pressure and requires approximately 20 cu. ft. per minute. The adjustable air column can be made tunable over a vibration frequency range of roughly 50 to 300 cycles per second, with the use of seven "trombones" provided with the fatigue tester.

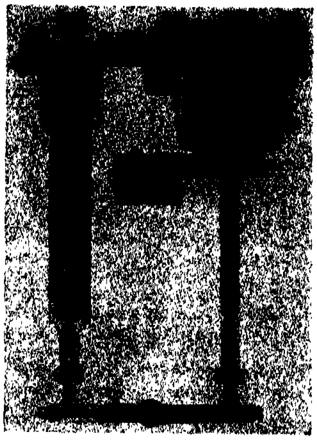
A telescope mounted on the fatigue motor is used to measure the displacement of the vibrating specimen directly in thousandths of an inch.

The pressure regulator maintains a constant air pressure on the fatigue motor up to 20 lb. and can be used for air pressure up to 90 lb. Since the power available from the fatigue motor is a function of air pressure, the pressure regulator is adjusted to the air system, to obtain maximum power. Generally, 20 to 30 lb. per sq. in. is sufficient to drive most specimens.

An air valve is supplied for insertion in the air line between the pressure regulator and the fatigue motor. This is used to control vibration displacement of the specimen.—GENERAL ELECTRIC COMPANY, *Schenectady 5, New York.*

High Accuracy Mercury Manometer

A new type of mercury manometer has been designed and built by the Taylor Instrument Companies to meet requirements of positive actuation, dependable performance, and greater adaptability in flow, liquid level, and differential pressure measurement. The new manometer is designated as Model 1500 to signify its 1500 p.s.i. working pressure and is available in differential pressure ranges of 10 to 400" of water. It is built for use on indicating, recording, or controlling instruments, and two manometers can be mounted on a single case for recording two flows or ratio flow control.



A few of its outstanding features include: (a) *Greater energy output* which is made possible by the use of a large diameter float and long float travel. (b) *Specially designed pressure tight bearing* of stainless steel with Teflon bearing surfaces—the new synthetic plastic whose self-lubricating characteristic assures no freezing, reduces friction to a minimum, and gives leak-proof performance. (c) *Positive overrange protection* is provided with positive-acting, non-sticking check valves submerged in mercury. These valves give protection against loss of mercury from overrange, sudden fluctuations, and flow reversal. (d) *Leakless damping adjustment* under full-rated pressure is assured with an uniquely designed damping device. (e) *Interchangeable range chambers* contribute greatly to the adaptability of the new manometer which now gives continuous ranges from 10 to 533" of water. No piping changes are necessary when changing from one range to another.—TAYLOR INSTRUMENT COMPANIES, *Rochester 1, New York.*

Piezoelectric Gauges

For those who need to measure pressures of "instantaneous" or "explosive" nature, piezoelectric gauges which will give faithful measurements of transient pressures varying from a few pounds to 30,000 p.s.i. are now available commercially.

The remarkable piezoelectric gauge, developed during the war under U. S. Navy contract, is now available for peacetime industrial and laboratory applications. The gauge works on the principle that when certain types of crystals are placed under sudden compressive stress, an electric charge is generated which is proportional to the stress. This charge can be measured and the stress computed, or indicated by suitable instrumentation.

Piezoelectric gauges are applicable only to rapid transient pressures or "explosive" pressure rises. They will not record slow pressure changes regardless of amplitude. Their usefulness lies in their ability to measure shocks of high magnitude when transmitted through liquids, gases, and, in some cases, through solids. Piezoelectric gauges were used to measure air and underwater pressure at the Bikini atom bomb tests. They are used in measuring "artificial earthquakes" set up in geophysical oil field exploration. They may also be used for such applications as measuring the explosive forces in the firing chambers of big guns and in the cylinders of internal combustion engines. The large gauge shown is for blast pressures in gaseous mid-air, and the small one is for underwater use.—Cambridge Thermionic Corporation, *Concord Avenue, Cambridge 38, Massachusetts.*

Earth-Shock Acceleration Detector

A new instrument which measures the intensity of explosion shock waves passing through the earth has been announced by General Electric's Special Products Division.

Called the "earth-shock acceleration detector," the new device is about the size of a small tin can. It is designed so that it can be buried near the scene of test explosions, enabling engineers to determine the underground velocity and acceleration of shock waves caused, for example, by the use of high explosives on large construction projects. The instrument can register shocks up to 1500 times the force of gravity, and as many as 10,000 impulses per second.

The acceleration detector contains crystals which generate a voltage when under stress. Signals from the crystals are carried through cables to amplifiers and delicate recorders above ground.

Four of the new instruments, recently used on the site of Watauga Dam, near Elizabethton, Tennessee, gathered data on what sort of shocks occur 130 ft. below a half-million pounds of high explosives. The explosions were set off by the Tennessee Valley Authority in constructing an earth dam.

These acceleration detectors are not stock items but are "custom built." In each different case, the specific design of the detector is determined by the individual application for which it is to be used. For further information contact the Special Products Division, General Electric Company, *Schenectady 5, New York.*

Manufacturers' Literature

Instrument Notes—8-page brochure, No. 5, Oct.-Nov. 1948, on temperature compensation of bridge-type transducers, describes methods of compensation for two types of errors caused by ambient temperature variations; it includes circuit diagrams.—Statham Laboratories, Inc., *9328 Santa Monica Boulevard, Beverly Hills, California.*

Technique—Vol. 2, No. 4, *Muirhead Journal of Instrument Engineering* features articles on phase displacement, variable air capacitor of zero loss angle, and screens and guard rings in electrical measurements.—Muirhead and Company, Limited, *Beckenham, Kent, England.*

Tracelog—12-page house organ, No. 13, features a description of the improved radiation survey meter, includes a list of more available C-14 tagged compounds, and other items of interest.—Tracerlab, Inc., *55 Oliver Street, Boston, 10, Massachusetts.*

The Experimenter—8-page General Radio bulletin, Vol. XXIII, No. 5, gives a complete description of a new coaxial connector for the laboratory, with cut-away photographs, sketches, and charts.—GENERAL RADIO COMPANY, *275 Massachusetts Avenue, Cambridge 39, Massachusetts.*

National Bureau of Standards, Washington, D. C.

Titanium

Titanium, one of the least exploited metals, is widely distributed as a minor constituent or impurity in many minerals and is the ninth most abundant of the elements, being 23 times as abundant as carbon. The fact that it is difficult to separate from its ores as a pure metal has kept it in the class of laboratory curiosities until quite recently, and little is known concerning the metallurgy and properties of its alloys. A successful method of refining it was developed by the Bureau of Mines recently, and it is now being produced in a ductile form by du Pont in a pilot plant having 100 pounds daily capacity.

It is a silver-white metal having a density of 4.5 and a melting point of 3140°F. Its yield strength is about 70,000 p.s.i. in the annealed form, and about 100,000 p.s.i. when cold worked. In the ductile form it is easily worked. Also, it has excellent corrosion-resistant properties. Tests have shown that, without protection it withstands atmospheric and salt-water corrosion better than most structural materials. In strength and corrosion resistance it compares with 18-8 chromium-nickel stainless steel, but weighs only about half as much per unit volume.

The use of titanium oxide, as a pigment in paints, and for certain other special applications, has been realized commercially during the past 20 years, but the possible industrial uses of the metal itself have not been explored. Enough is known to indicate that it can be used where a high strength-weight ratio is needed. An early major use may be in high speed planes. It may find applications in corrosion resistant equipment, particularly where heat and pressure are great.

Research on titanium metal and its alloys is being actively pursued by a number of organizations. It is now available in sponge form (99.5 percent pure) at a price of $5 per pound in 100 pound lots, and will shortly be produced in ingots. Mass production will, of course, make it possible to reduce the price sharply. The du Pont Company will supply small samples without charge to industrial and university laboratories for testing.—E. I. DU PONT DE NEMOURS AND COMPANY, *Wilmington 98, Delaware.*

Small Aluminum Tubing

A kit, containing an assortment of small bore aluminum tubing, has been made up for the use of instrument repairmen, to match the mass and inertia of instrument pointers which must be replaced. *3-S* aluminum alloy tubing in outside diameters of 0.0155, 0.019, 0.023, and 0.026 inch and *52-S* aluminum alloy with an outside diameter of 0.019 inch are included. Wall thicknesses are 0.0015 and 0.002 inch. The tubes are of convenient lengths and the kit contains a total of 25 feet of tubing.—PRECISION TUBE COMPANY, *3826 Terrace Street, Philadelphia 28, Pennsylvania.*

Castable Refractory

Firecrete 3x, a new castable refractory for use up to 3000°F, is supplied dry and mixed with water just before use. It may be cast or poured into wood or metal forms to produce special shapes such as burner blocks, door linings, covers, and complete furnace linings. The casting is air-cured for 12 hours and then heated slowly to a temperature above that at which furnace operation will be held. A cubic foot of construction requires 135 pounds of material. Shrinkage is said to be negligible.—JOHNS-MANVILLE SALES CORPORATION, *22 East 40 Street, New York 16, New York.*

Heat-Resistant Polystyrene

Koppers P-8, is a heat-resistant, low shrinkage, polystyrene molding compound made by a new process in which a close control is held over molecular structure. It is stated to mold as easily as the regular grades of polystyrene and to result in a glass-clear product. The manufacturer reports that it has a heat-distortion temperature of 204°F or better when tested in accordance with ASTM D648 and that when a molded piece supports only its own weight, short-time immersion in boiling water does not soften the material enough to warp it materially. Molded articles were unaffected by a 15-minute immersion in boiling water.—KOPPERS COMPANY, INC., *Chemical Division, Pittsburgh 19, Pennsylvania.*

Plastic Pipe

Light-weight plastic pipe, designed for working pressures up to 650 p.s.i. and temperatures up to 100°F, is now being produced on a commercial scale. Standard tees, ells, and joints can be used with this pipe. It is stated to handle a variety of fluids including water, organic solvents, alkalis, etc., as well as natural and manufactured gas. 3½ feet of the 1″ pipe weighs 1 pound. This pipe is now available in standard, heavy-wall pipe sizes from ½″ I.D. to 3″ I.D.—EXTRUDERS, INC., *8509 Higuera Street, Culver City, California.*

Thermosetting Adhesive Film

Scotch-Weld Bonding Film, is applied as a transparent film between surfaces to be joined. Pressures from 25 to 100 p.s.i. and temperatures from 300 to 500°F, for times from 5 to 60 minutes are used in bonding. In a test application, 0.064″ aluminum bonded to itself, was said to develop a shear strength of 3500 p.s.i. in the joint. Only conventional cleaning is required to prepare surfaces. The film is available in rolls of from ¼″ to 36″ width and in film thicknesses from 0.002″ to 0.008″. It is not tacky to the touch when removed from the roll.—MINNESOTA MINING AND MANUFACTURING COMPANY, *902 Fauquier Avenue, St. Paul 6, Minnesota.*

Ultra-Fine Abrasive Powders

Type A-5175 alpha-aluminum oxide has a hexagonal crystal structure and a hardness of 9 on the Moh scale. Its particle size is 0.3 micron, and its apparent density is 4 g/cc. *Type B-5125* gamma-aluminum oxide has a cubic structure and a hardness of 8. Its particle size is under 0.1 micron, and its apparent density is 3.6 g/cc. Both are suitable for metallographic or other fine polishing work and may be applied either dry or in slurry. Both are also suitable for use as ingredients in the manufacture of phosphors and as catalyst carriers.—LINDE AIR PRODUCTS COMPANY, *32 East 42 Street, New York 17, New York.*

Rust Preventive Wrapper

Nox-Rust Wrapper is a special kraft paper impregnated with a chemical which, on slow vaporization, passivates the surface of metal to prevent corrosion. The presence of the impregnant does not particularly alter the appearance or strength of the wrapper, and it is stated to be non-toxic and odorless. Its action does not depend on the package being sealed, and its stability is such that its protection is "for an indefinite period of time." The manufacturer reports tests which show complete protection to the contents of unsealed packages over a period of 45 days in a relative humidity of 100 percent at a temperature of 120°F. Since it does not require sealing and is effective on uncoated metals, it should offer considerable economies in packaging steel parts.

Samples and further information may be secured from the manufacturer.—NOX-RUST CHEMICAL CORPORATION, *2419 South Halstead Street, Chicago 8, Illinois.*

Lens Cleaner

Klr-Vu, a liquid cleaner for optical glass surfaces, is stated to leave an invisible film which gives long-lasting protection against fogging or frosting under severe conditions. The manufacturer also states that glass which has been treated with the liquid has measurably increased light transmission and remains clean considerably longer than normally.—SAX KLEEN COMPANY, *11 Bleeker Street, Albany 2, New York.*

Trochotron Design Principles

G. W. MONK* AND G. K. WERNER
Carbide and Carbon Chemicals Corporation, Oak Ridge, Tennessee
(Received July 23, 1948)

A simple derivation of the perfect focusing properties of the trochoidal type mass spectrometer, which leads to convenient methods of correlating the many variables for design purposes, is given. Nomographs and general trochoids are given which apply to charged particles in crossed, uniform, electric, and magnetic fields.

I. INTRODUCTION

THE perfect focusing properties of the crossed electric and magnetic fields of a trochotron were first pointed out by Bleakney and Hipple[1] who also described two small experimental units and gave a chart to simplify calculation of the focal distance of such an instrument. A much larger prolate instrument with a focal distance of 40 cm was built at this laboratory and described briefly by Monk, Horton, and Graves,[2] while more recently a 9-cm trochotron for low mass isotopic assay was also constructed here. All of these instruments demonstrated that the unique focusing properties of the trochotron are easily obtained in practice with moderately precise equipment.

Many of the following advantages of the trochotron were first pointed out by Bleakney and Hipple:[1]

(a) The focal distance is independent of the angle with which the ions enter the analyzing fields. This is true for all angles and means that only two precise slits are required, one to define the position of the source and the other placed at the focal point to limit the mass range received by the collector plate. If photographic detection is used, only the source slit is required.

(b) The focal distance is independent of the energy or velocity with which the ions enter the analyzing fields. This, in combination with (a) means that any of a great variety of sources can be used since any ions passing through the source slit will be focused at a distance dependent only upon m/e and the fields.

(c) For fixed analyzing fields the focal distance is proportional to m/e of the particle. If a photographic plate is used for a detector, the masses will be linearly spaced along the plate. This linearity also indicates that the trochotron has twice the resolution of a 180° instrument with the same focal distance.

The disadvantages are predominantly ones of size or mechanical consideration:

(a) The magnetic field must be maintained uniform over a larger region than in any other type of mass spectrometer of the same performance.

(b) A uniform electric field must be maintained over a relatively large region inside the vacuum tank.

(c) The focal point for a given m/e is not unique in that ions of different m/e may pass through that focal point on the way to their own focus, and negative ions of the same numerical m/e will be focused at the same point as the positive ions if they have enough energy to enter the analyzer. This difficulty is easily eliminated in a practical design.

(d) The number of variables which can take a wide range of values makes calculations of performance under various conditions somewhat more involved than with conventional instruments.

The motion of ions in crossed, uniform, electric, and magnetic fields has been studied, both neglecting[1,3,4] and considering[5,6] the relativity effect. The purpose of this paper is to present a simple method of demonstrating the focusing properties of such fields and give practical curves, nomographs, and equations as an aid to computation.

[6] W. R. Smythe, *Static and Dynamic Electricity* (Edwards Brothers, Inc., Ann Arbor, 1936).

Coggeshall[4] describes another arrangement having perfect focusing properties in which the magnetic field is uniform but the electric field strength is proportional to the distance from some axis along the magnetic field. No advantage over the uniform fields is apparent, however, and the difficulty of maintaining such an electrostatic field is great.

The term "trochotron" apparently was first used in a published paper by Monk, Graves, and Horton[2] but recently[7] was also applied to a vacuum tube in which the electron paths were trochoidal.

II. FOCUSING PROPERTIES OF CROSSED, UNIFORM, ELECTRIC AND MAGNETIC FIELDS

Consider a rectangular coordinate system oriented as shown in Fig. 1 with the origin on the ion of mass m, and charge e—at a time when its velocity is v—making an angle, θ, with the positive x axis. Relativity effects will be neglected and, unless otherwise specified, c.g.s.-electrostatic units will be used—except in the case of the magnetic field which will be measured in gauss and assumed large compared to the electric field E.

Instead of calculating the force exerted by the magnetic field on the particle as a result of its total velocity, v, consider two components of v, as shown in Fig. 2, so that one, v_A, is equal to Ec/H along the positive x axis.[8] This component is of such a magnitude and direction that the magnetic force, Hev_A/c, generated by it along the negative y axis, is just equal and opposite to the total electrostatic force, Ee. Thus the problem reduces to combining this uniform translatory motion with the motion that results from a velocity, v_P, in the magnetic field alone. Of course, if this v_P were the velocity of the ion in the magnetic field alone it would execute a circle in a time given by

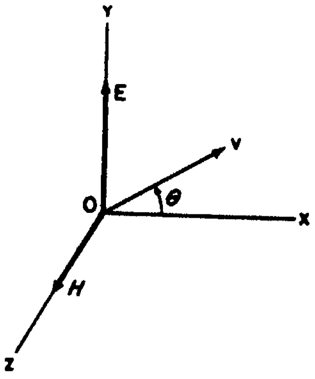

FIG. 1. Orientation of the axes with respect to the fields and the charged particle.

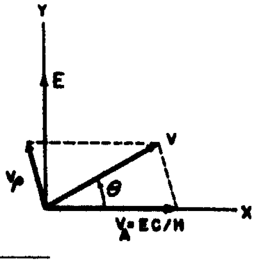

FIG. 2. Components of the initial velocity, v, that are used in the derivation.

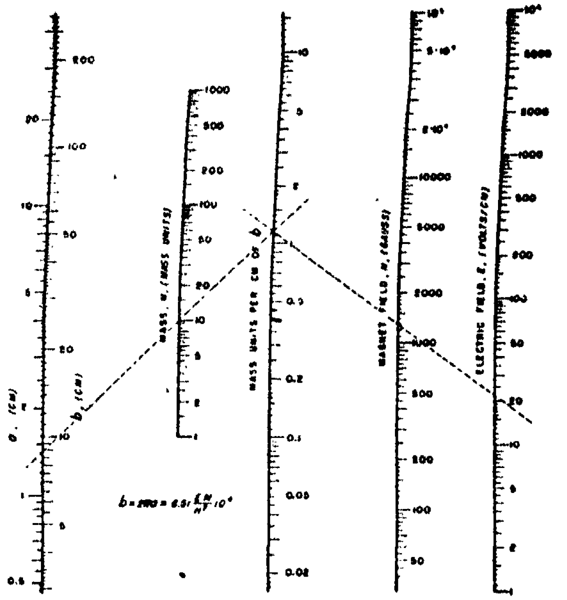

FIG. 3. Nomograph for correlating the variables in Eq. (4). The dotted lines show typical operating values of a trochotron having a focal length of 8.9 cm and receiving mass 10.

$$T = 2\pi mc/He, \tag{1}$$

which is independent of v and θ. At the end of this time the entire circle will be traversed and the translatory velocity, Ec/H, will have moved the particle along the x axis a distance

$$b = v_A T = 2\pi mc^2 E/H^2 e, \tag{2}$$

which is also independent of v and θ. *Thus the particle executes circles while simultaneously being carried along the x axis at a uniform rate, and the length of a cycle does not depend upon the angle or velocity with which the ion enters the fields.*

Such a path is trochoidal in shape and, if the translated circle is thought of as being carried along by a rolling circle, the latter must be assigned a circumference b and hence a radius

$$a = b/2\pi = mc^2 E/H^2 e. \tag{3}$$

However, the concept of a rolling circle can be very confusing because of the difficulty in locating the line along which it rolls for given initial conditions.

The value of v_P can be obtained easily from Fig. 2 by the law of cosines, and hence the radius, ρ, of

[8] A somewhat similar demonstration was used by W. G. Dow, *Fundamentals of Engineering Electronics* (John Wiley & Sons, Inc., New York, 1937), pp. 66–70.

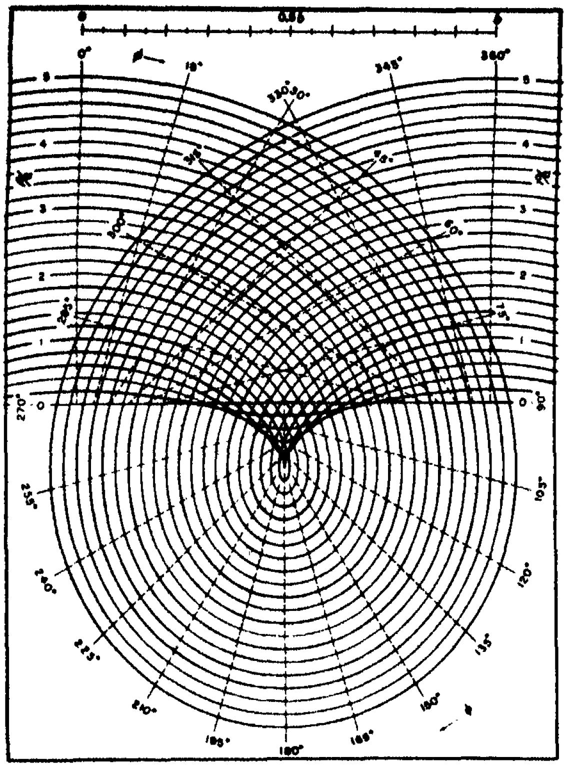

FIG. 4. General trochoids drawn by machine with the same b and difference values of ρ/a.

the circle being translated is calculable. If $\rho > a$, the path will be called a prolate trochoid; if $\rho < a$, it will be called a curtate trochoid; if $\rho = a$, it will be called a cycloid. This definition of prolate and curtate agrees with Bleakney and Hipple[1] but is reversed from that given by Page and Adams.[3,5] Actually the calculation of v_ρ and ρ is not necessary in determining the details of the path by means of the nomographs and charts to be given here.

III. USE OF THE NOMOGRAPHS AND GENERAL TROCHOIDS

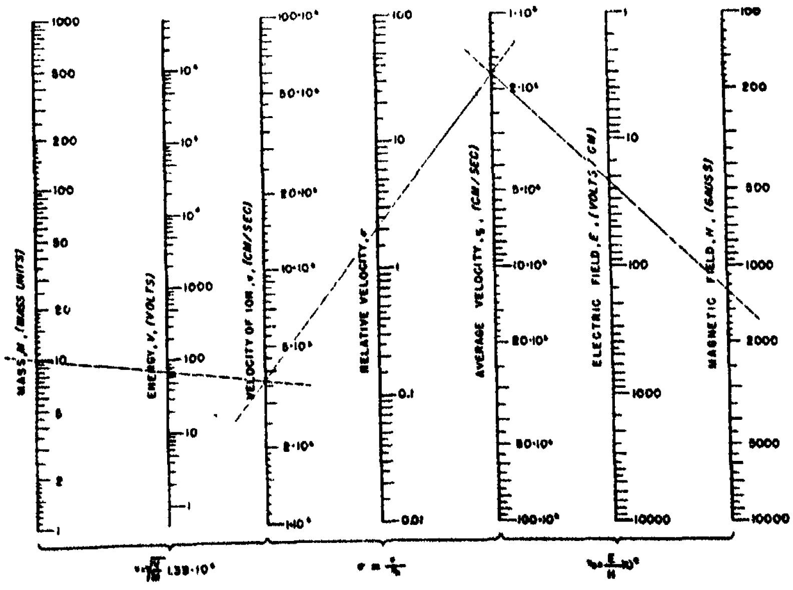
The focal length of a trochotron is given by Eq. (2), which can be written in the more practical form

$$b = 6.51(ME/H^2)10^4 \text{ cm}, \tag{4}$$

where M is the mass of a singly charged ion in mass units, E is the electric field in volts per cm, and H is the magnetic field in gauss. Figure 3 is a nomograph for correlating the variables of Eq. (4). Any two straight lines that intersect the center index at the same point connect values of b, M, E, and H that satisfy (4). The center index is calibrated in mass units per centimeter of b to indicate the "mass density" along the focal plane. The dotted lines show typical operating conditions for the 8.9-cm trochotron receiving mass 10.

General trochoids, drawn by machine with different values of ρ/a but the same b are reproduced in Fig. 4. It is intended that the starting point in this chart for given conditions be ascertained by the method to follow, tracing paper laid over the curves, and the proper trochoid sketched in, to give a scale drawing of the ion paths. To find the starting point, first find the ratio, σ, of the initial velocity, v, to the average velocity, v_A, by means of the nomograph given in Fig. 5. The dotted lines are for typical operating conditions in the 8.9-cm trochotron. Now using this value of σ and the given initial angle, θ, construct the triangle shown in Fig. 6 with the vertical leg one unit long. The angle ϕ will be the phase angle given in Fig. 4 and is determined by the fraction of b that the translatory velocity has carried the center of the circle, and is equal to the angle of rotation of the rolling circle. The manner of measuring ϕ in Fig. 6 has been adjusted to correspond to the way the trochoids were

FIG. 5. Nomograph for computing the ratio of the initial velocity to the average velocity.



constructed in Fig. 4. The side opposite θ in Fig. 6 will be equal to ρ/a. Now the trochoid corresponding to this ρ/a can be located on Fig. 4, and its intersection with the proper ϕ coordinate will determine the starting point at which the ion had the velocity v at an angle θ. Other points on the path have the same ρ/a, but σ and θ change as the ρ/a vector in Fig. 6 rotates clockwise. Sketch the curve in the direction of increasing ϕ up to $\phi=360°$. Then move the tracing so that this end falls on the same ρ/a curve at $\phi=0°$ and complete the cycle.

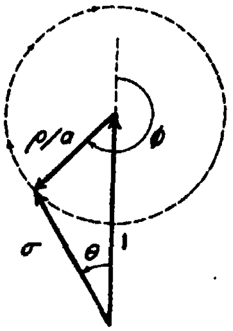


FIG. 6. Construction to allow the graphical evaluation of ρ/a and ϕ.

The y coordinate of the particle is equal to the y coordinate of the end of the ρ/a vector in the construction. The x coordinate of the particle is equal to the x coordinate of the end of the same vector plus ϕ (in radians).

The validity of this construction is easily shown by dividing each side of the velocity triangle in Fig. 2 by $v_A=Ec/H$. Lines of constant σ and lines of constant θ could be superimposed on the general trochoids of Fig. 4 to eliminate the need of any construction; this method was tried, but the result was found to be crowded and confusing.

The curves in Fig. 7 were traced according to the procedure outlined using initial conditions for the 8.9-cm trochotron. Curves 1, 2, and 3 are for the normal operating conditions indicated on the nomograph of Fig. 5 for an accelerating voltage of 75 volts and entrance angles of 75°, 90°, and 105°, respectively. Curves 4, 5, and 6 are for the same angles and mass but with an accelerating voltage of 100 volts. Curve 7 shows part of the path of an ion of twice the mass leaving the source normally at 75 volts when the electric field is one-half its value for the other curves.

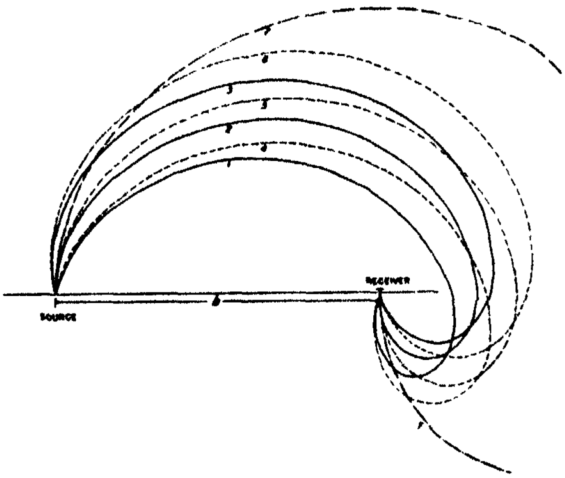

FIG. 7. Typical ion paths in a trochotron sketched from the general trochoids in Fig. 4.

The general theorem of Bleakney[9] is, of course, applicable to the trochotron and indicates that for particles of different e/m to follow the same path from source to collector tuning should be accomplished by varying either the magnetic field or the initial velocity in proportion to the electric field. In the case of the trochotron, this latter possibility implies that with a fixed angle of entrance the accelerating voltage could be varied proportionally with the electric field to avoid changes in the path of the received ion.

This document is based on work performed during 1947 under Contract No. W-7405-eng26 for the Atomic Energy Commision at the Carbide and Carbon Chemicals Corporation, Oak Ridge, Tennessee, and was released for publication on July 19, 1948.

THE REVIEW OF SCIENTIFIC INSTRUMENTS VOLUME 20, NUMBER 2 FEBRUARY, 1949

A Servo Employing the Magnetic Fluid Clutch

E. S. BETTIS AND E. R. MANN
NEPA Project, Fairchild Engine and Airplane Corporation, Oak Ridge, Tennessee

(Received August 13, 1948)

A simple servo unit is described. The device utilizes the electromagnetic fluid clutch developed by J. Rabinow of the National Bureau of Standards. Simplicity in design and construction, relatively high torque inertia ratio obtainable, and high power transmission capabilities appear to be the chief merits of such a servo system. Performance data on a prototype servo unit are submitted.

INTRODUCTION

SERVO-MECHANISM design is often a difficult process. The complexity of the process is increased when it becomes necessary to meet rigid specifications of performance and reliability. Hence, a laboratory not equipped to develop a servo system satisfying its unique application requirements must either adapt a commercially available unit, or rely upon servo development by a specially qualified organization. Excessive expense and lack of versatility are too frequently the results of these practices.

Utilizing the principle of the electromagnetic fluid clutch (developed by Rabinow at the National Bureau of Standards),[1] a prototype positioning servo unit has been constructed in the Controls and Instrumentation Section of the Air Force-Fairchild Engine and Airplane Corporation's NEPA Project in Oak Ridge, Tennessee. With this assembly, the applicability of the clutch to use in a servo mechanism has been studied, and preliminary determinations of its torque, response, driving speed, reliability, and other pertinent characteristics have been made.

In the electromagnetic fluid clutch, the air gap of a conventional magnetic coupling is replaced by a fluid having high magnetic susceptibility. Such a fluid is an oil base containing a suspension of fine particles of magnetic material, such as soft iron. The coupling efficiency of the clutch can thus be increased appreciably, and wide variations in transmitted torque can be obtained by means of a simple and continuous control.

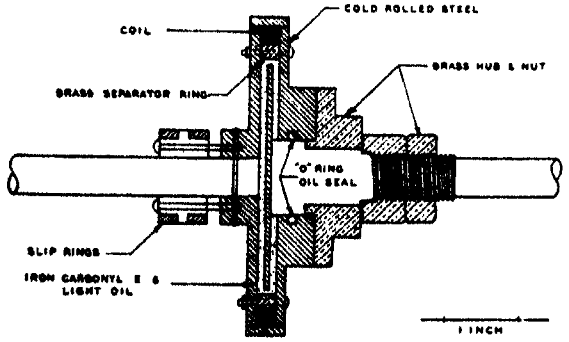

FIG. 1. Magnetic clutch.

Exciting coils for the electromagnet can be arranged in parallel to provide a low inductance electrical circuit. As a result, the exciting current can be varied quickly, producing a rapid response to a command signal.

The possibility of applying this clutch to the solution of a servo problem is apparent. Simplicity of design and construction is one of its more practical advantages. In an operational sense, proportional power transmission control is possible with a relatively weak signal, and the system possesses inherent charactoristics of high torque-inertia ratios, which offer short time responses. Advantage may therefore be taken of the system's momentum, to supply the peak power necessary for the rapid motion of large masses.

The prototype servo assembly noted above incorporates the simplest form of magnetic clutch mechanism. Clutch faces, consisting of cold-rolled steel disks, are arranged in such a manner that the surrounding fluid is energized by a single exciting coil. The fluid in current use is comprised of GAF carbonyl iron powder "*E*" suspended in light oil in proportions of three units of iron to one of oil by weight. Construction details of the clutch are shown in Fig. 1.

Control of the torque transmitted through the clutch is obtained by varying the exciting current in the coil, thereby changing, in a corresponding manner, the intensity of magnetization of the iron particles suspended in the fluid. Since these particles do not have the property of permanent mag-

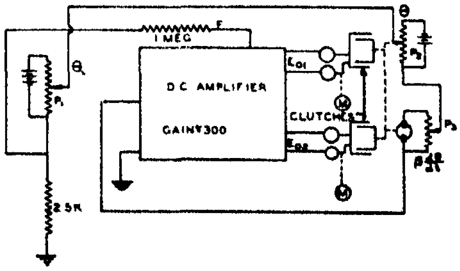

FIG. 2. Servo block diagram.

---

[1] Jacob Rabinow, United States Department of Commerce, National Bureau of Standards Technical Report 1213.

netism, the only torque transmitted between the clutch faces in the de-energized state is that caused by viscous drag in the fluid.

To provide forward and reverse motion, two contra-rotating clutch systems, with an intermediate power take-off, are utilized. Thus the direction and degree of motion may be chosen by energizing the corresponding clutch. The driven clutch faces are mechanically interconnected, with the result that the viscous drag of each balances that of the other. Motive power is provided by two quarter-horsepower electrical motors. An alternate arrangement might incorporate reverse gearing with a single motor.

A small d.c. derivative generator, connected to the output linkage, provides adequate damping of the system; accurate setting of the critical damping is accomplished by varying the generator output.

THEORY AND DESCRIPTION OF EXPERIMENTAL UNIT

A block diagram of the servo system is shown in Fig. 2. The operation of the servo as indicated by the block diagram is quite straightforward. The input to the d.c. amplifier consists of the sum of three voltages: (i) a voltage proportional to θ_i, the angular displacement of potentiometer P_1; (ii) a voltage proportional to θ, the angular displacement of P_2; (iii) a fractional part of the voltage $\beta(d\theta/dt)$ determined by the setting of potentiometer P_3, where β is the e.m.f. of the generator produced by an angular velocity of one radian per second. When the sum of these voltages is of the order of one volt with respect to ground, the amplifier output voltages Eo_1 and Eo_2 are equal to zero, and the servo is at rest position.

As shown on the diagram, potentiometer P_2 is connected to the servo-mechanical output, while P_1 can be rotated in any desired manner to introduce a displacement request signal to the system. The potentiometer P_3 is set to provide proper damping of the system from an equilibrium point.

If P_1 is rotated, the input voltage to the d.c. amplifier produces a signal at either Eo_1 or Eo_2, depending on its direction of rotation. This signal energizes one of the clutches, so that a change in the servo-mechanical output occurs. This change, by reason of the directly coupled potentiometer P_2, causes the voltage proportional to θ to compensate for the initial signal at P_1, and a new equilibrium point for the system is reached. The voltage $\beta(d\theta/dt)$ operates in the usual manner of a derivative signal, providing the equivalent of an anticipatory balance voltage proportional to the rate of change of the servo displacement, thereby preventing servo overshoot.

The connection "*F*" between the amplifier and the input circuit represents degenerative feedback for stabilizing the high gain d.c. amplifier. The schematic of the amplifier is shown in Fig. 3. The amplifier is extremely stable, and has caused no trouble in the numerous applications in which it has been used. The gain, without degeneration, is 1200. For the servo application this is degenerated to approximately 300, which provides ample sensitivity for the purpose.

The output of the d.c. amplifier is fed into 6AS7 tubes connected as cathode followers as shown in the schematic of the circuit. The bias on the followers places their operation on the linear portion of the characteristic curve. In the set-up used, each clutch has an overlap in exciting current, as the balance point of the amplifier energizes each with about 100 milliamperes. The linearity obtained by operating the 6AS7 tubes at this point is better than that experienced when higher bias with resulting lower clutch current is used.

The exciting coils for the clutches are scramble

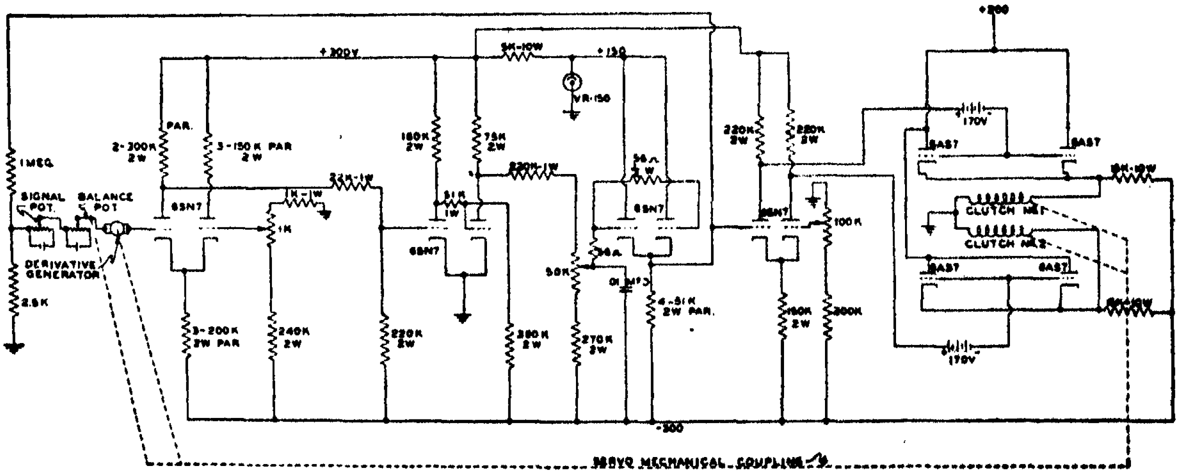

FIG. 3. D.c. amplifier schematic.

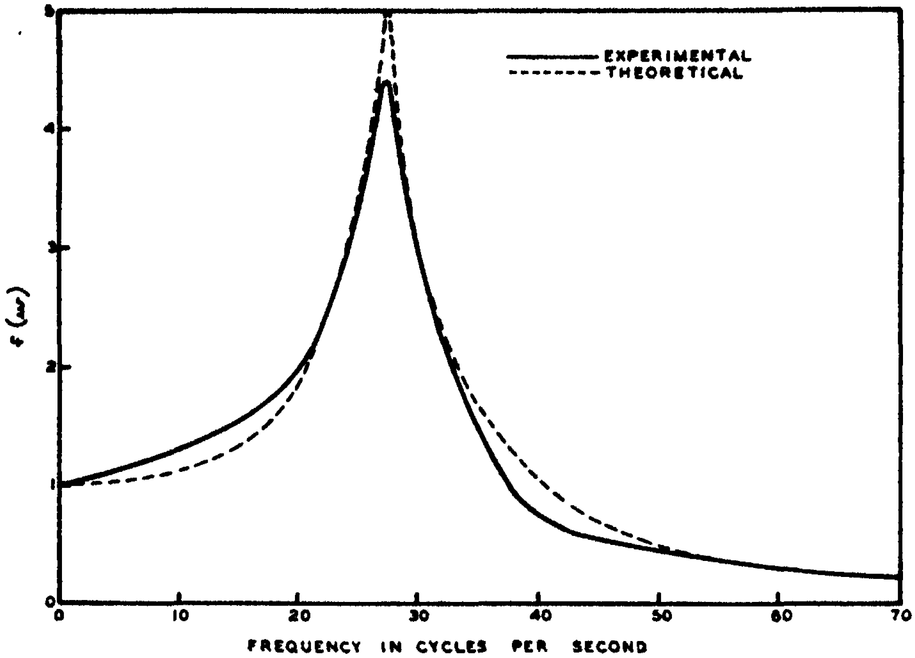

FIG. 4.

wound of No. 34 Formvar wire and have a d.c. resistance of 170 ohms. The inductance of the coils measured on a bridge at 1000 cycles is 0.13 henrys. These values do not necessarily represent optimum points. They are given only to indicate the design characteristics of the prototype servo.

The voltage impressed across the exciting coils ranges between zero and 75 volts as the input signal is changed. With an exciting current of the order of 500 mils, maximum torque is transmitted from the motor through the excited clutch. For values of exciting current between zero and 500 mils, the transmitted torque is proportional to the magnitude of the exciting current.

The differential equation for a damped servo system of the above type is

$$J(d^2\theta/dt^2)+K\beta(d\theta/dt)+K(\theta-\theta_i)=0, \qquad (1)$$

where J = moment of inertia, $\theta-\theta_i$ = angular displacement error, θ_i = requested angular position, K = gain of amplifier and clutch (in torque per unit angular displacement), and β = e.m.f. in volts of derivative generator produced by angular velocity of one radian per second.

If a sinusoidal voltage is used as a request signal, then

$$\theta_i=\theta_m \sin\omega t, \qquad (2)$$

where θ_m = amplitude, ω = angular frequency, and the differential equation (1) becomes

$$J(d^2\theta/dt^2)+K\beta(d\theta/dt)+K\theta=K\theta_m \sin\omega t. \qquad (3)$$

The solution of this equation for θ is

$$\theta=K\theta_m \sin(\omega t-\alpha)/[K^2\beta^2\omega^2+(K-J\omega^2)^2]^{\frac{1}{2}}, \qquad (4)$$

where α is the phase lag between θ and θ_i.

DISCUSSION OF PERFORMANCE

In Eq. (4) the factors K, β, and J represent servo parameters. These parameters were determined by rather indirect means, primarily because the moment of inertia, J, of the system was not known, and

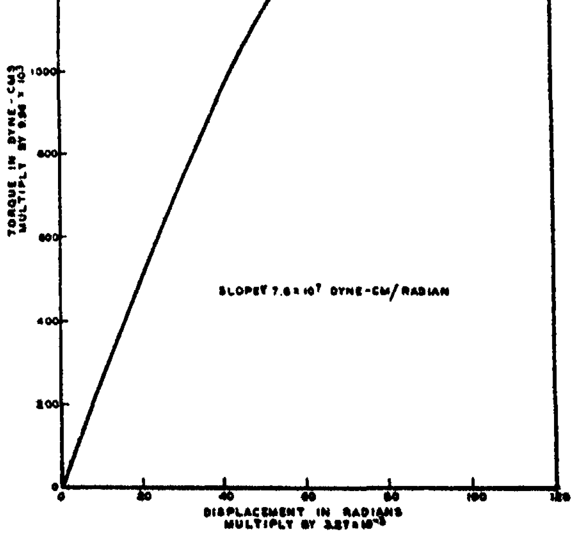

FIG. 5.

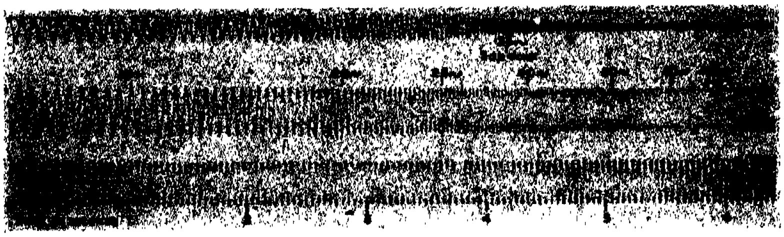

FIG. 6.

because the exact natural resonant frequency could not be determined directly. The frequency response, determined experimentally by driving the servo with an audio oscillator, gave the solid curve shown in Fig. 4. Here the peak amplitude does not occur at the exact undamped resonant frequency, but is shifted slightly below the resonance point. The magnitude of this shift is a function of the damping.

In the above equation, if it is assumed that θ_m is unity, the amplitude of θ can be expressed as a function of ω such that

$$f(\omega)=1/[\beta^2\omega^2+[1-(\omega/\omega_0)^2]^2]^{\frac{1}{2}}, \qquad (5)$$

where $\omega_0=(K/J)^{\frac{1}{2}}$ = resonant angular frequency of the system.

In Fig. 4, the dotted curve is a plot of $f(\omega)$ as a function of frequency for a hypothetical servo of identical type having the values $\beta=10^{-3}$ (i.e., 1 millivolt) and $\omega_0=182.1$, or $f_0=29$ cycles per second.

The close agreement between the two curves in Fig. 4 indicates that the parameters of the actual and hypothetical systems are for all practical purposes the same. Therefore, this value of $f_0=29$ cycles per second was taken as the undamped natural frequency of the actual system.

For the conditions $\beta=0$ and $\omega_0=182.1$, the denominator of Eq. (4) vanishes, and the quotient $K/J=\omega_0^2=33{,}160$. Either K or J must be determined in order to evaluate the desired parameters.

Figure 5 is a plot of torque (in dyne centimeters) *versus* angular displacement of the input signal potentiometer (in radians) for the servo system. Data for this curve were obtained by clamping a lever arm on the servo output shaft, and connecting a spring balance to this lever arm in such a way as to measure the stalled torque of the system. The input signal was introduced by rotating the input potentiometer in incremental steps and taking the resultant torque for each angular step of potentiometer rotation.

This curve is seen to be linear for values of torque output from zero to about 12×10^6 dyne-centimeters. Beyond this value, saturation of the amplifier output followers occurs, and the relationship becomes non-linear. Over the linear range, the slope of this curve gives the over-all gain of the system, K. This slope is determined (from the curve) to be 7.6×10^7 dyne-cm per radian. Substituting in the equation $K/J=33{,}160$ gives a value of $J=2300$ g-cm^2.

The frequency response oscillogram (Fig. 6) is self-explanatory. The bottom trace is a twenty-cycle timing wave, the middle trace is the sinusoidal input signal to the servo, and the top trace is the servo response. The input signal frequency was increased approximately uniformly by manually turning the frequency dial of the input signal generator.

Figure 7 is an oscillogram of the response of the system to a step request. A toggle switch was used to introduce a voltage step which demanded a rotation of 120° of the output shaft. The timing wave in this oscillogram had a frequency of 100 cycles per second.

CONCLUSIONS

Data obtained to date with the magnetic servo described above cannot be accepted as optimum for a family of such assemblies, yet they indicate the high degree of applicability of the magnetic clutch to servo use. In comparison to commercially available units, the magnetic servo offers relatively short response times. Perhaps the most important practical feature of the magnetic servo is its comparative simplicity of design and construction. This places servo development well within the reach of the average laboratory, using readily available tools in the hands of shop technicians.

One undesirable feature of the current magnetic clutch servo assembly has become apparent during experimentation. Because of the abrasive property of the iron-oil mixture, and resultant wear on bearing and sealing surfaces, some difficulty has been experienced in retaining the fluid with conventional

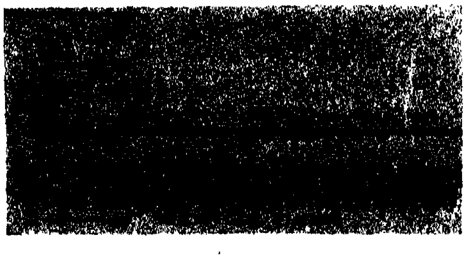

FIG. 7.

oil seals. Although preliminary experimentation has indicated that this effect is slight, its significance can be more rigorously determined during life tests of the assembly. This feature, if significant, may be eliminated through the use of improved seals or varied clutch geometry. Investigation of the problem of oil leakage is being continued, and various seals are being given extensive life tests.

The authors are indebted to Mr. G. R. Nelson, Mr. Lyle Martin, Mr. E. E. St. John, and Mr. J. B. Ruble of NEPA Project for development work on the prototype unit.

A method is proposed for the simplification of computers designed to solve certain types of partial differential equations. The equations are those in which the spatial derivatives may be replaced by finite difference expressions. The resulting difference—differential equations are reformulated as a system of linear simultaneous equations by making use of Laplace transforms and matrix notation is introduced. By applying a similarity transformation to the matrix a new system is obtained which lends itself more readily to the construction of an analog. As an example, the analog of the equation of the vibrating string with fixed ends is discussed.

THE electrical analog computer method for solving problems involving linear simultaneous algebraic or ordinary differential equations has received some attention in recent scientific and engineering publications.[1] This method is applicable also to linear partial differential equations since they may always be approximated by difference-differential equations.

The authors have been concerned with the development of an electrical analog computer to solve certain linear partial differential equations subject to special boundary conditions. The formulation is reduced to a linear difference-differential equation, after replacing the spatial derivatives by their finite difference equivalents. Operational units are then assembled in a manner dictated by the given equation. The differentiations and integrations with respect to time required are performed continuously by electronic differentiating or integrating amplifiers. Initial conditions are set in each element as proportional electrical quantities before the computing begins. Now it may happen that the analog will be somewhat simplified if a change of variables is made in the difference-differential equation before constructing the analog. If this new equation is then solved by analog methods, the solution of the original problem is known from the equation giving the new variable in terms of the old. Thus the analog yields not the solution directly but something bearing a known relation to it. A group of such transformations which will take a system described by a matrix equation with certain characteristic roots into another system with these same roots is the "similarity" transformation.[2]

Let us consider the solution of

$$F(y,y',y'',\cdots,y^{(n)})=a_1\frac{\partial y}{\partial t}+a_2\frac{\partial^2 y}{\partial t^2}+\cdots+a_n\frac{\partial^n y}{\partial t^n},\qquad(1)$$

where F is a linear function. This can be written in the form

$$F(y,y',y'',\cdots,y^{(n)})=L(p)y+K(p)\qquad(2)$$

by making use of Laplace transforms. Initial conditions are absorbed in $K(p)$. After replacing y', y'', etc. by their finite difference equivalents we have a system of equations which can be written in matrix form as

$$[A_{ij}]Y_j=L(p)Y_j+K_j(p),\qquad(3)$$

where $[A_{ij}]$ is composed solely of numbers. This might also have been written as one difference-differential equation. We call the analog for this system A_1.

Let us now apply to $[A_{ij}]$ a similarity transformation in the following manner. Between $[A_{ij}]$ and Y_j we can insert $[Q_{ij}][Q_{ij}]^{-1}$ without altering the equality. We next premultiply both sides of the equation by $[Q_{ij}]^{-1}$. The only restriction we need make on the matrix $[Q_{ij}]^{-1}$ is that it be non-singular. Then, letting

[2] C. C. MacDuffee, *Theory of Matrices* (Chelsea Publishing Company, New York, 1946), p. 69.

$$[Q_{ij}]^{-1}\cdot[A_{ij}]\cdot[Q_{ij}]=[B_{ij}], \tag{4}$$

$$[Q_{ij}]^{-1}Y_j=\tilde{Y}_j, \tag{5}$$

we have

$$[B_{ij}]\tilde{Y}_j=L(p)\tilde{Y}_j+\bar{K}_j(p). \tag{6}$$

If (3) gives rise to a stable solution, i.e., if the roots of the characteristic equation in the transform variable p do not lie in the right-half p-plane, then (6) is also stable, by the nature of the transformation. Consider the analog of this new system of equations, calling it A_2. It may happen that A_2 is more economically realized or easier to construct than A_1. To get the answer to the original problem, however, requires premultiplication of $\tilde{Y}_j$ by $[Q_{ij}]$. For a particular $[Q_{ij}]$ it may happen that this additional premultiplication is of a fairly simple nature, while the analog A_2 is preferred over A_1 for reasons of economy.

It might be pointed out that the transformed mathematical formulation may not appear to have any physical significance, but this need not affect the feasibility of building an analog for it.

Example: We shall consider the case where the difference-differential expression is of the form (the classical vibrating string problem)

$$X_{j+1}+X_{j-1}-2X_j-k\frac{\partial^2 X_j}{\partial t^2}=0, \quad j=1,2,\cdots n \tag{7}$$

and the boundary conditions $X_0=0$, $X_n=0$. Taking Laplace transforms,

$$\bar{X}_{j+1}+\bar{X}_{j-1}-(2+kp^2)\bar{X}_j=-p\bar{X}_j(0)-(\partial\bar{X}_j(0)/\partial t). \tag{8}$$

The stability of this analog may now be determined by investigating the eigenvalues of this set of equations.[3] In this case we are assured that the system is stable since it describes the particle-loaded string.[4] Note that on the left hand side of the equation quantities appear with both algebraic signs. An extra component will be required, in general, to change sign. Therefore it may be advantangeous to build an analog, not of Eq. (7), but rather of the following equation

$$\bar{\bar{X}}_{j+1}+\bar{\bar{X}}_{j-1}+2\bar{\bar{X}}_j+(\partial^2\bar{\bar{X}}/\partial t^2) =p\bar{\bar{X}}_j(0)+(\partial\bar{\bar{X}}(0)/\partial t). \tag{9}$$

This equation may be obtained by transforming the original matrix in the following manner:

$$\begin{bmatrix} 2+kp^2, 1, 0, \cdots \\ 1, 2+kp^2, 1, 0, \cdots \\ 0, 1, 2+kp^2, 1, 0, \cdots \\ \cdot \quad \cdot \quad \cdot \quad \cdot \quad \cdot \quad \cdot \\ \end{bmatrix} = \begin{bmatrix} 1, 0, 0, \cdots \\ 0, -1, 0, \cdots \\ 0, 0, +1, 0, \cdots \\ 0, 0, 0, -1, \cdots \\ \cdot \quad \cdot \quad \cdot \quad \cdot \end{bmatrix}$$

$$\cdot\begin{bmatrix} 2+kp^2, -1, 0, \cdots \\ -1, 2+kp^2, -1, 0, \cdots \\ 0, -1, 2+kp^2, -1, 0, \cdots \\ \cdot \quad \cdot \quad \cdot \quad \cdot \quad \cdot \quad \cdot \quad \cdot \\ \end{bmatrix}\cdot\begin{bmatrix} 1, 0, 0, \cdots \\ 0, -1, 0, \cdots \\ 0, 0, +1, 0, \cdots \\ 0, 0, 0, -1, 0, \cdots \\ \cdot \quad \cdot \quad \cdot \quad \cdot \quad \cdot \end{bmatrix}$$

where $[Q_{ij}]$ is now merely

$$\begin{bmatrix} 1, 0, 0, \cdots \\ 0, -1, 0, \cdots \\ 0, 0, 1, 0, \cdots \\ \cdot \quad \cdot \quad \cdot \quad \cdot \end{bmatrix}.$$

This corresponds to a desired change in the analog since a sign change is removed. The actual physical change corresponding to $[Q_{ij}]$ may be as simple as a polarity inversion created by adding or removing a stage of amplification. Since the analog solves for $\bar{\bar{X}}_j$, x_j must be found from the relationship

$$X_j=[Q_{ij}]\bar{\bar{x}}_j.$$

Although a group of acceptable transformations has been found, the particular one used in any given analog will depend on the economy it introduces and upon its mathematical complexity. This may call upon more than a little ingenuity on the part of the designer in finding the optimum relationship between an economical analog and an easily interpreted transformation.

---

[3] It has been demonstrated by Professor J. A. Krumhansl of Brown University that the solution of the difference-differential equation always converges to the solution of the partial differential equation it approximates.

THE REVIEW OF SCIENTIFIC INSTRUMENTS VOLUME 20, NUMBER 2 FEBRUARY, 1949

Exposure Meter for Precision Light Dosage

HERBERT F. LAUNER[*]
National Bureau of Standards, Washington, D. C.

(Received September 9, 1948)

The exposure meter is an electronic device of the type in which a photo-tube charges a capacitor to the firing voltage of a trigger tube, whose pulse is amplified by a thyratron. The device has been adapted to high intensity sources and is used for the regulation of carbon arc light dosage in the standardization of light-sensitive paper at the National Bureau of Standards. The device, including a modification for automatic extinction of the source when the desired light dosage is obtained, is described, and is shown to be capable of very high reproducibility. Two instruments simultaneously viewing a gradually aging monochromatic source gave count values whose ratios showed a coefficient of variation of 0.32 percent in two weeks of continuous measurement. One instrument, viewing a controlled tungsten lamp, showed a coefficient of variation of 0.18 percent in counts per watt hour over a period of nine days, after which the values changed—the result, presumably, of changes in the lamp.

The instrument was tested for suitability of application by comparing counts with reflectance changes of light-sensitive paper under arc exposure. The results showed that the instrument could control light dosage adequately in spite of large changes in arc voltage, glass filters, and time of exposure.

The instrument was used to test the variability of the uranyl oxalate actinometer, frequently used in photo-chemical work, by simultaneous exposure to a carbon arc. It was found that the actinometer was capable of higher precision than previous investigators had found, in that the coefficient of variation was 1.4 percent, less than ¼ as large as formerly believed.

I. INTRODUCTION

THE technique of precision light dosage appears to be a relatively unexplored field. It involves a device which totals the light, or more strictly, radiant energy, during an exposure, and allows the exposure to be promptly terminated, manually or automatically, when the desired quantity has been received.

The need for such a device arose in connection with the development and production, at the National Bureau of Standards, of light-sensitive papers,[1] used as controls for industrial testing arcs and for technological and scientific research. A carbon arc is employed as a master lamp to produce secondary comparison standards from the papers by exposure to standard light doses. This arc changes, principally because of small variations in controlled voltage, in cored carbon electrodes, and in the glass filter for excluding the far ultraviolet. For precision light dosage, a totaling device, usable over extended periods of time and responding only to the effective portion of the spectrum (near ultraviolet and visible violet blue) of the arc, was required.

Approximate totaling of light is frequently accomplished in photo-chemistry by obtaining the product of time × power, assuming constant behavior of the light source between the isolated radiometric measurements. This simple procedure usually meets photo-chemical needs, and can be considerably improved by continuous radiometric measurement using a recorder but, if applied to a carbon arc, is still incapable of giving immediate, precise values because of the necessity of integrating areas under the erratic power curves.

The ordinary type of thermopile is difficult to correct for the infra-red. The differential thermocouple, developed by Coblentz, Stair, and Hogue,[2] can be corrected to a considerable extent, and a differential thermopile with automatic filter changer was constructed for use with a recorder, but the arrangement was found to lack the required degree of precision.

Certain types of photo-tubes are spectrally suitable but are not constant when operated at a level sufficient to drive the most sensitive recording microammeters available at present, 0 to 10 microamperes, which, furthermore, are not precision instruments.

Another method of totaling light depends upon photo-chemical changes of pure substances or of standardized materials. Among the former, the uranyl oxalate actinometer, in which the photochemically decomposed oxalic acid is determined by titration with permanganate, has received the most intensive study as a laboratory device by Büchi,[3] Leighton and Forbes,[4] Forbes and Heidt,[5] Brackett and Forbes,[6] and for industrial applications by Werkenthin and associates.[7]

Although this actinometer is superior, for relative studies, to intermittent radiometric measurement, experimental evidence** establishing its precision as adequate for the present application is lacking; it is, furthermore, ill adapted for giving an immediate running indication of light totals.

In the class of standardized materials, the light-sensitive paper[1] previously discussed has found application as a relative light-totaling control without fixed standards, and is able to give a fairly prompt running indication, but it is not normally intended for high precision use.

For precise, immediate indication, electronic devices appear the most promising. The fundamental basis for one such device is a photo-tube which charges a capacitor to the firing voltage of a "trigger" tube, the pulse of which is amplified to operate an electromagnetic counter. Each count then represents a definite quantity of light, and the total count shows the total light received. Instruments of this type have been developed by Rentschler[8] and Kuper, Brackett, and Eicher,[9] among others. The latter estimated a precision of 1 to 2 percent for their instrument under laboratory conditions. Several commercial models of this type are available for photographic and similar purposes.

Another type of device recently developed by Gilbert[10] totals electric current over time intervals by utilizing the time period of a galvanometer relay actuating an electromagnetic counter. If the source of current is a barrier layer cell or thermocouple, light can be totaled in this way.

Douglas[11] has developed a device for use in atmospheric transmissometry, employing a circuit particularly promising for precision application. Several instruments of this type were constructed with the modifications required by the relatively intense arc to which they apply. In this form no data for precision or reproducibility were available.

The purpose of this paper is to describe the instrument used at the Bureau for predetermined light dosage of light-sensitive papers and to show its suitability for the purpose.

II. DESCRIPTION OF THE INSTRUMENT

The Douglas[11] transmissometer and instruments of like type were specifically designed for measurements at extremely low intensities, and are thus much too sensitive for the relatively enormous intensities involved in the present application. The radiant power, 1080 watts, of the arc to be controlled, is far higher than can be tolerated for reliable performance of photo-tubes, directly exposed, except at impractical distances. For example, using the unmodified transmissometer, the counting rate would be some 20,000 times too high. The optical and electrical changes, along with other features, necessary to adapt the instrument for the present purpose, are described in the following.

A. Optical

The light-sensitive paper, during standardization, is mounted at 25 cm from the arc on a drum rotating horizontally at 1 r.p.m. A position on this drum is a logical place for a receiver, which thus scans the arc from all angles and eliminates effects of arc asymmetry. At this distance the radiant intensity must be decreased some 400-fold to keep the photo-tube current below one microampere, even when allowing for a blue filter. The device for achieving this must be quantitatively unaffected by long exposures to intense light, at temperatures above 60°C in the presence of water vapor, and should preferably be spectrally non-selective from 300 to 490 millimicrons.

The use of metal screens is not practical because of their high transmissions, usually over 30 percent. Recently, Banning[12] has described the use of films of evaporated Chromel A, and has shown them to be almost non-selective in the visible. Although no data on stability are available, such films appear promising for applications of the present nature.

A simple and satisfactory reduction of intensity was obtained by using the first reflection of polished glass. Reflection from the second surface was eliminated by choosing a red glass of low transmission, <0.05 percent, for the wave band of interest. Since the reflectivity of one piece of glass is near 0.05, far too great for the purpose, two pieces were used at 90° from each other. The arrangement is indicated in Fig. 1, showing the receiver *R* mounted on drum *D*, which rotates around the arc. The photo-tube is inside the case near the "*R*," facing away from the arc. It views, through a Corning polished filter 5850, the lower piece of the 90° red glass double reflector, which in turn receives its image of the arc from the upper red glass. A piece of ultraviolet transmissive glass, Corning 791, keeps dust from the reflectors. The fraction of the incident beam coming from the double reflector varies somewhat with the refractive index of the red glass from 0.00258 at 303 millimicrons (calculated from the Fresnel expression, taking the angle of incidence at 45°) to 0.00224 at 486 millimicrons, thus producing a small spectral distortion in favor of the shorter wavelengths.

After passing through a Corex-D glass filter, the portion of the arc spectrum usually effective for

testing materials extends roughly from 290 to 490 millimicrons, with the principal maximum near 388 millimicrons. This region lies within the sensitivity range of the RCA 929 photo-tube, which—corrected with the 5850 filter—extends from 300 to 490 millimicrons with a median maximum near 385 millimicrons.***

B. Electrical

The circuit is shown in Fig. 2. It was developed by Douglas for this type of application and is considerably simpler than his circuit for the transmissometer,[11] notable differences being the use of the cold-cathode trigger tube**** instead of the neon tube and the use of the thyratron-operated electromagnetic counter without previous signal inversion.

The size of C_1, the silver-mica totaling capacitor, determines the counting rate inversely, and was made as large as physically convenient in order to obtain a desirable counting rate. As used, C_1 was 10^2 to 10^3 times larger than usual, and thus introduced uncertainty concerning the ability of the trigger tube to handle the unusually large discharge.

The exposure meter consists of a shielded, grounded receiver connected by a shielded cable to an amplifier counter. It is imperative that the components of the receiver be close together, connected by air-insulated conductors, to reduce the leakage that is usually too high in even the best of insulated cable. It is, therefore, not permissible, although it would often be very convenient, to separate the photo-tube from the trigger tube. Beyond the trigger tube, the effect of leakage becomes negligible.

C. Mechanical

(*1*) *Slip Ring Connection for Receiver*

The rotation of the receiver around the arc necessitated sliding electrical contacts. This was done by means of a polystyrene-mounted copper slip ring, *S*, and a copper graphite brush, *B*, shown in Fig. 1. The other side of the receiver circuit was grounded to the rotating drum, which was, in turn, grounded through a steel spring contact (not shown). Good contacts are necessary since any interruption in the circuit gives rise to spurious pulses. This arrangement has been functioning satisfactorily for two years.

(*2*) *Thermostating of Receiver*

Since the temperature within the receiver hovered near 50°C, the maximum permissible for the photo- and trigger tubes, cooling was necessary. Since, furthermore, the photo-tube output varies 0.3 percent per °C, positive control is necessary. The receiver frame was, therefore, provided with a water jacket and fed from an annular trough (not shown) mounted on top of the rotating drum, which received water maintained at a constant temperature. Thus, constant liquid contact was provided, and the temperature was controlled to within 0.5°C.

III. PREDETERMINED COUNTER

It was desirable to provide for the automatic extinction of the arc when the desired light dosage had been received. Devices for this purpose are commercially available but are very costly, usually require more power than simple counters, and some of them do not indicate the current light dosage.

By a few simple modifications of the electromagnetic counter† used in this work, the counter itself was made to extinguish the arc at any desired count. When all of the digit wheels indicate

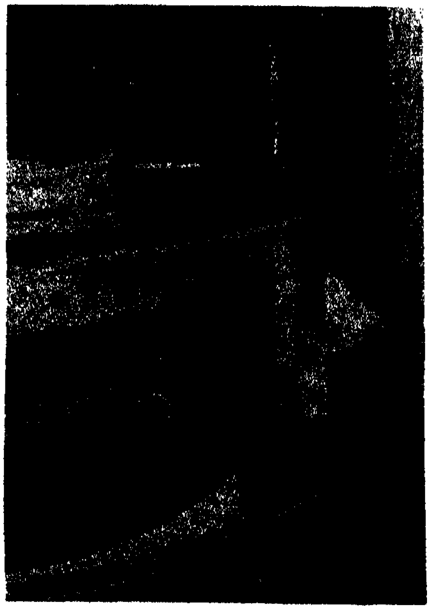

FIG. 1. Exposure meter. Receiver *R* is mounted on rotating sample drum *D*, thus scanning arc at 1 r.p.m. Pulses reach amplifier through slip ring *S* and brush *B*.

*** The photo-tube-filter combination has a very small response to red and infra-red. This was determined by interposing a piece of Corning 2404 glass, which transmits only red and infra-red, between the receiver and the arc. No pulses were recorded in the time interval normally giving 600 pulses. The same experiment was repeated with a tungsten incandescent lamp, arranged to provide some threefold higher infra-red intensity, under which conditions 1 pulse was recorded through the red glass compared to 600 without.

**** The trigger tube, known as the WL-759 Glow Relay Tube, was purchased from the Westinghouse Co., Bloomfield, N. J. as being specially selected for constancy of performance over the anode voltage range 245 to 270 volts. Its characteristics have been studied by W. B. Nottingham, Rev. Sci. Inst. 11, 2 (1940).

† Wizard counter, model EC-7 made by Production Instrument Company, Chicago, Illinois.

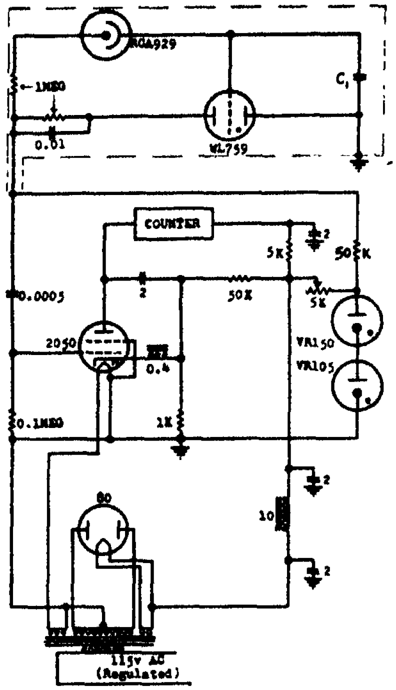

FIG. 2. Circuit diagram of exposure meter. C_1 is the totaling capacitor (must be silver-mica type) whose size determines the counting rate. For the present application it was 0.025μf. The two 5*K* and the 50*K* resistors are rated at 10 watts. The current through the *VR* tubes is adjusted to 20 m.a. The counter is a Wizard model EC-7, rated at 115 v d.c., made by Production Instrument Company, Chicago, Illinois. *Other counters of similar load characteristics will answer* the purpose, but may require some changes in circuit constants. A ¼-watt neon lamp (not shown) is in parallel with the counter and its 5*K* resistor, thus furnishing a visual indication of each pulse. A switch in series with the counter has also been found very convenient. The 2-μf capacitors are of the type Cornell Dubilier TLA6020. Power transformer and 10-henry choke are Halldorson L66 and B4-839 products. Any 0.4-henry choke will suffice, and often a 100-ohm resistor may be substituted.

nines, one more count moves all wheels to zero simultaneously. By placing a lifting cam on the extreme left wheel a small switch was made to operate on the last count. The cam consisted of a thin finishing nail with a rounded polished head, and the switch was made of two 8-mil phosphor bronze spring strips, 4×30 mm, mounted on Bakelite. This switch has been handling its load of 40-ma a.c. satisfactorily.

In the commercial counter the digit-wheel shaft is notched for the width of all the wheels, so that the latter may be simultaneously, but not singly, turned to zero. This shaft was replaced by one 1½" longer, with a notch the width of only one wheel at 1¾" from the left end. By sliding this shaft laterally, each wheel may be turned separately to set up any desired number. To eliminate groping, the left end of the shaft indicates the position of the notch on a marked glass tube placed over the protruding end of the shaft to exclude dust.

Operation of the switch on the desired number is secured by setting up the complement, minus one, of the desired number. For continued use it was desirable to cover the digits with bandage tape, stamping numbers in the reverse order thereon. It is thus a simple matter to turn up the desired number on the wheels. In operation, the counter uncounts, showing, at any time, the counts still needed to reach zero, whereupon one more count extinguishes the arc. In the present application this was done by breaking the holding coil circuit of a manual reset switch. The counter in its present form requires appreciably no more power than normally and is interchangeable with the conventional type.

IV. VARIABILITY OF THE EXPOSURE METER

The variability of the instrument may be expressed as the variation in counts for a given quantity of light received.

No high precision reference method of measuring and totaling light quantities was available, but variability may be determined with a constant tungsten incandescent lamp, measuring time or electrical energy input *versus* counter values. An entirely different method of determining variability consists of two instruments viewing the same monochromatic light source, which need not be constant in output. The results using these two methods are described in the following.

A. Test with Controlled Light Source

A tungsten incandescent lamp, in an arrangement described in footnote (a), Table I, was used as light source in combination with a blue glass filter, Corning 5850.

TABLE I. Test of exposure meter with a constant light source.[a]

Mean[b] power input[c] to lamp watts	Mean[b] counts per watt hr.	Mean[b] counts per minute[d]
507.5	6.052	51.20
508.8	6.042	51.24
508.9	6.044	51.27
508.2	6.043	51.18
508.4	6.031	51.10
508.0	6.044	51.17
507.9	6.062	51.32
508.3	6.062	51.36
508.1	6.062	51.33
508.8	6.010	50.96

[a] The light source was a 500-watt, 115-volt tungsten incandescent airport beacon lamp operated at 110 volts from a 500-watt Raytheon voltage stabilizer. To avoid a conventional socket, the prefocus base of the lamp was securely soldered into a brass tube, itself rigidly mounted with respect to the receiver at a distance of 62 cm. The leads to the lamp terminals were soldered. The equipment was housed in a temperature- and humidity-controlled room, with due precautions to avoid stray light. During dark periods the stabilizer was kept at equilibrium operating conditions with a dummy lamp of equal rating. The source was always burned at least ½ hr. before measurements.

[b] Each of the ten values is the mean of ten individual runs. These 100 experiments lasted ten days.

[c] Power input was calculated from energy input, measured with a certified G.E. standard watt-hour meter, model IB10 to the nearest 0.01 watt hour.

[d] Time was measured with a stopwatch to the nearest 0.2 sec. The experiments lasted 10 to 26 minutes each.

Ten continuous series of ten experiments each were performed with a dark period, either overnight or ten minutes, between each series. The quantities measured were counts, time, and energy input to the lamp in watt hours, noting lamp voltage once each experiment, which lasted from 19 to 26 minutes, to give 1000 to 1400 counts. From these quantities were calculated the watts, the counts/watt hr., and counts/min.

The means of each series of ten experiments are given in Table I. The first nine mean values for counts/watt hr. and counts/min. indicate a high precision and constancy for the exposure meter over a period of 9 days, with coefficients of variation[††] of 0.18 and 0.17 percent, respectively. Within each individual series the coefficients of variation were, for counts/watt hr., 0.48, 0.57, 0.46, 0.42, 0.34, 0.40, 0.43, 0.31, 0.39, and 0.46 percent, in the order of Table I. The voltages within a series varied by 0.3 to 0.4 volt. The 10th mean values show a deviation from the first nine. It was of interest to determine the direction of any further deviations, and the experiments were repeated three weeks later.

Mean of ratios: 1.9502.
Coefficient of variation: 0.32 percent.

[a] Two receivers were rigidly mounted, as close together as possible, at 175 cm from a 400-watt, type H-1, mercury vapor lamp, also firmly mounted on the same soapstone slab. A light-tight ventilated box over the lamp prevented stray light. All but the middle 76-mm portion of the arc was normally masked, although in another series of experiments the unmasked portion was only 12 mm. The light emerged from the box through Corning filters 5850 and 3389, absorbing all but the 436-mμ line and some red and infra-red lines to which the response was negligible. The lamp was operated at constant voltage to avoid erraticisms in the gradual decrease of intensity through lamp aging.

[b] "Time" and "Counts per hr." are not used for the determination of the ratios but are given as guides. The latter indicate the gradual aging of the lamp and were calculated for meter No. 1.

The next 100 runs gave results as constant as before but the average counts/watt hr. was 5.936, 1.8 percent lower than before, whereas the wattage input increased by only 0.05 percent. After this second series of 100 runs, the next 20 runs resulted in an average of 5.896 counts/watt hr., another decrease of 0.7 percent. The cause of this large change lay either in the lamp or in the receiver[†††] or both. It should be pointed out that the lamp was used much more drastically than corresponds to the usual radiometric practice, and, therefore, these results might be regarded as tentative.

Although it had been hoped to develop, in this manner, a fairly reliable, simple method for checking the performance of such instruments, it is apparent that this procedure must be used with caution and that a comparison against specially designed standard incandescent lamps, operated with all possible precautions (including the measurement of color temperature), is required at intervals of approximately two weeks, for precision over long time periods. For the present application, such refined checks are to be carried out by the Photometry and Colorimetry Section of the Bureau.

B. Test with Two Exposure Meters

If a part of the change noted in the last section arises from variability of the exposure meters, this should manifest itself when two instruments are viewing the same monochromatic source. If an instrument always gives a certain number of counts for a given quantity of light, then two reproducibly functioning instruments should maintain a constant *ratio* of counts, even if the intensity of a monochromatic source is changing. However, if two instruments do *not* maintain a constant ratio, one or both must be varying. It is the fact of such variation which it is desirable to establish, and for which the following experiments (Table II) were planned.

Two receivers viewed a monochromatic source in an arrangement described in footnote a, Table II. The ratios of counts given in column 5, with a coefficient of variation of 0.32 percent, in fair agreement with the results in the foregoing section using a different method, show that the two instruments functioned reproducibly with respect to each other over a continuous period of almost two weeks (terminated by a thyratron failure), in spite of the extensive decrease in intensity of the lamp by aging,

---

[††] Coefficient of variation, percent $= 100s/\text{mean}$, where $s =$ standard deviation $= [\text{sum of (deviations)}\ 2/(n-1)]^{\frac{1}{2}}$.

[†††] The amplifier of the instrument was checked for itr pulse-counting fidelity by parallel operation with anothes amplifier, and found to be perfect for many thousands of counts. Furthermore, minor changes in *VR* tubes were noted, but changes of 5 to 10 percent in voltage on the particular trigger tubes were found to have negligible effect.

TABLE III. Comparison of exposure meter results with reflectance change of light-sensitive paper under various arc conditions.[a]

Exp. No.	Type of filter[b]	Arc volts[c]	Exposure time hr.	Counts[d]	Change in reflectance[e]
	Experiments excluding short ultraviolet				
1	New Corex-D	42.5	13.7	18823	0.202
2	Old Corex-D	42.5	15.4	18823	0.200
3	Old Corex-D	43.5	15.0	18823	0.197
4	Old Corex-D	40.0	18.1	18823	0.198
5	New Pyrex	42.5	14.0	18823	0.196
6	Old Pyrex	42.5	14.3	18823	0.197
	Experiments including short ultraviolet				
7	Corning 791	42.5	14.2	18823	0.276
8	No filter	42.5	13.6	18823	0.396
9	Corning 791	42.5	9.5	12654	0.210
10	No filter	42.5	3.7	5111	0.203

[a] The changes in conditions given in this table are much more extreme than ever obtained in practice. See footnotes b and c.

[b] The new filters were completely unused; the old filters had been used approximately 4000 arc hr. Neither would be used in practice. Ordinarily, a filter is allowed to burn-in 100 hr. and is discarded after 2000 hr. From these data, for the particular samples used, it appears that Pyrex is the more resistant to solarization. Pyrex, Corex-D, and Corning 791 ("high-silica") differ principally in their ascending order of ultraviolet transmission, the last having a cut-off near 220 mμ. The ultraviolet differentially transmitted by the first two glasses, especially when new, occurs in the region below which the photo-tube-filter combination is sensitive and explains the slightly higher reflectance changes in experiment 1. For the same reason it was not expected that experiments including short ultraviolet would give valid results. The values were included to show the extent of departures in reflectance (experiments 7 and 8) when the counts were used as a guide, and in counts (experiments 9 and 10) when reflectance was used as a guide.

[c] The arc voltages are the mean values for each run, taken from a recording voltmeter curve. Since the voltages were measured at the electrode holders, they include the *IR*-drops along the electrodes. This amounts to approximately 3.6 volts, which must be subtracted from the values in Table III to give true arc volts. These voltage differences between experiments 2, 3, and 4, or even between 2 and 3, 2.3 percent, are much larger than may be expected in practice, since the primary voltage is controlled by a mechanical regulator operating over a band width of ±0.5 percent.

[d] Exposure to a given number of counts corresponds to the usual practice.

[e] Changes in reflectance were obtained by measuring the reflectance at 45° from normal incidence, for 578 mμ, near the wave-length of greatest change, before and after exposure. For further details see references 1 and 13.

as indicated in column 6. This is evidence that the instruments were individually constant in operation, inasmuch as systematic variations necessary to give fortuitously constant ratios are improbable in view of the complexity of the electronic processes.

The experiments were repeated a number of times under a variety of conditions: (1) the receiver circuit was operated from very constant B-batteries instead of rectified a.c.; (2) the totaling capacitor was changed from 0.025 to 0.0005μf, thus decreasing the size of the electric pulse fiftyfold; (3) the diaphragm opening limiting the size of the arc was decreased from 76 to 12 mm, thus improving the geometry of the arrangement considerably; (4) the receivers were accurately thermostated; (5) the photo-tubes†††† were replaced by others of the same type; (6) the receivers and lamp were more rigidly mounted on a steel beam instead of a soapstone table top; (7) the counting rates were increased fivefold. None of these changed conditions affected the constancy of ratios appreciably.

The results in Table II were obtained for only one wave-length, but it is not reasonable to expect essentially different behavior at other, nearby wave-lengths. The experiments were intended, furthermore, to afford an insight into the reproducibility of photo-tube response under the ideal conditions of constant photon energy. The performance of the instrument for the spectrally varying and inhomogeneous carbon arc is shown in the next section.

This type of experiment suggests the desirability of having two or more instruments viewing the arc at all times, thus providing a ratio which should serve as an indication of the behavior of the exposure meters. This, combined with frequent checking against a working standard incandescent lamp (taking trends caused by aging and other causes into account) and the whole referred to highest precision incandescent standard lamps, appears to afford a reliable method of measuring light dosage over extended periods of time.

V. SUITABILITY OF THE EXPOSURE METER FOR THE APPLICATION

The arc[1] used for the standardization of light-sensitive papers is usually fairly constant in operation, with occasional extreme differences of three to four percent, and light dosage may thus be approximated on a time basis, but fractional parts of a given light dosage are rendered uncertain by the variation of arc power with electrode length. Furthermore, the glass filter, which surrounds the

TABLE IV. Precision of the uranyl oxalate actinometer[a] using the exposure meter to measure light dosage.

Coefficient of variation, percent		1.4

[a] The chemical procedure given in Federal Specification for Rubber, ZZ-R-601a, II-18, "Resistance to light," was followed, except for slight changes in titrimetric technique. The central 80 percent of the face of the thin silica cell was exposed through a diaphragm, and the rest of the cell was covered by a light-proof, internally blackened, snugly fitting case. The case was rigidly mounted on the drum, rotating about the arc at 1 r.p.m., and faced away from the arc, at such an angle that the cell was illuminated by the image of the arc in a piece of polished red glass, also rigid with respect to the case. This reduced the light intensity 20-fold, as described in Section IIA, and allowed exposures up to 12 hr., instead of ½ hr. with direct exposure. The photon receiver was also mounted on the drum. Another method of reducing the intensity, by mounting the cell in a fixed position at 170 cm from the arc, next to a photon receiver mounted there, gave essentially the same results.

[b] The amount of oxalic acid decomposed was calculated from difference in permanganate titer of the uranyl oxalate solution before and after exposure, and usually amounted to 8 to 9 ml of 0.1*N* $KMnO_4$.

---

†††† The original photo-tubes in the two receivers had similar responses, within a few percent, to the 365, 405, and 436-mμ mercury lines; the replacement tubes differed almost two-fold.

arc to eliminate short ultraviolet, deteriorates with use, undergoing a decrease in transmission—and thus causes a gradual decrease in intensity, especially in the shorter wave-lengths. The use of a device for measuring out light doses and fractions thereof is, therefore, required, and it must be responsive to the same factors that affect quantity and quality of radiant energy as the light-sensitive papers.

Experiments designed to test these points were performed. Light-sensitive paper of uniform initial reflectance was exposed for an equal number of counts under conditions varying much more than expected extremes: high and low arc voltage, old and new filters of both Pyrex and Corex-D glass, and normal electrode variations. The reflectance changes undergone during exposure by the light-sensitive paper were measured.[1, 13] These changes in reflectance must correlate with counts for the various conditions under which the exposure meter is to indicate light dosage reliably (see Table III).

The results given in Table III show that, in spite of the abnormally large variations in conditions, the exposure meters reliably indicated light dosage for the light-sensitive paper, provided that the short ultraviolet was eliminated. When the latter was included, as in experiment 7 with Corning 791, a glass transmitting down to 220 millimicrons, or as in experiment 8 without a filter, the fading of the paper was much greater than the exposure meters indicated, or conversely, as in experiments 9 and 10, for equal fading, far less time and fewer counts were required. It is of interest to note the large differences in time for the various conditions.

VI. COMPARISON WITH THE URANYL OXALATE ACTINOMETER

The possibility of precise light dosage using the exposure meter led to a comparison with the uranyl oxalate actinometer, inasmuch as the latter was, at one time, considered for use in measuring light dosage in the standardization of light-sensitive papers. From the very careful work of Leighton and Forbes,[4] for their typical experiments 14–27, a coefficient of variation of 5.8 percent may be calculated. The uncertainties involved in their method of intermittently measured light dosage, however painstaking, may account for much of the variation.

Several series of experiments were performed, using the actinometric technique developed in the rubber industry[7] and using the standardizing arc, measuring light dosage with an exposure meter. The details are given in the footnotes to Table IV.

The results given in Table IV show a coefficient of variation of 1.4 percent. Two other similar series showed 1.9 and 1.1 percent, but in the latter series a result differing, unexplained, by 8 percent from the mean, was omitted. The results, furthermore, were from one batch of C.P. reagents; another batch gave mean values differing consistently from the others by more than 20 percent, pointing to the necessity of great care in purification, as already stressed elsewhere.[4] These results do not indicate the reproducibility of the uranyl oxalate actinometer for a variety of carefully purified batches of reagents, which would constitute the real criterion of its usefulness, but they do indicate that this actinometer is less variable, for a given set of reagents, than had been previously reported.

The writer thanks Paul J. Shouse for assisting in construction and measurement, and William K. Wilson for performing some of the uranyl oxalate experiments.

THE REVIEW OF SCIENTIFIC INSTRUMENTS VOLUME 20, NUMBER 2 FEBRUARY, 1949

A Capillary Collector for Measuring the Deposition of Water Drops on a Surface Moving through Clouds

BERNARD VONNEGUT[*]
Massachusetts Institute of Technology, Cambridge, Massachusetts

(Received September 24, 1948)

An instrument has been devised for the purpose of measuring the amount of water impinging on a small area moving through clouds, rain, or snow. From measurements of this sort, the liquid water content of the atmosphere can be evaluated.

The instrument uses capillary phenomena to collect and retain water drops striking a small porous surface. Its function is the same as small scoops which have been used to measure water collection in flight, but it has the advantage that its response rate is sufficiently rapid to measure collection rate over a very short interval of time. It has been successfully used in wind tunnel and flight tests. With slight modification, the instrument should find application in measurements on other liquid aerosols.

PRINCIPLES OF OPERATION

Components

THE device consists of a collector made of porous material exposed to the air stream so that particles suspended in the air collide with its collecting surface. Figure 1 shows schematically the essential parts of the apparatus. The collecting head of the unit consists of a piece of porous material held in a holder sealed around its edge so that one surface is exposed to the atmosphere while the other is on the inside of the holder. The holder is connected by a tube to the measuring part of the apparatus, in this case a calibrated glass tube. The apparatus is filled with water from the collecting head to the measuring system. If the proper constants are used in the design of the apparatus, the drops from the atmosphere which hit the surface of the porous material will be drawn into the system and their volume can be measured almost immediately on the measuring device.

Capillarity

Figure 1 includes a greatly enlarged idealized drawing of the cross section of a pore in a piece of porous material such as is used in this instrument. It can be seen from the drawing that the interior of the apparatus is filled with water which forms a meniscus in each pore of the porous material on the outside surface. If we assume that the pores are circular, having a radius r, the liquid has a surface tension γ, and contact angle of the liquid with the pore walls is θ, then the pressure difference, P, between the inside and the outside of the meniscus is given by

$$P=(2\gamma\cos\theta)/r. \tag{1}$$

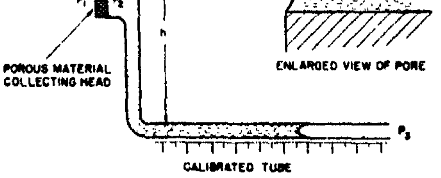

FIG. 1. Schematic diagram of collector.

This pressure difference resulting from surface tension forces causes the pressure in the liquid phase to be less than that in the gas phase when the contact angle is less than 90° (that is when the liquid wets the porous material). If one causes the pressure of the liquid phase to vary with respect to the gas phase, the contact angle of the liquid will change so that the surface tension forces balance the pressure difference. If the pressure difference is increased, the contact angle will decrease. The maximum pressure difference which the surface tension forces will support is limited by the smallest contact angle which the meniscus of the liquid can assume with the wall of the pore. For surfaces wet by the liquid, this angle is substantially zero. Therefore, the maximum pressure difference which can be supported is

$$P=(2\gamma)/r. \tag{2}$$

Because the pressure of the liquid is less than that of the atmosphere, water drops touching the surface of the porous material will be drawn into the body of the liquid while air will remain on the outside. The meniscus can be regarded as sort of a semipermeable membrane, admitting liquid but excluding gases.

We may analyze the situation in the apparatus in Fig. 1 by letting P_1 = pressure on air side of porous material in dynes/cm², P_2 = pressure on liquid side of the porous material in dynes/cm², P_3 = pressure of air at end of measuring tube in dynes/cm², r_1 = pore radius of porous material in cm, r_2 = radius of measuring tube in cm, θ_1 = contact angle of porous material and water, θ_2 = contact angle of measuring tube and water, γ = surface tension of water in dynes/cm, h = height of collector above measuring system in cm, and ρ = density of water in g/cm³. The pressure difference existing across the porous collector (P_1-P_2) is then (neglecting the density of air)

---

[*] Present address: General Electric Company, Research Laboratory, Schenectady 5, New York.

$$(P_1-P_2)=\rho gh+\frac{2\gamma\cos\theta_2}{r_2}+(P_1-P_3). \qquad (3)$$

The maximum pressure difference which the surface tension forces of the liquid in the porous material can support is, from Eq. (2),

$$P_{\max}=(2\gamma)/r_1. \qquad (4)$$

By adjusting P_3, the pressure at the end of the measuring system, so that P_1-P_2 is less than $2\gamma/r_1$ but greater than zero, the system is made stable so that all water touching the collector is immediately drawn into the system while no air is admitted. Because of the incompressibility of the liquid column, the rate of response is very rapid when the viscous forces opposing motion of the liquid are small.

Porous Materials

The porous collector can be made of a great variety of porous materials. Sintered metal, alundum, fritted glass, porous clay, cloth and leather have all been used. Sintered metal seems to be the most desirable material because of its strength, ease of fabrication, and uniformity. The porous metal used was furnished by the Moraine Products Division of the General Motors Corporation in Dayton, Ohio. The metal is made by sintering together a uniform powder of very small bronze spheres. Their product, Porex grade 3, having an effective pore size of approximately 30 microns, was used. After fabrication the collector was thoroughly cleaned of any oil film by washing it out for a few minutes with sulfuric acid-potassium dichromate cleaning solution. The presence of an oil film increases the contact angle of water on the metal and thus lowers the maximum air pressure which the wet porous material will support. Porex grade 3, when clean, should support air pressures of from 40 to 50 centimeters of water. The maximum air pressure which wet porous material will support is limited by the capillary effects in the largest pore, so that uniformity of pore size is very important. Occasionally, samples of porous material are unusable because of a single large pore.

Aerodynamic Pressure Effect and Pore Size

In the discussion concerning the pressures existing in the various parts of the apparatus, it was assumed that a uniform pressure existed in the atmosphere over the collecting area of the porous material. When the collector is moving through the air, the pressure over the collecting surface will not be uniform because of aerodynamic effects. Consequently, provision must be made in the design so that at no point will the pressure drop across the material either force air into the porous material or suck water out of it. The maximum pressure variation which can exist over the surface of any shape of collector is probably several times the pitot static head, but by proper design this pressure variation can be greatly reduced. In the case of collectors having a large aerodynamic pressure variation over the collecting surface, it is necessary to use a porous material having a very small pore size in order to withstand the pressure range. The maximum rate at which water will flow through the porous material is governed principally by the size of the pores. Greater suction can be used with material having a small pore size, but the viscous forces opposing flow increase rapidly as the pore size is decreased. For a given shape and size of collector, the maximum flow rate is approximately proportional to the pore diameter. The maximum flow rate of a collector should, of course, exceed the maximum rate at which water is to be collected. The maximum flow rate can be readily determined by flooding the surface of the collector with water and measuring the rate at which it enters the system.

The early instruments had a wide range of aerodynamic pressure variation over their surfaces and it was, therefore, necessary to use a collector having very small pores. A suction of about six feet of water was used. The maximum flow rate possible through the collector was barely enough to handle the highest liquid water content produced in the wind

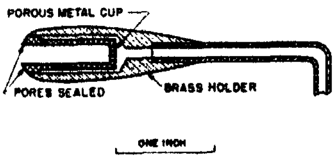

FIG. 2. Section of collector head.

FIG. 3. Collector head.

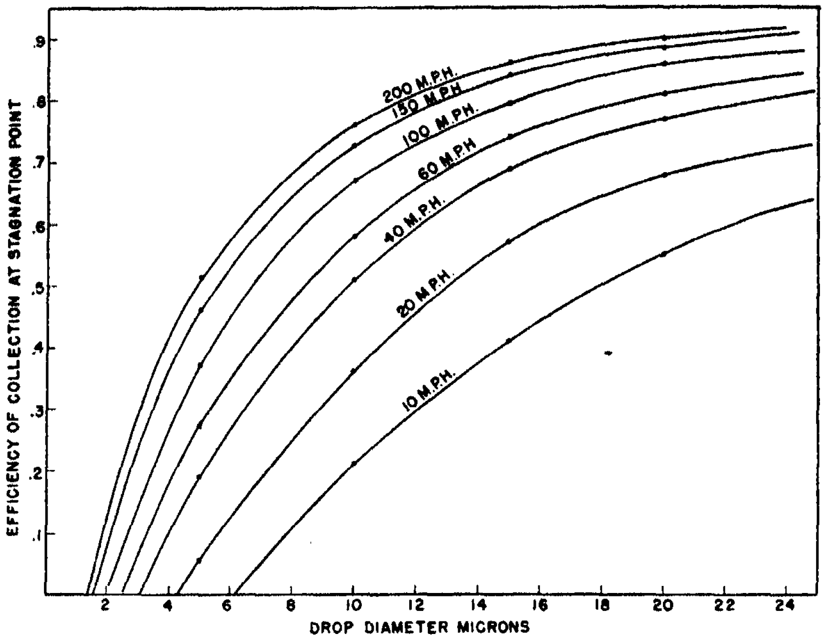

FIG. 4. Approximate efficiency of collection of capillary collector as a function of air speed and drop size from computations of Langmuir and Blodgett. Calculation based on efficiency of collection at the stagnation point of a one-half inch diameter sphere at a pressure of 960mb and a temperature of 10C.

tunnel. It was found that the maximum flow rate gradually decreased with time because of clogging of the pores, and thus caused difficulty. The present design minimizes the aerodynamic pressure variation, permitting the use of larger pores, lower suction, and greater flow rates.

When the porous collector is used at high air speeds, the aerodynamic pressure difference between the collecting head and the measuring system must be taken into account. The most satisfactory method of doing this is to balance out this pressure by connecting the measuring system to a total head tube in the air stream.

Evaporation Losses

Because the water in the pores of the collector is exposed to the atmosphere, evaporation takes place from the system when the atmosphere is not saturated with water vapor. The rate of evaporation from the collector is approximately proportional to the pressure difference between the saturation vapor pressure of water and the partial pressure of water in the atmosphere. The rate of evaporation is also proportional to the airspeed. This can be expressed analytically as follows:

Let V = true air speed in m.p.h., L = evaporation loss in g per minute per sq.cm of projected collecting area, p_s = vapor pressure of water at temperature of collector in centimeters of mercury, p_p = partial pressure of water vapor in the air in centimeters of mercury, and K = constant of evaporation loss for collector. Then

$$L=KV(p_s-p_p). \tag{5}$$

The constant of evaporation loss varies considerably with the design of the collector. It can be reduced to a minimum by constructing the collector so that the airflow over the porous surface is as small as possible. The present design of the collecting head, which is described in the next section, is constructed with this in mind. The constant as measured for this design is 2×10^{-4}. This means, for example, that if measurements are being made in rain at a temperature of 60°F, a relative humidity of 60 percent, and a velocity of 200 m.p.h., the correction for evaporation is 0.021 g/cm²/min. This corresponds to a correction of 0.04 gram per cubic meter, which is not very large compared to rain densities usually measured.

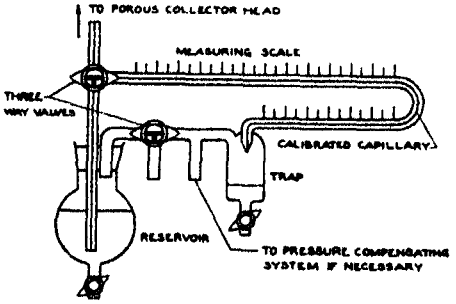

FIG. 5. *Measuring system for capillary collector.*

When the instrument is used for measurements in clouds above freezing, the evaporation rate is negligible because the atmosphere is saturated. Even under conditions when saturation exists, there will be a slight evaporation loss because of the adiabatic temperature rise of the air flowing around the collector. With air speeds of around 200 m.p.h., the temperature differences of a few degrees cause negligible evaporation. At much higher speeds, the temperature rise becomes appreciable, and evaporation losses must be corrected for.

When the capillary collector is used at air temperatures below freezing, the collecting head must be heated. Preferably its temperature should be maintained at a constant value just above the freezing point. The maximum rate of evaporation loss when the atmosphere is below freezing will occur at very low temperatures, when the partial pressure of the water vapor in the atmosphere is negligible compared to the vapor pressure of water at the freezing point. The maximum rate of evaporation for a heated collector of the present design operated at very low air temperatures can be computed from Eq. (5). Substituting the vapor pressure of water, 0.456 cm of mercury, for the term $p_s - p_p$, at 200 m.p.h. gives an evaporation loss of 0.018 g/cm^2/min. Several designs of electrically heated porous collectors have been made and tested, both in the wind tunnel and in flights. Their operation was quite satisfactory in the wind tunnel where the heat losses were quite constant and the temperature regulation was not difficult. However, in flight the temperature control system was found inadequate and large temperature fluctuations occurred in the collector causing excessive and variable evaporation losses of the same order of magnitude as the rates of collection.

DESIGN OF CAPILLARY COLLECTOR SYSTEM

Collecting Head

A wide variety of shapes and sizes of capillary collector heads have been used in wind tunnel tests. The design can be varied to suit the conditions of use. For the purposes of our work, the design shown in Figs. 2 and 3 has proved the most satisfactory.

The hollow shape of the collector gives a large area of porous material in relationship to the collecting area, thus providing a large flow capacity. With a suction of 25 cm of water, the collector can handle a flow rate corresponding, at 200 m.p.h., to a liquid water content in excess of 50 grams per cubic meter. As has been mentioned, the evaporation loss is quite low for this design. The hollow shape is well adapted to measurement of rain and snow. Rain drops or snowflakes have sufficient mass to carry them into the end of the cup, and there is very little loss from splash. The pores of the collecting cup have been sealed for a distance of $\frac{1}{8}$ inch inside of the cup to lower the aerodynamic pressure effect and to cut down the evaporation on the edge of the cup where the air flow is quite rapid.

In general, an object moving through a cloud collides with only a fraction of the particles in the volume it sweeps out. This fraction, known as the collection efficiency, is a function of the size of the collector, its velocity, and the drop size. The smaller the size of the collector, the higher is its efficiency of collection. Using the computations of Dr. Langmuir and Dr. Blodgett** of the General Electric Company Research Laboratory, R. Cunningham has calculated the approximate collection efficiency of this collector under different conditions (Fig. 4). These calculations were made on the assumption that its collection efficiency is the same as that at the stagnation point of a sphere of the same diameter (0.50 inch).

If two or more collectors having different sizes are used simultaneously in making measurements, the average drop size can be computed from their relative collection rates. The liquid water content can then be computed if the average drop size is known.

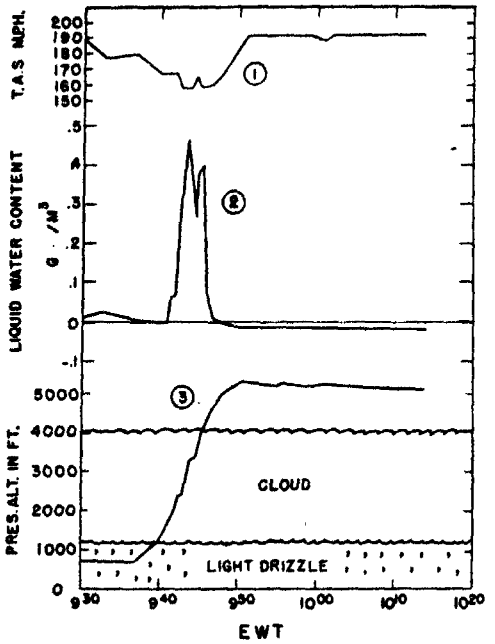

FIG. 8. Flight data taken with collector near Boston, May 19, 1945.

Measuring System

In most of the work a calibrated fine bore glass capillary tube having a volume of 0.01 cc per cm has been used to measure the rate at which water is being collected. The design of this system is shown in Fig. 5. By manipulation of the stopcocks, the system can be filled or drained. Measurements are made by observing the position of the water in the capillary tube as a function of time. One or two successful flights have been made using a microrotameter type of flow meter to measure the rate of water collection. It is planned to describe this in a later paper.

Flight Tests

A number of flights with the capillary collector have been made at temperatures above freezing. These tests were made in a B-17 airplane through the cooperation of the M.I.T. Radiation Laboratory. Photographs of the installation of the collector and measuring system are shown in Figs. 6 and 7. The results of data taken on one of these flights is shown in the diagram in Fig. 8. The instrument is in regular use at the present time on flights being carried out by the M.I.T. Weather Radar Group.

ACKNOWLEDGMENTS

This work was done under U. S. Army Contract W-33-038-ac-5443 (for the period July 1, 1944 to June 30, 1945). The author wishes to thank Mr. W. V. Westerlund of Wright Field and his associates for their help in this work as well as Professors H. G. Houghton, R. M. Cunningham, R. E. Katz, and the members of the M.I.T. De-Icing Research Laboratory for their advice and cooperation. The author is indebted to Dr. V. J. Schaefer of the General Electric Company for his helpful suggestions, to the Moraine Products Company for their cooperation in fabricating the porous metal parts, and to Mr. J. W. Miller and Mr. Arthur Bent of the M.I.T. Radiation Laboratory for arranging flight tests from the Bedford Air Base.

THE REVIEW OF SCIENTIFIC INSTRUMENTS VOLUME 20, NUMBER 2 FEBRUARY, 1949

An Apparatus for the Production of Large Metallic Crystals by Solidification at High Temperatures[*]

Louis Gold
Metals Research Laboratory, Brown University, Providence, Rhode Island

(Received September 28, 1948)

The design and operational aspects of an apparatus suitable for large-scale production of metallic crystals is described and the various high temperature difficulties indicated.

1. INTRODUCTION

THE commercial production of large single crystals is rapidly making available specimens of inorganic compounds for research purposes and special applications. The Harshaw Chemical Company is growing halide crystals in pound denomination;[1] the earlier researches of Stockbarger are being used to good advantage.[2] The Verneuil method for preparing synthetic sapphires[3] has been developed by the Linde Air Products[4] who are producing not only large sapphires, but a number of other refractory oxides. Considerable interest in the problem of growing adequate sized piezoelectric quartz crystals has been manifested, and progress is being made in this direction.[5]

The literature contains ample evidence of extensive investigations pertaining to the preparation and properties of metallic crystals. In general, only the lower melting metals such as zinc, lead, cadmium, etc., have been grown with some consistency with dimensions that might be considered as appreciable;[6] copper and certain alloys (gold-copper, alpha-, and beta-brass, for example) have been prepared in sizes of some note,[7] but beyond the range of approximately 1100°C, the results are quite sporadic.[8]

Although large crystals of metals having high melting points can be prepared by other methods which avoid high temperature complications,[**, 9] solidification from the melt apparently is most amenable to large-scale operation.[10]

Recently there has developed as a result of wartime researches marked awareness of the need for large metallic crystals.[11] In particular the desirability of suitable delay lines and similar storage devices[12] have intensified the importance of such materials.[13] The present paper is an outgrowth of these developments.

The apparatus to be described evolved from the desire to fulfil the considerations of having a relatively simple arrangement for growing large crystals of metals with design features which would allow for reasonable flexibility. The various schemes for growing crystals from the gaseous, liquid, solid, and solution states were critically re-examined and the decision to prepare the specimens from the melt made.

2. THE APPARATUS DESIGN AND CONSTRUCTION

The sundry variations of growing the crystals from a melt are all based on the underlying process of controlled solidification with due observance of the principles of nucleation and growth. The techniques of Bridgman,[14] Stoeber,[15] Czochralski,[16] and Obreimov-Schubnikov[17] were carefully evaluated,

FIG. 1. General view of apparatus.

and the Bridgman method finally selected because of its apparent popularity. Descriptions of apparatus utilizing the Bridgman method, some of which are rather crude and other which are quite elegant in their construction, may be found in the literature.[18] The vacuum furnaces used by Nix[19] and Siegel[20] were considered as best representative of what could most probably serve effectively for most metals since the exclusion of air is generally mandatory. The wire suspension arrangement for raising and lowering the specimens into and out of the furnace was thought to be inadequate for large melts of reactive metals; the method of moving the melt on a mercury column which had been used by both Quimby *et al.*[21] and Gwathemly and Benton[22] in different forms was further modified as will be described.

Figure 1 shows the equipment which has been used to prepare a wide variety of large metallic crystals; copper specimens of the order of 2 inches in diameter and 6 inches in length, for example, have been produced with relatively little difficulty. Metals and alloys in the range from 1100°-1600°C have also been grown in reasonable denominations with the basic limitation of resistance type furnaces restricting operation beyond this range. Although the apparatus has been limited to vacuum operation, it can readily be adapted to usage with inert atmospheres if desired, as would be the case when dealing with highly volatile metals. The apparatus will now be described in terms of its basic components, which are

A. The vacuum system.
B. The furnace chamber.
C. The furnace unit.
D. Power supply and temperature control.
E. The lowering-raising mechanism.

A. The Vacuum System

Gasket seals, waxed joints, and stopcocks were eliminated wherever possible, particularly on the high vacuum side to minimize leak troubles; most of the joints were hard soldered or welded. A vacuum of 5×10^{-6} mm could be maintained with the usual arrangement of Welch Duo-Seal two-stage fore-pump and Distillation Products three-stage vertical diffusion pump. In the course of a run, however, severe out-gassing would reduce the vacuum to approximately 10^{-3} mm. Because of the wide variations in gas composition, it was found that the standard gauges were not serviceable in this range. Instead, a Lepel high frequency oscillator (commonly known as a spark-coil) was used to gain an approximate estimate of the pressure; in any event, it could detect if and when a leak occurred.

B. Furnace Chamber

Figure 2 shows the furnace chamber extending to the bottom of a mercury well (33) on one end and sealed at the top by a steel cover and gasket (7), (8). The steel sidearm pumping lead, hard soldered to the chamber, is bolted to the diffusion pump and the seal made via an indium metal gasket. *** There are several openings on the chamber. Three windows (21) each at a different level provide for sighting. These were not used in any of the runs made, but should prove of value in studying solidification or other processes at much lower temperatures. These windows are made by a special process and are adequately described in the Tube Shop Handbook of the M.I.T. Radiation Laboratory. Their novel feature is the distortionless view one sees through them—of material importance in many instances. Below the bottom window is another opening (22) through which a thermocouple (23) can be inserted. The outside of the chamber is wrapped with approximately 150 feet of ⅜-inch copper tubing (9) which is soft soldered into place; the water cooling provided will dissipate more than 5 kw with the chamber wall running a bit warm. A steel ring (25) was welded into place on the inside to support the furnace unit.

C. Furnace Unit

Because of the high temperatures and prolonged periods of operation, and because of the gradient requirements necessary for single crystal propagation, the furnace design proved to be most formidable; the difficulties appeared to be most marked when attempting to grow the larger sized specimens. Also there were complications resulting from vapors attacking ceramics and the general misbehavior of the insulation at high temperatures.

*** Indium is better than lead for this purpose because it is softer and less inclined to work-harden.

An Alundum core (16) RA-98 or RA-1139 (supplied by the Norton Refractory Company) is wound with the required number of turns of molybdenum wire (15) of predetermined diameter. A layer of special grade Alundum cement (silica free) (14) is applied over the windings and pre-fired up to 300°C. The current carrying capacity of the return leads is enhanced by using three strands of wire, each of which is encased in an individual alundum tube (12) for protection. The core is slipped over the lip (19) of a steel bucket (11) which is then filled with coarse grain silica free Alundum sand (13). A pair of holes close to the upper rim of the bucket allows for the ready insertion and removal of this unit by a pair of steel hooks. The bare wires protruding above the level of the sand are inserted into a stainless steel sleeve (6) and held firmly in place by a number of set-screws; this arrangement provides the necessary rigidity for facilitating the job of making electrical contact in a vacuum and also serves to protect the embrittled "moly" leads from repeated handling.

The stainless steel sleeves pass through a Lavite plug (10) which centers them and also offers insulation above the furnace. Two lock nuts (7) fasten the power-leads in place. A pair of connectors (5) are fastened to the power-leads by set-screws. Between steel bucket and ledge is a section of Lavite insulator (24) which is braced by a thin steel section not shown.

D. Power Supply and Temperature Control

Evidently temperature control in high power-high temperature furnaces cannot be handled in conventional fashion.[23] For temperatures over 1000°C thermocouples cannot be relied upon for dependable performance. There are two recommended approaches:

(1) Control thermocouple at some convenient point in furnace below 1000°C, but so arranged as to give temperature control in the hot zone which may be well above this temperature.

(2) Maintenance of constant power by using a voltage-stabilized supply.

Because of the uncertainty of the nature of the gradients within the furnace, method (2) seemed preferable; for a furnace relatively free of gradients, method (1) is inherently capable of more accurate control, but method (2) will generally be adequate since, in the range of temperatures of present interest, temperature control better than a few degrees is practically meaningless—primarily because of the limitations of the temperature measuring devices.[24]

A General Radio 7 KVA variac rated at 220 v and 30 amps was operated off a two-phase 60-cycle 220 v-30 amp. line. The power was introduced into the vacuum furnace by means of the power leads (4) indicated in Fig. 2. These leads were made up as a unit which was then soft soldered into the steel cover plates. They are very sturdy in nature and can be made to sizes which will carry currents of the order of hundreds of amperes. A long section of 705-2 glass permits one to see the contact made. For high vacuum operation the contact is best made by dry fits, but for low vacuum or inert atmosphere operation mercury contacts may be used.

The temperatures were read with a Leeds and Northrup optical pyrometer through the 1-inch window (3) by sighting a glass prism (2) in the brass housing (1). In actual practice, no apparent temperature fluctuations were observed during the course of operation of the furnaces. The thermal inertia of the furnace was such as to eliminate rapid fluctuations of temperature even though the voltage were to fluctuate for any reason. Moreover, some approximate data taken on the voltage-temperature characteristics of the furnace indicated that a one-volt change would result in a temperature change of only a few degrees. Still another

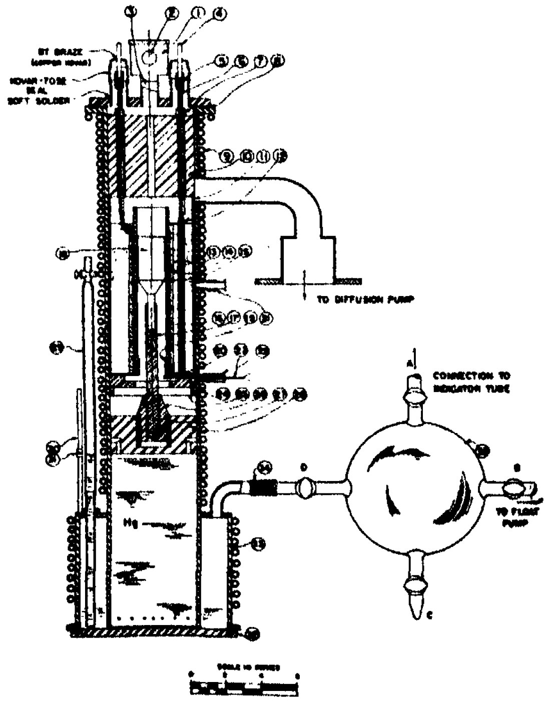

FIG. 2. Sectional view of furnace chamber.

[23] N. R. Stansel, *Industrial Electric Heating* (John Wiley & Sons, Inc., New York, 1933).

[24] American Institute of Physics, *Temperature, Its Measurement and Control in Science and Industry* (Reinhold Publishing Corporation, New York, 1941).

indication of the temperature regulation possible was shown by the ability to hold a constant temperature on some particular object in the furnace for hours at a stretch by merely setting the voltage at a given level.

E. The Lowering-Raising Mechanism

Reference to Fig. 2 will indicate the arrangement used to vary the position of specimens in the furnace chamber. The principle of altering the height of a mercury column which was used successfully by Quimby and independently by Gwathemly and Benton was carried out by the former by draining off mercury through a rotating stopcock into an evacuated chamber and by the latter simply by varying the height of a leveling bulb which was slowly lowered by a gear reduction system.

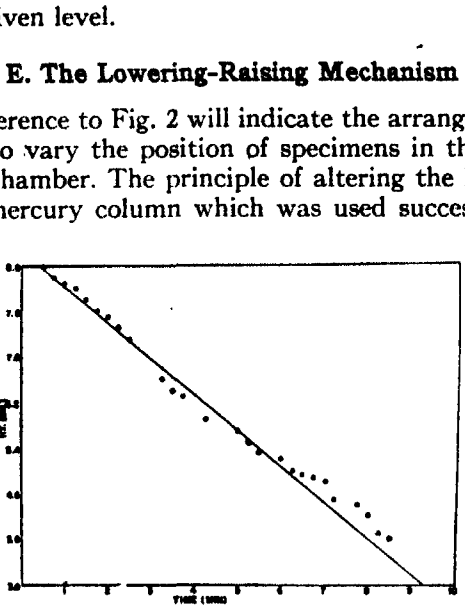

FIG. 3. Typical plot of mercury level *vs.* time showing fluctuations at rapid lowering rates.

The present design is thought to have advantages over the afore-mentioned techniques; the height of the mercury column is varied by regulating the pressure in the steel reservoir (33). This was done by a sequence of manipulations on the stopcocks attached to the volume tank (35); bellows (34) were inserted as indicated to minimize the stresses on the glass connections during the various stages of manipulation. An indicator tube (29) provided with a scale and lens viewer (30) and (31) was used to determine the height of the column (and thus the position of the specimen).

A uniform rate of lowering is possible only under certain conditions, foremost of which is the maintenance of relatively lower pressures in the volume tank than in the reservoir.[25] The uniformity of lowering was checked up to rates of approximately 6 mm per minute, at which point slight fluctuations of the kind shown in Fig. 3 were noted. Since the rates used in the crystal growing runs were never greater than 2.5 mm per minute, the lowering rate was uniform; exceedingly slow rates of the order of mm per hour were not amenable to careful regulation because of stopcock difficulty—it was found important that stopcock *D* be greased properly if good performance were to be had. Grease or dirt in the stopcock hole will give trouble. This possible source of interference could be readily eliminated by inserting a tee branch between the reservoir and the volume tank; one branch could be used for evacuation and raising purposes, while the other could have a metal capillary valve for the lowering process. This suggestion is made for future experimentation.

The steel float (28) is inserted into the chamber prior to the installation of the mercury and the bottom plate (32). The float design was carefully considered in terms of the amount of tilting which would be experienced by melts supported at some distance from the face of the float. If the fit between the float and chamber is too close, there is a tendency for sticking and general erratic behavior; on the other hand, if too loose, the tilting effect is enhanced. Thus, it was necessary to make a simple analysis of the variation of the amount of tilting with the degree of clearance between the float and the furnace chamber. A working formula which applies for the conditions prevalent is

$$\delta = [L(W-w)/h],$$

where delta (δ) is the amount of horizontal displacement, W is the inside diameter of the furnace chamber, w is the diameter of the float, L is the length of the crucible support plus crucible length, and h is the height of the float. For the set-up used calculation based on the above formula indicated that a clearance of several thousandths should not give significant values for delta (δ). It is also a safe precaution to have the inside wall of the chamber free of scratches and bumps.

Figure 2 shows a particular pedestal arrangement (17), (20), and (27). In the course of developing growth techniques for various metals and alloys a variety of pedestal designs were devised. These are shown in Fig. 4. The shapes and materials of construction were altered to modify the temperature gradients in the charge. In general, they were composites of graphite, firebrick, and Lavite.

To achieve the proper levels of the specimen, both during the melting operation and the final solidification state, it was necessary to select the proper relative dimensions for the reservoir and the furnace chamber. Some degree of flexibility was required to accommodate the different sizes and weights of the many specimens; this was accomplished by varying the amount of mercury in the reservoir. The mercury can be siphoned in and out through the indicator tube as the situation might demand. Occasionally the indicator tube, as well as the mercury in it, would become sufficiently dirty to make readings difficult by virtue of the meniscus becoming anomalous and the general obscuring of its position. The tube and mercury were readily cleaned from time to time by admitting dilute nitric acid, water, and acetone in proper sequence via the stopcock shown. It is important to eliminate all traces of water or acetone in the tube prior to starting up again for operation; if this is not done, bubbles will form beneath the mercury in the tube to interfere with proper operation by rising to the surface when a run is in progress.

3. OPERATIONAL PROCEDURE

Having described the individual design aspects of the components, we will now delineate the manner in which the apparatus may be used for a typical run. By no means are the following details unique: a broad range of variations is possible and, as a matter of fact, additional modes of operation have been utilized. The operational sequences can conveniently be classified as:

A. Loading.
B. Starting-up.
C. Out-gassing and pre-heating the furnace.
D. Raising and melting the specimen.
E. Lowering the specimen.
F. Finishing the run.

A. Loading

The specific nature of the run determines the kind of pedestal, crucible, and furnace to be used. The pedestal is inserted into the hole of the steel float with the crucible or crucible holder in place; the maximum and minimum position of the crucible is then checked by raising and lowering the mercury column. The column is raised by connecting stopcock *A* or *C* to a compressed air line and then keeping the proper cocks closed or open. Lowering is accomplished by simply letting the compressed air in the volumn tank escape. The maximum and minimum position of the crucible in the furnace can be adjusted by varying the quantity of mercury in the reservoir and the height of the pedestal. Different sizes and denominations of specimens require that these adjustments be made.

With these preliminaries dispensed with, the furnace is then lowered onto the Lavite insulator above the steel shelf by means of a pair of steel hooks. The task of getting the crucible into the furnace opening is facilitated by having the float completely lowered before the furnace is inserted. Having set the furnace into position, one can again check the maximum and minimum positions of the crucible.

The Lavite plug is then slipped over the protruding stainless steel connecting rods and lowered into position by a pair of pointed tongs inserted into the sighting hole. The lock nuts are put into place to hold the connector-rods rigidly in place and the connector-cups fastened into place.

The gasket on top of the furnace chamber is well greased and the steel cover carefully lowered into place as the power-leads make contact with the connector-cups. The steel cover is subjected to a slight rotary motion which serves to assure good contact and to spread the grease film under it to effect a good seal.

B. Starting-Up

A rubber hose connection is made between the indicator tube and stopcock *A* on the volume tank. The float pump is then started up and the mercury column slowly raised up the entire length of the indicator tube and just beyond the opening of the stopcock to eliminate all the air. The indicator tube is closed off and the hose connection removed. The volume tank is next evacuated with stopcock *D* on the closed position.

At this point the fore-pump is turned on and the furnace chamber evacuated. To prevent the mercury column rising too far into the chamber, it is important to balance the pressures on both sides of it. This is accomplished by noting when the mercury in the indicator tube begins to fall and as it does, stopcock *D* is slowly opened to decelerate the downward motion of the mercury column. With both sides of the mercury column evacuated, the diffusion pump is then turned on, followed by the water cooling system.

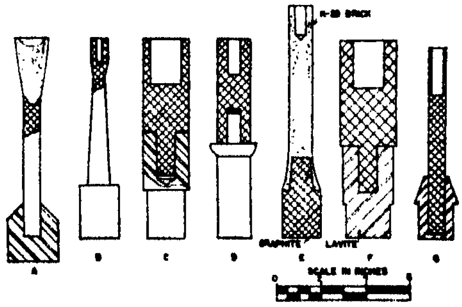

FIG. 4. Pedestal design.

C. Out-Gassing and Pre-Heating the Furnace

The power supply is connected to the furnace leads, and the power gradually increased. Too rapid heating is avoided in order to prevent thermal stresses from causing cracking of the furnace core or crucible. A furnace being used for the first time gives off voluminous amounts of water vapor and carbon dioxide. A new furnace is generally out-gassed overnight at a dull red heat. Subsequent usage of the furnace will not require out-gassing periods of long duration. The furnace is heated above the maximum point of operation to be effective in the melting operation to drive off gas that might otherwise be slowly evolved at the lower operating point.

D. Raising and Melting the Specimen

The specimen is slowly raised into the furnace by careful manipulation of the stopcocks on the volume tank. The raising process is watched through the window on the steel cover via the right angle prism in the brass case. When the specimen has been raised to desired height (as shown by the position of the mercury level in the indicator tube), stopcock *D* is closed and the volume tank evacuated in readiness for the lowering operation.

Temperature readings are taken periodically to follow the progress of the melting operation. If the power required to effect melting has not been predetermined in some preceding run, the voltage is gradually increased until melting is noted. Since some specimens will not show a clear liquid melt,† it is of considerable help to plot the temperature readings *versus* time and get a heating curve from which the melting halt can be detected. After some experience, the halts can be noted without the necessity of plotting the data, but in some instances this cannot be dispensed with.

The temperature readings are subject to a number of sources of error and must therefore be corrected.[26] Where a clear liquid surface can be observed (as in the case of copper, for example) it is not unusual to experience an apparent drop in temperature although actually the temperature has increased. In some instances the drop has been as much as approximately 150°C. This phenomenon can be attributed to the marked change in the spectral reflectivity at the melting point.

To minimize possible reactions of the melt with the crucible or even of the crucible with the holder, and also to minimize evaporation, it is important to avoid overheating the molten change. Yet, one must be certain to have effected complete melting.

E. Lowering the Specimen

Having melted the specimen and allowing sufficient time for the elimination of any solid present in the melt, the solidification process is initiated. The temperature is stabilized at approximately 100°C above the melting temperature. Lowering the specimen out of the furnace is then begun by cautiously turning stopcock *D* to the open position; the volume tank must first be completely evacuated to the point where no glow discharge can be excited with a spark coil. Air escaping into the volume tank as stopcock *D* is opened will give rise to the glow discharge and thus indicate that lowering has commenced. The opening of the stopcock is adjusted until the desired rate of lowering is achieved. This is done by a series of alternating back and forth maneuvering, sufficient time being allowed for equilibrium to set in for each stopcock setting.

F. Finishing the Run

When the specimen has reached the minimum position, or when solidification is known to be complete, the power is gradually reduced. Reducing the power too rapidly may cause cracking of the furnace core or other ceramic materials in the hot zone. With the power completely off it may take hours for the furnace to cool, particularly if it is well insulated. So to accelerate the cooling process the specimen may be raised back into the furnace after the furnace has cooled below the melting point region. This step will simultaneously anneal the specimen and remove thermal stresses that might have been left by the original gradient condition that existed during the solidification.

The cooling operation completed, the usual operation of shutting the diffusion pump and the fore-pump is followed by admitting air through the bleeder-valve on the steel cover. It has been found advisable not to attempt to remove the specimen while the furnace is still in place. By removing the furnace first, one can carefully extract the crucible containing the specimen.

4. DISCUSSION

In the course of the numerous runs made with the apparatus, the complexities arising from prolonged, large scale operation at high temperatures were made evident. A number of these are directly attributable to the presence of a metallic charge and others originate because of the inherent difficulties of high temperature operation.

The crucible problem for metallic melts is much more severe than for inorganic compounds. The technique of thin-walled metal crucibles devised by Stockbarger[3] cannot be utilized because of obvious alloying effects. Refractory crucibles made of Alundum, beryllia, graphite, etc. when in contact with molten metals for prolonged periods will react or show marked penetration. This gives rise to contamination and sticking; silicon, for example, in an Alundum crucible will not come out readily and the crucible needs to be broken away. The need for high gradients also causes difficulty with crucibles by favoring thermal stress cracking.

---

† Reactive metals such as aluminum, beryllium, etc. form oxide skins even in a high vacuum. The oxide skin on the surface of the melt obscures the nature of the charge below.

[26] W. E. Forsythe, *Measurement of Radiant Energy* (McGraw-Hill Book Company, Inc., New York, 1937).

Resistance-wound furnaces are a potential source of trouble because of a number of deleterious effects, foremost of which is electrical breakdown at elevated temperatures. This can be reduced somewhat by designing the furnace for low voltage—high current operation; one cannot carry this process too far because of the wire size limitations. Resistance-wound furnaces are also subject to attack metal vapors. Some degree of minimization of this difficulty is possible by proper shielding of the furnace walls. One cannot, however, completely obscure the surface of the charge because of the necessity of sighting it during the course of a run.

The longevity of such furnaces is seriously handicapped by gradual evaporation of the resistor element and increasing embrittlement of the furnace core. The presence of high gradients is certainly not beneficial.

There appears to be some evidence which indicates that the Bridgman method may not be the best means for introducing the gradient into the molten charge. The large cross-sectional area of melts with relatively high thermal conductivity tends to level-off the gradients existing at the bottom of the furnace. For this reason it was found necessary to support the crucibles on graphite pedestals in order to create sufficiently high thermal gradients in the charge. The graphite pedestals, however, markedly increased the power requirements. It was found necessary to use combinations of graphite and insulators such as Lavite and firebrick to compromise between power-loss and thermal gradients. The Obreimov-Schubnikov technique of instituting the gradient after melting has taken place by introducing a heat sink was surmised to be a more efficient procedure. Some preliminary attempts in this direction were quite encouraging.

The relatively higher degree of impurities in the metal specimens further distinguishes the growth of metallic crystals from inorganic crystals. Insoluble matter in the metal will settle out when the specimen is kept molten for some time. The presence of the insoluble impurities is probably responsible for the observance of an optimum rate of solidification for producing large crystals.

It was generally evidenced that increasing the dimensions of the specimens not only altered the optimum conditions, but also augmented the tendency of parasitic grains appearing. Although a number of specimens were not truly single crystal, i.e., such parasitic grains were evident, their general usefulness was not seriously interferred with. Thus, the term single crystal was avoided in the title of this paper for the sake of completeness and accuracy; moreover, the distinction between the true single crystal and the mosaic crystal is not well enough defined to permit one to use the terminology of single crystal with impunity.

ACKNOWLEDGMENT

The author is indebted to several members of the Metallurgy Department of M.I.T. for making this research possible. In particular, the interest and advice of Professors Chipman, Cohen, and Kaufmann served as a source of constant encouragement during the difficult stages.

Thanks are also due Mr. Holbrook for operational assistance and Mr. Sanroma of the Research Laboratory of Electronics for most of the basic constructional work.

THE REVIEW OF SCIENTIFIC INSTRUMENTS VOLUME 20, NUMBER 2 FEBRUARY, 1949

A Large Helium Liquefier

J. G. DAUNT AND H. L. JOHNSTON
The Cryogenic Laboratory, Department of Chemistry, and The Department of Physics, The Ohio State University, Columbus, Ohio

(Received October 2, 1948)

A large helium liquefier is described which produces 7.5 liters of liquid helium per hour through a Joule-Thomson expansion valve when operated from a compressor giving 21 cu ft./min. flow at a pressure head of 320 lb./sq. in. The liquid helium can readily be transferred into exterior cryostats. The consumption of liquid hydrogen, used to pre-cool the helium gas, during the process of liquefaction is 1.3 liters of hydrogen per liter helium. The liquefier fits into a container 6′ long by 8″ in diameter.

I. INTRODUCTION

A LARGE helium liquefier has been put into satisfactory operation in the Cryogenic Laboratory at the Ohio State University, and in view of the simplicity and stability of its operation, it is thought that a brief description of it might be of interest.

The liquefier is based on some features of the designs for small scale helium liquefiers using the Joule-Thomson expansion method of liquefaction previously developed both at the Ohio State University[1] and at the Clarendon Laboratory, Oxford[2] and utilizes some features of the large helium liquefier in use at the University of California (courtesy of Professor W. F. Giauque).

The liquefier is an all-metal construction immersed in a glass Dewar which contains liquid hydrogen. It is therefore possible to view continuously the level of liquid hydrogen through slits in the silvering of the Dewar, a feature which is found convenient during the operation of the liquefier.

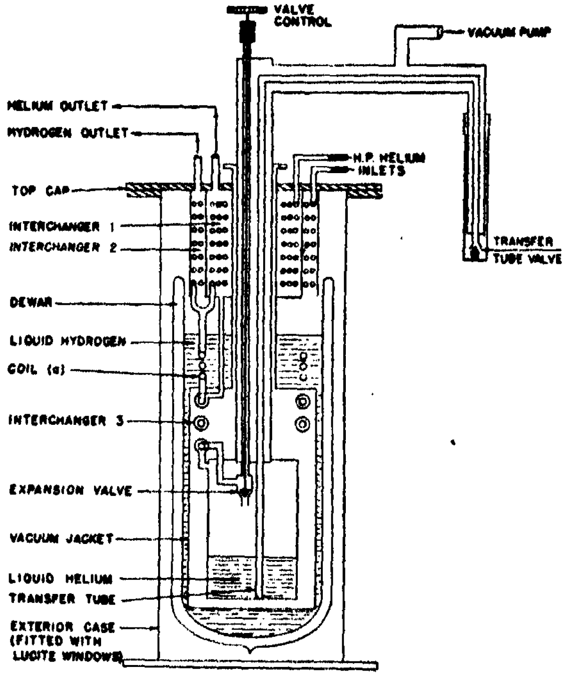

FIG. 1. Helium liquefier.

Observation of the level of liquid helium produced is not critical, since the volume of helium liquefied can be readily obtained from observation of the helium gas-holder level. It was therefore decided to dispense with a direct visual observation of the helium chamber, a process which greatly simplified the construction.

The liquefier does not use liquid air or liquid nitrogen as a pre-coolant, but instead the high pressure input helium gas is allowed to enter at room temperature and to be cooled to liquid hydrogen temperatures by means of heat interchangers. This interchanging system between room temperature and liquid hydrogen temperature is in two parallel sections, one interchanging with the return cold low pressure helium gas and the other with the hydrogen evaporating from the Dewar.

The liquid helium is transferred out of the liquefier into exterior cryostats or storage vessels by means of a vacuum jacketed transfer tube built integrally with the liquefier. It is found that the losses in transfer are small and that the rate of transfer is very fast, a few seconds being sufficient to transfer 1 liter of liquid helium into an exterior cryostat.

II. GENERAL DESCRIPTION OF LIQUEFIER

A schematic diagram of the liquefier is given in Fig. 1 and Fig. 2 shows to scale detail of the more important dimensions.

The helium high pressure input is split into two parallel paths outside the liquefier and the two inputs lead separately to interchangers 1 and 2. Both these interchangers are built concentrically and are of the Hampson type, using a construction developed and patented by Giauque.[3] Interchanger

FIG. 2.

1 has 6 layers of copper tubing ($\frac{1}{8}''$ o.d. and 35 thousandths of an inch wall thickness), and is comprised of 15 high pressure tubes in parallel each of length 23 ft. 8 inches. The return low pressure helium passes through the moderately open network between the high pressure tubes. Interchanger 2 is of the same general construction having 3 layers of the same $\frac{1}{8}''$ copper tubing comprising 9 parallel high pressure paths of length 34 ft. 8 inches each. The evaporating hydrogen vapor passes through the spaces left between these high pressure tubes.

The lower 10 inches of this double interchanger system fits into the top of a glass Dewar vessel which is 54 inches long by $5\frac{5}{8}$ inches i.d. This Dewar is placed in a brass vessel, fitted with Lucite windows, similar to the hydrogen cryostats developed at Ohio State University by one of us,[4] and serves to hold the liquid hydrogen. By this construction the level of the liquid hydrogen within the liquefier can be readily inspected.

Below the room temperature to liquid hydrogen temperature interchanger system, within the Dewar, the liquefier follows essentially the construction described for the small liquefiers previously developed.[1,2] The main components are (a) a high pressure helium coil immersed in liquid hydrogen, serving to cool the incoming helium gas to 15°K, which is the temperature maintained by the liquid hydrogen, (b) a vacuum jacket, which is continuously evacuated by an oil diffusion pump, (c) an interchanger (interchanger 3 of Fig. 1) between 15°K and helium temperature (4.2°K). This interchanger uses the cold of the returning low pressure helium gas which is not liquefied at the expansion valve, (d) an expansion valve, (e) a helium chamber to collect the liquefied helium and (f) a transfer tube which enables the liquid helium to be drawn off into a cryostat outside the liquefier.

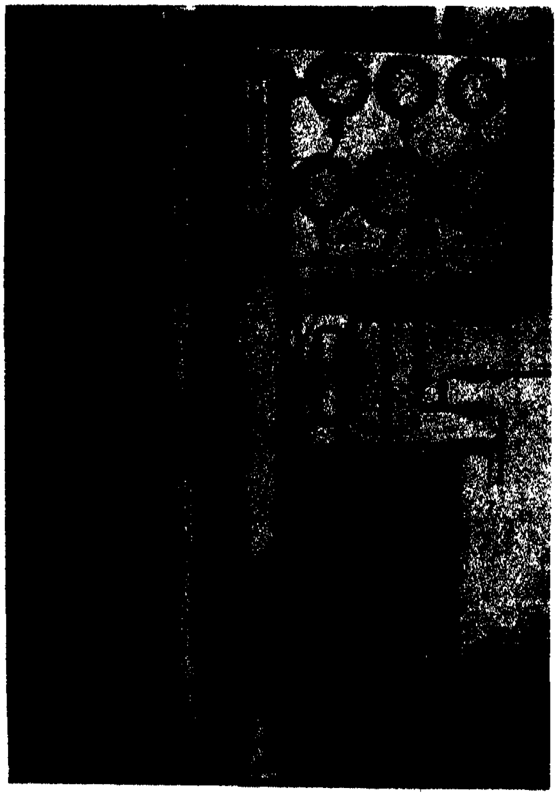

FIG. 3.

In addition, not shown in Fig. 1, there is a gas thermometer attached to the expansion valve and a "valve warmer" which consists of a small bore tube leading directly from a supply of pure helium gas at room temperature outside the liquefier to the expansion valve so that warm gas can be blown onto the valve. This is used if the valve sticks at low temperature.

The high pressure helium coil (a) consists of 4 parallel paths constructed of $\frac{3}{16}$-inch copper tubing, wall thickness 35 thousandths of an inch, each of approximate length 19 ft.

The vacuum jacket (b) is made of monel tubing 5-inch o.d. and 45 thousandths wall thickness. The length of the vacuum jacket is $24\frac{5}{16}$ inches.

The interchanger (c) between hydrogen temperatures and helium temperatures is of the Linde type, chosen in order to minimize conduction losses to the helium chamber. This interchanger is made from $\frac{1}{2}$-inch o.d. copper tubing, length 20 ft., in which is placed four $\frac{1}{8}$-inch o.d. copper tubes, the whole arrangement then being wound in the form of a helix and bound rigidly with asbestos string. The four $\frac{1}{8}$-inch copper tubes take the high pressure gas, the tubes being arranged in parallel. The return helium gas flows back through the space left between the $\frac{1}{8}$-inch tubes inside the main $\frac{1}{2}$-inch tube. In order to increase the length of the return path, the high pressure tubes had wound on their outsides a helical coil of 22 a.w.g. wire of open pitch, the wires subsequently being soldered at intervals to the $\frac{1}{8}$-inch tubes. From the observed high liquefaction coefficient it is evident that this construction is highly efficient.

The expansion valve (d) is a needle valve operated from the top of the liquefier by means of a $\frac{3}{16}$-inch o.d. monel tube, 25 thousandths wall thickness, this control rod being contained in a sheath made from $\frac{1}{4}$-o.d. monel tubing, 15 thousandths wall thickness. The valve was arranged so that the sheath was at high pressure. This arrangement insures a minimum risk of air impurities flowing through the packing at the top of the control mechanism and also serves to allow an easy attachment to be made at the top of the liquefier to measure the high pressure at the valve. It should be mentioned that the valve is mounted *inside* the helium chamber, thereby allowing the operation of a valve warmer.

---

[4] A detailed description of this is being submitted to The Review of Scientific Instruments.

The helium chamber (e) is made from a 4-inch o.d. monel tube 11⅝ inches long. The capacity for helium is approximately 2.2 liters, when allowance has been made for the position of the valve, etc. It is possible therefore to collect helium in amounts of the order of 2 liters between any two transfers to the cryostats outside the liquefier.

The transfer tube (f) consists of a ⅛-inch thin walled monel tube which is carried in a vacuum isolated jacket outside the apparatus into the external cryostats. The exit end (cryostat end) of this transfer tube bears a needle valve to open and close. This transfer tube, the valve and valve controls, the gas thermometer and the valve warmer are all mounted as a unit on a 1¼-inch o.d. monel tube which extends the whole length of the liquefier. This tube can be withdrawn easily without disturbing any of the interchangers, etc., and consequently makes the problem of construction and repairs greatly simplified. At the top of the liquefier this tube makes a vacuum tight joint to the rest of the vacuum jacket by means of a rubber gasket (Fig. 2).

The remaining general arrangements are illustrated in Figs. 1 and 2 and are self-explanatory. A photograph showing the completed liquefier suspended alongside its brass cryostat is given in Fig. 3.

In addition to the liquefier itself a purifier is used to clean the incoming high pressure helium gas. This purifier consists of a high pressure charcoal trap mounted in liquid air. The activated charcoal is contained in a spiral tube 1 inch o.d. and 25 ft. long, which fits inside a glass Dewar vessel 36″ long by 5½″ inside diameter. Between this charcoal trap and room temperature an interchanger is mounted so that the outcoming high pressure helium is approximately at room temperature and so that a minimum loss of liquid air occurs.

TABLE I.

Output	7.5 liters liquid helium/hour
Liquefaction coefficient	14 percent
Temperature of hydrogen bath	15°K
Input pressure	320 lb./sq in.
Gas flow	21 cu ft./min.
H_2 consumption (liquid)	1.3 liters per liter liquid helium

The interchanger consists of four Linde type interchangers mounted in parallel.

III. PERFORMANCE

The performance of the liquefier is given in Table I.

To start the machine it is initially cooled with liquid nitrogen. About one hour is required for this. After liquid N_2 temperature has been reached, the liquid nitrogen is syphoned out of the Dewar and liquid hydrogen introduced. The initial consumption of liquid hydrogen required to cool the machine to 15°K is approximately 20 liters. 10 minutes is allowed to elapse after the introduction of hydrogen and then the helium gas flow is started, and simultaneously the pumping of the liquid hydrogen to low pressure is commenced. Helium liquefaction commences approximately 30 minutes after the flow is started. The high liquefaction coefficient and the liquid hydrogen consumption are comparable with that for other large liquefiers described elsewhere[5] and indicates good interchanger efficiencies.

The liquefier is easy to handle and shows excellent running stability.

IV. ACKNOWLEDGMENTS

This work was carried out with the assistance of a contract between the Office of Naval Research and The Ohio State University Research Foundation.

Design of the Radiofrequency System for the 184-Inch Cyclotron

K. R. MacKenzie,* F. H. Schmidt,** J. R. Woodyard, and L. F. Wouters
Radiation Laboratory, Department of Physics, University of California, Berkeley, California

(Received November 2, 1948)

A description is given of the frequency-modulated oscillator and its associated r-f circuits, as used in the 184-inch cyclotron for accelerating deuterons to 190 million volts or alpha-particles to 380 million volts. A 9C21 water cooled tube is used in a grounded-grid circuit, which is tightly coupled to the single-dee resonant circuit so that the oscillator follows the frequency of the dee over the wide range required. During normal operation the oscillator delivers approximately 20 kw of r-f power to the dee system at an efficiency of 60 percent, giving 20 kv at the front of the dee, although the oscillator is capable of considerably more output. The frequency is swept from 12.5 mc to 9.0 mc approximately 100 times per second by a rotating condenser connected to the dee by a half-wave transmission line. Much of the history of the design, and reasons for choices made, are given, as it is felt this may be useful to others designing frequency-modulated oscillators for cyclotrons.

GENERAL FEATURES

THE design of the radiofrequency system for the 184-inch cyclotron was started about April, 1946, shortly after the successful demonstration of the synchrocyclotron principle by the 37-inch cyclotron at Berkeley.[1] Initial thoughts regarding the exact form of the design were varied, but a single dee with some form of mechanical frequency modulation by a rotating condenser were fairly certain features. Consideration was given to the arrangement in which a rotating condenser is mounted directly at the rear of the dee, but eventually it was decided to build a high power version of the system used on the 37-inch cyclotron. This system had been tested and, although cumbersome, it seemed easier to design and build and was known to work; in retrospect, the exceptional ease of operation of the 184-inch cyclotron may be attributed in no small measure to this decision and to the experience gained with the smaller synchrocyclotron.

The r-f resonant system thus consists of a single dee and separate rotary capacitor connected by a transmission line, operating with a node near the middle, i.e., essentially the half-wave mode. The frequency range required for 200-Mev deuterons is 11.5 to 9.8 mc. Additional leeway is provided for tolerance and adjustment. It may be worth while to review the considerations involved in the initial choice of this arrangement for the 37-inch, and subsequently for the 184-inch cyclotrons:

(1) The rotary capacitor could operate outside of the magnetic field. (2) Dee and capacitor design and construction could proceed independently. (This saved considerable time, as the dee design was essentially complete before a number of basic questions regarding the rest of the r-f system had been answered.) (3) Many of the problems involved in the design of the capacitor had been worked out. (4) Vacuum systems for the cyclotron dee and for the capacitor could be independent; little was known at that time concerning the relative vacuum requirements of the two units. (5) It was shown in the 37-inch cyclotron that positive bias on the dee very often increased the beam current, and it was felt desirable to retain the possibility of similarly biasing the 184-inch dee. In addition, a bias on the dee is the surest way of providing a sweeping field to remove electrons trapped in an r-f discharge. (6) The oscillator could be coupled to the r-f system in air near the nodal point of the transmission lines, greatly simplifying oscillator design and adjustment. (7) The system is readily adjustable to give the desired shape of dee voltage *versus* frequency.

DESIGN OF RESONANT SYSTEM

As mentioned, the theoretical frequency shift required is 11.5 to 9.8 mc. At the time it was considered undesirable to have the frequency-time curve convex upward in any part of the useful range. It was thus decided to allow most of whatever extra range was provided at the high frequency end. The ions could then start (as well as finish) where the curve was concave upward. The desirable frequency limits were tentatively set at 12.5 and 9 mc. In order to insure that the higher limit would be sufficiently high, the initial layout was designed for operation between 13 and 9.5 mc. It was planned to increase the line length in order to lower both limits if necessary, by insertion of an extra line section. For this reason, the oscillator and rotary condenser are mounted on a truck, which can move back as much as 3 feet on rails. The rail arrangement also permits more facile assembly and disassembly of the r-f system, as well as withdrawal of the dee face plate (also mounted on a truck) from the vacuum tank.

It was obvious that if the rotary condenser was

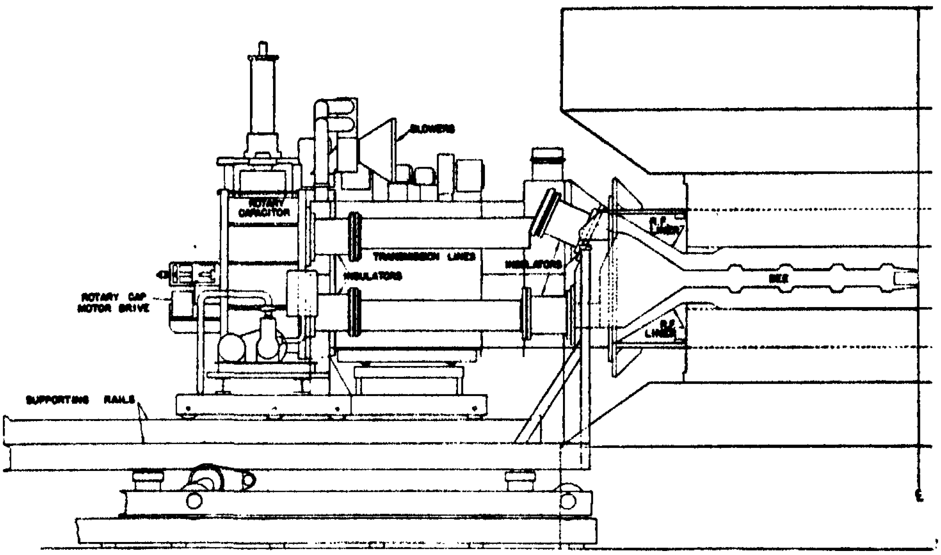

FIG. 1a. Resonant system —elevation.

to be in a negligibly weak field, the line connecting the dee to the condenser had to be quite long and, consequently, of the lowest possible impedance (around 10 ohms). An easy way to reduce impedance was to add lines in parallel, which had the advantage over a single low impedance line that something like an optimum ratio of inner to outer conductor could be maintained.

Since it seemed mechanically desirable to support both the dee and the rotary condenser stator assembly on sets of four large insulators, a four-line system was the natural choice. The arrangement shown in Figs. 1 and 2 has the advantage of permitting almost any desired degree of coupling to the oscillator without the use of auxiliary transmission lines. It conveniently permits an oscillator structure which fits in the distance between the capacitor and the dee tank.

The inner transmission line conductors consist of rolled sheet copper cylinders with appropriate cut-outs for the coupling loops, water lines, and so forth (Fig. 2). They are supported directly by their connections to the corresponding dee and condenser insulators. The outer transmission line conductor

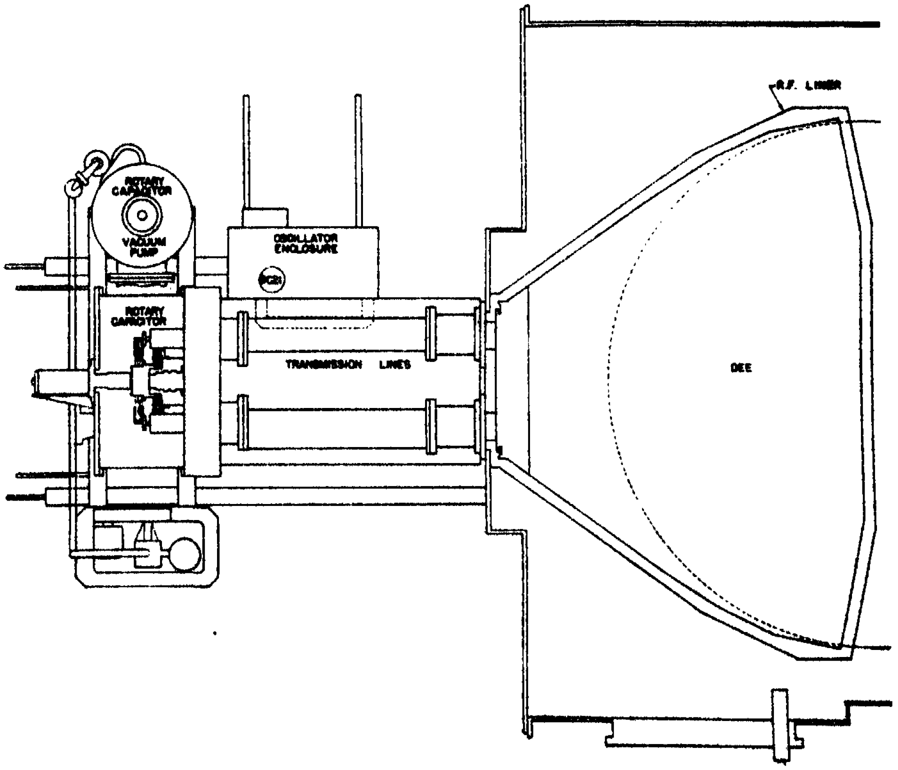

FIG. 1b. Resonant system —plain view.

FIG. 2. Transmission lines and rotary capacitor. Note slots in lines for coupling loops. The vertical pipes are air ducts for insulator cooling.

consists of an aluminum angle frame mounted on a truck, with provisions for increasing its length by replaceable end sections. This frame is the support for copper-lined masonite panels, reinforced on the edges by aluminum angles.

To minimize r-f power losses, all steel surfaces exposed to r-f fields are copper-plated. Wherever pressure contacts exist outside of the vacuum systems, good contact is established by the use of strips of thin soft copper sheet backed by foam rubber pads. Oscillator doors and transmission line covers are lined in this manner all around their edges. Under pressure from suitable clamp, these contact strips deform to match the irregularities of the surfaces which they contact, hence increasing manifold the contact area for r-f current flow.

The dee design progressed quite rapidly. In shape, it tapers from a maximum width of 15′3″ to a width of 4′3″, at the same time thickening from a height of 7″ to a height of 36″ at the back end (Fig. 1a), where the vacuum space bulges out around the pole pieces as illustrated. Its structure consists essentially of a copper covered frame having cross-wise reinforcing members, at the back of which are attached four long, sturdy, threaded shafts. These shafts support the weight of the dee on the four dee insulators, the mechanical system being so arranged that the upper two insulators are under pure compression, the lower two under pure tension. The threads permit slight lateral and vertical adjustment of the dee position. The r-f current is carried through the insulators by means of large sheet copper cylinders.

The r-f liners are simply copper sheets bolted to the magnet pole faces within the vacuum chamber. Their rear edges are crimped over the edge of the vacuum tank opening so that upon fastening the dee face plate, they contact a copper sheet lining on that face plate, thereby completing the r-f current return path within the vacuum system. On the air side of the dee face plate, the return path for the current carried to the condenser by the transmission lines is formed by the transmission line housing, whose ends are firmly connected to the insulator flanges both at the dee face plate and at the condenser vacuum tank cover plate.

The condenser copies the 37-inch rotary capacitor design in its fundamental aspects.[2] It is similar in general appearance, but of course has many more sets of blades as shown in Fig. 3. A total of seven disks, two feet in diameter, with 24 teeth each, are used in the rotor. The 8 stator rings with a matching set of blades are mounted by means of four cylindrical stems onto the four large insulators, which are in turn fastened to the condenser vacuum tank cover plate. The rotor ground coupling capacitor consists of seven solid rotor disks spaced 0.05″ from a similar set of grounded disks. In order to prevent appreciable bypassing of r-f current through the steel rotor shaft, the rotor parts are fastened to the shaft by means of two doughnut-like zircon insulators. The shaft is hollow and carries water cooling through a concentric pipe arrangement to the sealed hollow space within the rotor insulator. Because of the residual capacitance of the rotor to its shaft, 100 $\mu\mu$f or so, it is necessary to protect the bearings at each end of the rotor shaft by sets of brushes which bypass the residual r-f current.

The condenser rotor is mounted on the same steel plate as the stator insulator assembly in order to facilitate alignment of the two sets of teeth. The entire weight of the rotor is supported on a set of bearings fastened to this plate. It is driven by a removable shaft which engages the rotor at the other end and which also serves as a means of introducing the cooling water. This permits easy accessibility since the shell-like capacitor vacuum tank, and the driving shaft, together with the vacuum pumps, are mounted on a truck which may be moved completely out of the way on the rail system. The rail arrangement is shown in Fig. 1. In practice during repairs and overhauls, the capacitor cover plate (which is also mounted on its own truck), remains undisturbed. As was later determined, the effective capacity range of this rotary condenser is 400 $\mu\mu$f to 2400 $\mu\mu$f.

It should be mentioned that extensive air and water cooling is provided for all surfaces carrying r-f current, since operation at a power level as high as 100 kilowatts was originally contemplated. The condenser stator rings and support stems are cooled by copper water lines soldered to them, as are the insulator flanges and dee support stems. Likewise the dee and liners have a labyrinthian network of cooling pipes. All such pipes at r-f potential are brought to sets of hose connections in the vicinity of the nodal region; these connecting sections also serve to cool the transmission lines. The water circuit is completed to ground potential by means of sets of flexible polyethylene tubing, each several feet long. Treated water of low conductivity is used here to minimize current leakage resulting from the dee bias voltage.

---

[2] F. H. Schmidt, Rev. Sci. Inst. 17, 301 (1946).

Air blast cooling from a blower is directed onto the rotary condenser insulators. On its way through the transmission line housing the air serves to cool the outer panels. It finally funnels past the dee support insulators and leaves the system. Total air flow in this system is about 2000 c.f.m.

A major structural and electrical problem in connection with the resonant system design was posed by the feed-through support insulators used for both the dee and the condenser stator stems. These are 15 inches in diameter and 18 inches long. A test apparatus consisting essentially of a high-Q quarter-wave resonant line was constructed.[3] At the open end of the line, the insulators could be operated under simulated vacuum and electrical cyclotron conditions. Over 50-kilovolt r-f could be developed across the insulator at 13 mc by a 5-kilowatt oscillator. Under the most severe test conditions, air blast cooling of the insulators was found necessary.

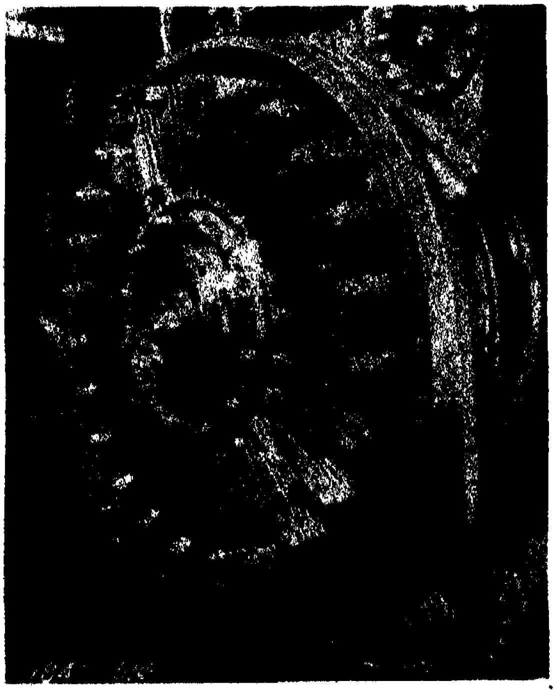

FIG. 3. Rotary condenser.

The same apparatus was employed to measure breakdown between test condenser blades under conditions likely to prevail in the actual rotary capacitor. It was found that a 0.080″ gap between copper or copper-plated surfaces having a reasonable polish would hold a maximum of 50 kilovolts at 13 mc at a pressure of about 5×10^{-6} mm. It was therefore expected that a voltage of about 40 kv could be held in the operating unit. The behavior of the capacitor and of the insulators in actual practice will be discussed.

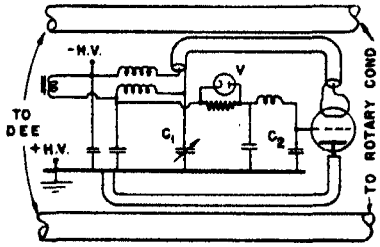

FIG. 4. Oscillator circuit: Two of the 4 lines from dee to rotary condenser are shown. The filament loop couples to the upper and the plate loop to the lower. $C_1=500$ $\mu\mu$f. $C_2=750$ $\mu\mu$f. V = rectifier to prevent positive d.c. on grid due to secondary emission.

SCALE MODEL TESTS

The design had thus progressed a long way, even though a number of dimensions were not well established. The rotary condenser capacitance and the transmission line length were particularly uncertain, but because of the flexible arrangement, they could be easily adjusted within reasonable limits. For the accurate determination of these values, as well as for determining r-f power requirements and testing oscillator layout designs, it was necessary to build a scale model of the r-f system. For reasons of convenience, a quarter scale was chosen. The resonant frequency is then increased fourfold and all inductances and capacitances are reduced by a factor of four. The frequency range is thus around 40 to 50 mc, which is still not too high to be handled by ordinary triodes. For a given dee voltage, the required power is doubled. If an accuracy scaled version of the coupling arrangement is used, the impedance as seen by the oscillator is halved, the Q of the scaled system being one-half the Q of the actual system.

The criterion used for determining the capacitance and line length, besides that imposed by the frequency range, was that the capacitor voltage should not exceed the dee voltage at the highest frequency. This is, of course, realized if the minimum capacity of the condenser just equals the effective capacity of the dee. The basis for this adjustment of the resonant system is that since the insulators are the weakest link in the r-f system, it is preferable to arrange matters so that the condenser insulators are not under any worse condition than the dee insulators.

---

[3] F. H. Schmidt, *High Frequency Insulator and Vacuum Breakdown Tests.* (AEC Report No. MDDC-473, declassified).

The scale model tests immediately showed that under such conditions the line length in air would have to be about 10 feet; at 12.5 mc the required capacitance would then have to be 700 $\mu\mu$f; at 10 mc it would have to be 1850 $\mu\mu$f. The dee and condenser voltage became equal at about 13.5 mc where the minimum capacitance is 500 $\mu\mu$f. This indicated that the effective dee capacitance would be 500 $\mu\mu$f, even though a capacitance measurement indicated it to be 1600 $\mu\mu$f. To the extent of this difference, the dee acts as a line, because of its appreciable size relative to a wave-length.

THE OSCILLATOR

The choice of a grounded grid oscillator was an almost foregone conclusion in view of the unequalled success of this arrangement in all recent Radiation Laboratory r-f installations requiring high power at moderately high frequencies. The oscillator circuit was chosen identical to that of the 37-inch oscillator,[4] since this type of circuit produces the desired[5] r-f voltage rise during acceleration (Fig. 4).

The oscillator unit is mounted on rails so that it can be rolled away from the dee stem enclosure for major servicing or replacement. The oscillator enclosure is made of $\frac{1}{4}''$ steel. Consequently, this house serves as a magnetic shield for the oscillator tube. A crude replica ($\frac{1}{16}$ size) was tested by the magnetic measurements group, using the $\frac{1}{16}''$ scale 184-inch model magnet, and this shielding was found sufficiently effective, the field being cut from 140 gauss to less than 20 gauss. This is further reduced at the 9C21 elements by means of a $\frac{1}{2}''$ steel sleeve over the cooling jacket. The magnetic force on the oscillator housing amounts to 450 lb. The housing and components are shown in Figs. 5 and 6.

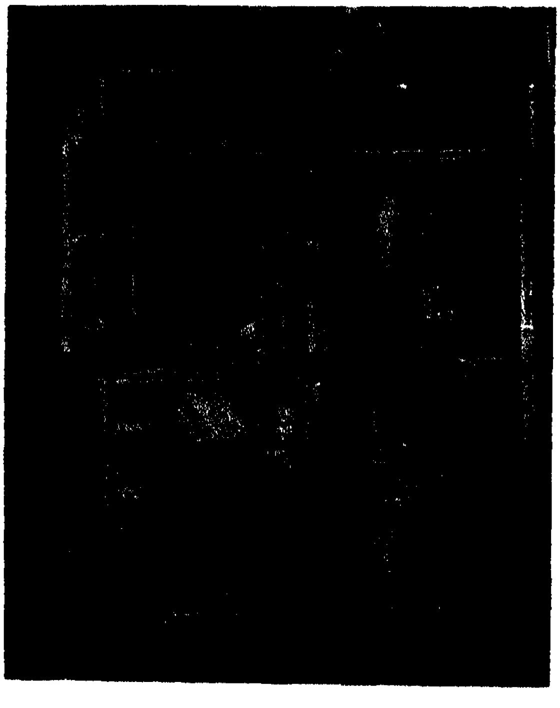

FIG. 5. Front view of oscillator with doors open. Anode water jacket is in lower right-hand corner, grid grounding capacitors in upper right, filament chokes and filament loop phase correcting capacitors in upper left, and filament transformer in lower left.

The choice of a 4-line resonant system makes it very easy to couple plate and cathode loops thereto with the shortest possible uncoupled lengths. These emerge through the rear wall of the oscillator box, each opposite a transmission line, and fit into slots cut in those lines to achieve maximum coupling with adequate high voltage clearance. These slots may be seen in Fig. 2. The end of each loop is thus automatically located opposite the particular tube electrode to which it is connected. The plate loop (lower) is directly grounded to the oscillator box at its other end. The high voltage power supply thus operates with its positive side grounded, eliminating the necessity of supplying low conductivity water to the tube jacket, the water lines being piped through the plate loop. The cathode loop (upper), which is bypassed to ground at its far end by means of a ring of 10 fixed vacuum condensers (about 500 $\mu\mu$f total), serves as one side of the filament heating circuit, the other side consisting of 4 heavy cables passing through the loop. The ring of high vacuum condensers also acts as the cathode circuit phasing capacitor to correct for the phase difference introduced between cathode voltage and plate voltage by the cathode loop self-inductance. Adjustment is obtained by exchanging one or more of the condensers for one or more of different value.

The grid is grounded for r-f voltage by a similar ring of fifteen 50-$\mu\mu$f capacitors. The total capacity is chosen so that in conjunction with the grid leak, its charging time is small enough when compared to the charging time of the resonant circuit to prevent intermittent oscillation.

In this coupling loop arrangement there exists a negligible amount of coupling between plate and cathode circuits; consequently, that parasitic mode in which most of the energy is in the plate loop cannot be excited.

The degree of amplitude modulation depends on the plate-loop resonant frequency, decreasing in percentage as this frequency is raised as far as possible above the cyclotron frequency. On the other hand, if the plate-loop resonant frequency can coincide with a harmonic of the dee system frequency, a serious dip will occur in oscillation amplitude as the f-m cycle passes through that frequency. Since the tube capacity and loop inductance put an upper limit to the plate loop frequency of about 20 mc, it was necessarily lowered by addition of the vacuum capacitors shown between water jacket and ground, until the frequency was under 18 mc (twice the lower limit of the cyclotron frequency). Again, this can be adjusted by exchange of vacuum condensers, hence serving as a convenient means of control of the percentage of amplitude modulation.

---

[4] K. R. MacKenzie and V. Waithman, Rev. Sci. Inst. 18, 900–907 (1947).

[5] D. Bohm and L. I. Foldy, Phys. Rev. 72, 649–661 (1947).

This argument does not apply to the filament loop, so that its frequency was made as high as possible by taking great pains to reduce the self-inductance not serving as mutual inductance in the dee circuit. This has the desirable effect of reducing the phase shift between cathode and plate r-f voltage, and of insuring that the excitation represents a fairly constant fraction of the dee voltage. Actually, because of the dee voltage rise with lowered frequency the excitation also rises, although not quite so rapidly. This is desirable, since the tube must supply considerably more power at the low frequency end, and consequently requires more cathode driving voltage. While this power increase is principally due to the increase in dee voltage, it is also in part due to the fact that the condenser losses are greatest when the teeth are fully meshed.

OSCILLATOR MODEL TESTS

For the purpose of coupling loop measurements, it was necessary to electrically duplicate in the scale model the behavior of the 9C21. The only low power tube then available which seemed to fit the scale requirements, as well as having easily accessible electrodes, was the 304TL. This tube operates with about the same effective plate resistance as the 9C21, but since the load impedance in the model is reduced by a factor of two (because of the non-scaling of Q) it was necessary to use two tubes in parallel. This arrangement had the fortuitous circumstance of having scaled interelectrode capacitances about equal to those of the 9C21. However, the 304-TL requires approximately twice the relative grid driving voltage. With a ¼-scale version of the coupling loops, the 304TL's were thus underdriven by almost a factor of two and operated at around 40 percent efficiency at the low frequency end of the range. This corresponds to about 75 percent efficiency in the actual cyclotron oscillator. Operation of the model under these conditions was thus much more difficult than of the full scale oscillator, but had the advantage that if the model worked, the full scale version was even more certain to work. Because of this non-linear scaling of efficiency it became difficult to predict the amplitude modulation shape from the behavior of the model. The ¼-scale model oscillator is illustrated in Fig. 7.

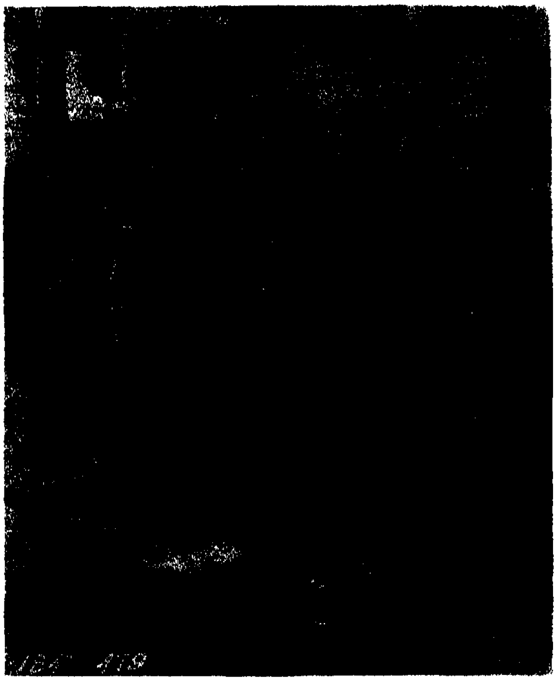

FIG. 6. Rear view of oscillator house showing coupling loops.

OPERATING CONDITIONS AND EXPERIENCES

Initial tests of the full scale r-f system disclosed a re-entrant cavity resonator mode between the two pole pieces of the magnet with the vacuum tank walls as the return circuit, resonant near the lower frequency limit. This was easily suppressed by strapping the pole pieces together at their outer edge. It was also found that the frequency range did not extend low enough by almost one megacycle, even after extensive padding of the resonant system. Since the extra line section had not been made, the easiest solution was the removal of one of the two transmission lines not associated with the oscillator coupling system. This more than sufficiently reduced the frequency limits (about 10 percent). While the effect of this change had previously been measured on the model, it had not been seriously intended that a correction be made in this way. The consequent reduction in efficiency was of no importance, as the high r-f dee voltage of 40 kv was not found necessary. The evident discrepancy in transmission line length was eventually traced to a cumulative error of about two inches in various small errors in model dimensions.

The plate circuit resonant frequency turned out to be too close to the second harmonic of the lower limit of frequency modulation, as evidenced by severe amplitude modulation. Considerable plate capacity was eventually added to improve this

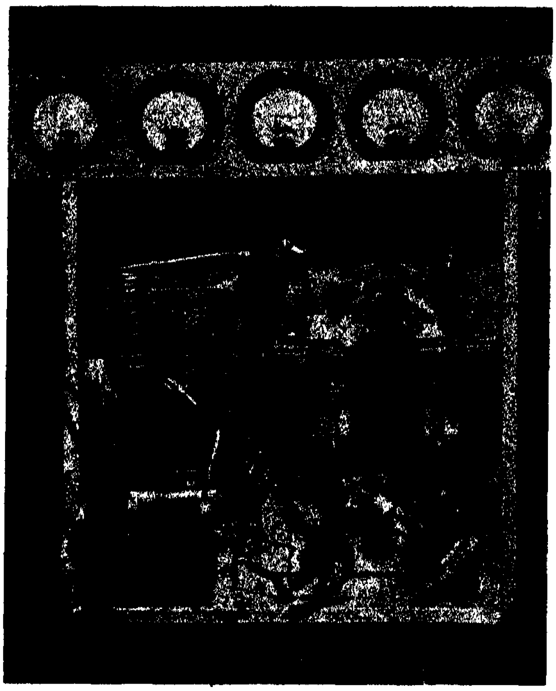

FIG. 7. Model oscillator using 304TL tubes. Front view.

situation. The lack of sensitivity of the beam to even such severe amplitude modulation is of particular interest. Figure 8 plots the amplitude and frequency modulations as a function of time.

Under vacuum, some difficulty was experienced as a result of discharges in the large spaces around the dee. It was easily shown that r-f field conditions can exist which permit electrons to execute resonant oscillations at these frequencies and the appearance of the discharges seem to fit such a theory fairly well. In the particular case of those discharges quite far removed from the immediate vicinity of the dee, where the r-f field is relatively weak, the picture of resonant electrons fits better than does the picture of the non-resonant type of discharge as exists in Philips ion gauges. It is suspected that secondary electron multiplication ("multipactor action") may also be taking place. This does not preclude the Philips gauge type of discharge near the dee, since here an electron has ample time and energy to perform numerous vertical excursions during a positive r-f cycle. All discharges were eliminated by cutting down the available volume by means of perforated shields around the sides of the dee, by adding a grounded "dummy" dee, and by applying a negative bias to the dee.

There is sufficient magnetic field at the rotary condenser to allow a Philips gauge discharge when positive bias is applied; a negative bias is therefore imperative. Fortunately the beam does not seem sensitive to bias, as it often was in the 37-inch cyclotron with positive bias voltage. The increase in beam obtained there may presumably have been due to just such a discharge which increased the ion supply near the ion source.

Several days after the beam was obtained with but 15-kv r-f dee voltage,[6] troubles occurred with the rotary capacitor, characterized by increasing sparking and mechanical sticking. This was found to be due to warpage of the copper-plated stainless steel disks used in the bypass condenser because of poor heat conduction. Spacings were increased, but this afforded only temporary relief. Copper replacement parts then became available and no further difficulties have occurred since their installation.

The blade gap only holds about 30-kv r-f and this may be attributable to the lessened clearance (0.06″ instead of 0.08″) in the final unit, in addition to the severe over-all roughening of the surfaces by discharges taking place during bakeout and sometimes during operation. Occasional water leaks occur around the rotor insulator gaskets, but these have been insufficiently frequent to warrant any major revision.

The r-f insulators have given no trouble whatever since installation one year ago, though at the time of assembly, their fragility was evidenced insofar as shear forces were concerned. The care taken in insuring that only pure tension and compression forces would be applied was thus well justified.

The average power required for a given dee voltage is essentially the same as predicted from the model and is around 40 kilowatts for an amplitude variation from 20 to 30 kilovolts through the f-m cycle. Provision was made in the power supply for arbitrary amplitude modulation by insertion of three parallel 893-power triodes in the d.c. plate power circuit, but they have been used thus far only as current limiters and voltage adjusters.

The authors wish to express their gratitude to Professor E. O. Lawrence and the staff of the Radiation Laboratory for advice and encourage-

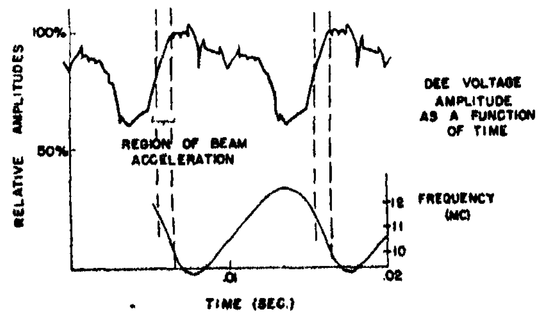

FIG. 8. R-f system frequency as a function of time. Dee voltage amplitude as a function of time.

THE REVIEW OF SCIENTIFIC INSTRUMENTS VOLUME 20, NUMBER 2 FEBRUARY, 1949

A Method for Measuring Very High Speed Transient Currents

A. M. Zarem* and F. R. Marshall
U. S. Naval Ordnance Test Station, Pasadena Annex, Pasadena, California

(Received October 2, 1948)

A deflection coil suitable for use in measuring very high speed transient currents is described. When used with a type 912 cathode-ray tube operated at a 15,000-volt accelerating potential, this coil provided a spot deflection of one inch at approximately 50 amperes of current.

A mutual inductance device was constructed to extend the range of measurement of the deflection coil. This device consists of two loops of wire ¾″ in diameter and coaxially positioned with adjustable spacing. The current under study is allowed to flow in one coil, and the other coil is connected to the deflection coil.

Results are given of an analysis of the transient response of such a circuit, taking into account increased losses caused by the transient skin effect. Accurate design of a transformer and deflection coil system to meet specific requirements is facilitated by the analysis.

The deflection coil and transformer described herein has excellent response for transients as long as two microseconds in duration.

IN the course of a recent investigation of spark discharges, there was a need for measuring transient high currents of microsecond duration. The use of a resistive shunt in conjunction with an electrostatic-deflection cathode-ray tube was not possible for the following reasons:

(a) The use of a current shunt of resistance high enough to develop directly the necessary voltage for deflection causes excessive disturbance of the circuit conditions.

(b) The use of a lower resistance shunt in conjunction with an amplifier proved unsatisfactory because of the frequency distortion introduced by the amplifier.

A subsequent study of magnetic deflection demonstrated that it was entirely feasible to obtain satisfactory fidelity by allowing the current under study to flow in a specially designed deflection coil. In Fig. 1 is shown the one-turn deflection coil used with the current path indicated by arrows. It is constructed of copper sheet for low inductance and resistance.

When used with a type 912 cathode-ray tube operated at a 15,000-volt accelerating potential, this coil provided a spot deflection of one inch at approximately 50 amperes of current. This sensitivity was much too great for the application, since currents of from one thousand to ten thousand amperes were under study.

A mutual inductance device was constructed to

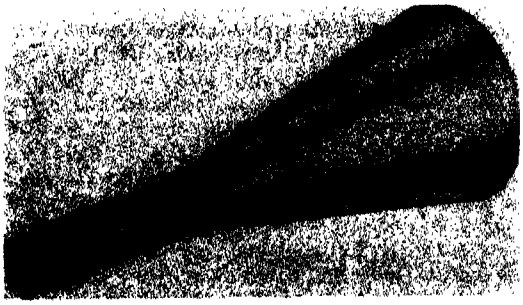

Fig. 1. Deflection coil. Arrows indicate the current paths.

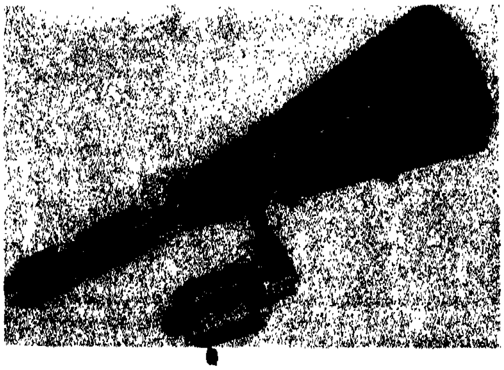

Fig. 2. Transformer and deflection coil in place on cathode-ray tube.

* Present address: Stanford Research Institute, Transamerica Building, Los Angeles, California.

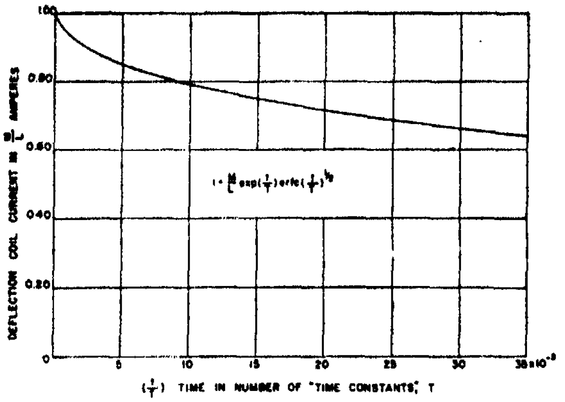

FIG. 3. Response of transformer for unit current suddenly initiated in the primary circuit.

extend the range of measurement of the deflection coil. This device consists of two loops of wire ¾″ in diameter and coaxially positioned with adjustable spacing as shown in Fig. 2. The current under study is allowed to flow in one coil, and the other coil is connected to the deflection coil. If the resistance of the secondary is neglected, the ratio of current flowing in the secondary i_s, to the current flowing in the primary i_p, is

$$i_s/i_p = M/L, \tag{1}$$

where M is the mutual inductance between primary and secondary, and L is the total inductance in the secondary—including the deflection coil.

An analysis of the transient response of such a circuit was undertaken to determine how closely the wave form of current in the deflection coil resembles the primary current. In this analysis it was necessary to consider the increased losses due to the skin effect of current flowing in the conductors. For unit current suddenly initiated in the primary at zero time, the secondary current is given by the expression

$$i_s = (M/L)\exp(t/T)\,erfc(t/T)^{\frac{1}{2}}. \tag{2}$$

Here

M = mutual inductance between coils of the current divider,
L = total inductance in the secondary circuit,
t = time,

$$erfc(x) = [2/(\pi)^{\frac{1}{2}}]\int_x^\infty \epsilon^{-x^2} dx,$$

T = a "time constant" of the secondary circuit giving a measure of the decay time due to skin effects under transient conditions,

$$T = [L/(l/s)(4\pi\mu\rho/10^9)^{\frac{1}{2}}]^2 \quad \text{(practical units)}, \tag{3}$$

where

l/s = ratio of length of conductor to perimeter of conductor (if the conductor perimeter is not constant, use the expression $\oint_l (dl/s)$),
μ = conductor permeability,
ρ = conductor resistivity.

Equation (2) is correct up to the time when current (initially flowing on the surface only) penetrates into the conductors for a distance comparable to the conductor radius. Thus the expression gives quite exactly the first part of the transient response (in which we are interested). A plot of Eq. (2) is given in Fig. 3 for values of time between zero and $0.035T$.

The design of a transformer and deflection coil system is approached as follows:

(a) Estimate the probable duration of the transient to be studied.

(b) Chose the acceptable distortion and determine the value of T from Fig. 3.

(c) Using the formula for T, determine the optimum design of circuit which will give the desired response.

The deflection coil and transformer shown in Fig. 2 (for which $T = 640$ microseconds) has excellent response for transients as long as two microseconds.

Laboratory and Shop Notes

Pulsed Oscillator for F-M Cyclotron*

J. W. Burkig, E. L. Hubbard, and K. R. MacKenzie
Department of Physics, University of California, Los Angeles, California

October 28, 1948

In the 41″ f-m cyclotron at U.C.L.A., the useful frequency range is 16 percent of the total cycle. Since the dee voltage is limited by the plate dissipation of the oscillator tubes, it has been possible to increase the dee voltage by pulsing the oscillator, so that it is in operation only during the useful part of the f-m cycle.

The cyclotron oscillator using four Eimac 304-TL tubes in parallel has been described by MacKenzie and Waithman.[1] The pulsing has been obtained by replacing the grid leak resistor of the oscillator by the plate to cathode resistance of a 304-TH tube. When this tube is conducting, the oscillator operates normally. When it is not conducting, oscillation is stopped, since the grid leak resistance becomes infinite.

A diagram of the circuit for the control tube is shown in Fig. 1. The loop L is inserted into the outer conductor of the transmission line connecting the dee and rotary capacitor, so that the loop and coil are magnetically coupled to the tank circuit of the oscillator. The coil is tuned just below the frequency at which the ions emerge (18 mc). When the frequency coincides momentarily with the resonant frequency of the coil, a high r-f voltage appears on the grid of the control tube which accordingly draws grid current and acquires a negative bias. As soon as the oscillator frequency passes beyond the coil resonance frequency (in the direction of decreasing frequency), the r-f voltage on the control tube vanishes and the negative bias prevents the flow of plate current. The 304-TL oscillator tubes, however, still draw grid current, and the accumulating charge rapidly biases the tubes to cut off. The charge leaks off the condensers c_1 and c_3, and the control tube becomes conducting again after a time dependent upon the time constant $R_2(C_1+C_3)$. R_2 has been adjusted so that the oscillator is off during about ¾ of the frequency cycle. Resistor damage due to r-f is prevented by the small condenser C_3.

The pulsing circuit is mounted in a shielded cage which is connected to the grids of the oscillator tubes. This cage is mounted on insulators adjacent to the oscillator tubes. The cage voltage to ground is equal to the oscillator plate supply voltage plus grid bias.

The repetition rate required is about 1000 c.p.s., which requires that the oscillator be shut off for a period of ¾ millisecond. The time required for sufficient charge to leak off condensers (C_1+C_3) is not easily estimated, since it is a function of the initial charge, which is in turn a function of the coupling between the loop L and the dee stem. R_2 and the coupling are adjusted empirically to give the required off time. The coupling is not critical and is adjusted to give around 1000 volts r-f on the grid. The resistor R_1 is necessary to damp any tendency of the circuit to act as an r-f amplifier for any stray pick-up coming in on the filament leads.

The 304-TH tube proved to be more satisfactory than the 304-TL for control purposes, since it was much easier to cut off. Trouble was experienced when the 304-TL was tried, because the tube was incompletely cut off, which allowed the oscillator to start oscillating before the 304-TL control tube d.c. plate resistance had reached a low enough value. The oscillator would then immediately cut off again, as in the usual "blocking" oscillation caused by too high a grid leak grid condenser time constant.

Installation of the pulse circuit has allowed a 50 percent increase in dee voltage with one-half the previous plate dissipation. The present normal average power consumption, under pulse conditions, is approximately 4½ kw input for 12 kv on the dee, although the tubes, operating with their present efficiency, will allow a 6-kw input. Operation at the higher power level is more unsteady due to frequent tripping of overload relays. Throughout the construction of this circuit the authors have been indebted to Mr. S. H. Plunkett for suggestions and assistance.

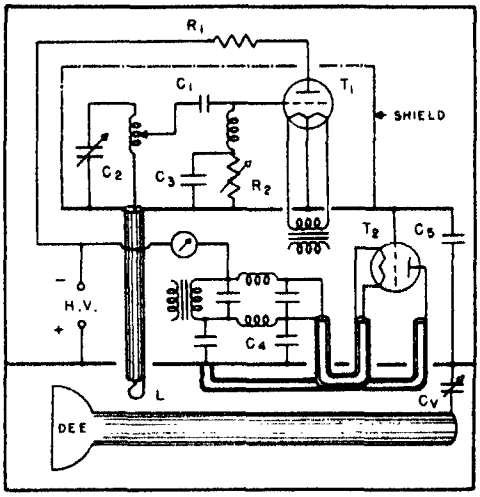

FIG. 1. Oscillator circuit. Pulse operation is obtained by replacing the oscillator grid leak by the components inside the shield. L = loop, C_1 = 0.001μf, C_2 = 0–500μμf, C_3 = 250μμf, C_4 = 200μμf, C_5 = 1500μμf, C_v = 200–700μμf rotary capacitor, R_1 = 100 ohms, R_2 = 150,000 ohms, T_1 = 304-TH, and T_2 = four 304-TL tubes in parallel.

Toggle-Operated Vacuum Valve

Ralph O. McIntosh and John W. Coltman
Research Laboratories, Westinghouse Electric Corporation, East Pittsburgh, Pennsylvania

October 21, 1948

A SIMPLE, compact, positive-action valve has been made for use on high speed, high vacuum systems. The valve utilizes a toggle mechanism to obtain positive wide opening and high closing pressure with simple construction. A standard mechanical shaft seal has been found to be suitable for use with high vacuum.

The design of the valve is shown in Fig. 1 in the open position. A circular plate (1) carries an O-ring[1] gasket (2) in a suitably shaped groove. This gasket seals against the smooth top surface of the lower flange (3). The toggle mechanism, which consists of a link (4) and a crank (5) operated by a shaft (6), is connected to the circular plate by means of a screw (7) for adjustment of closing pressure. A lock nut (8) for fixing the adjustment is provided. Maximum travel for the space occupied and a high mechanical advantage during compression of the gasket are features obtained by the use of the toggle action. A set-screw (9) is positioned in the body of the crank to bear against the link when the valve is closed. Adjustment of this screw permits convenient setting of the throw-over of the toggle to take advantage of its inherent locking action.

A cage is formed around the circular plate by three guide pieces (10) to act as a track for the plate in any position of the valve. The crank is set-screwed to the operating shaft (6)

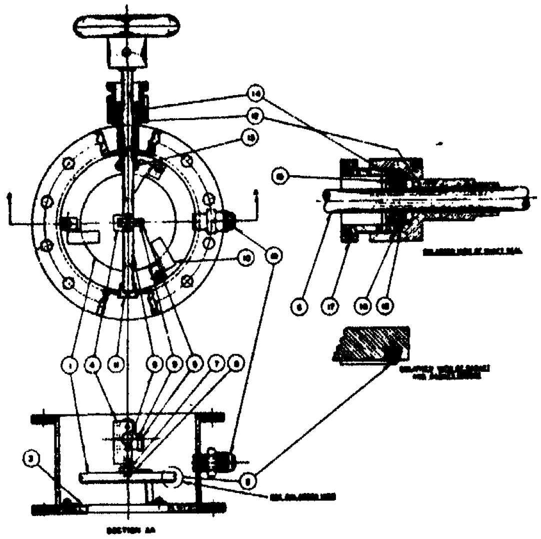

FIG. 1. 4-in. vacuum toggle valve.

which rotates in a blind bearing (11) and passes out of the valve body through a ventilated bearing (12), being positioned by a thrust collar (13). The shaft seal uses an assembly (14) which is commercially available[2] in a variety of sizes. This assembly is held in place by a sprocket-shaped screw (15) and is sealed on the outside rim of its metal frame by a Neoprene gasket (16) which is compressed by screwing in the ring (17) against a washer (18) which is slotted to clear the sprocket-shaped screw. The shaft is $\frac{1}{32}$ inch larger in diameter than the manufacturer recommends. If these sealing assemblies were obtainable with a Neoprene gasket bonded to the metal rim, the arrangement of the shaft seal could be greatly simplified. The assembly has been successfully mounted by soft-soldering it directly to the end of a simpler shaft bearing instead of using a clamping arrangement but great care is required during the soldering.

Several valves of this design have been in use for more than a year with very satisfactory results. The valve was intended to be used such that, when closed, the air pressure on the circular plate would tend to compress the seating gasket, but in practice no such precaution is necessary. A rough-down connection (19) was provided to reduce the pressure preparatory to opening the valve. This is useful to reduce the amount of gas admitted to the diffusion pump in the system, but the valve can easily be open with atmospheric pressure tending to hold it closed.

[1] The O-rings used here were obtained from Linear, Inc., Philadelphia, Pennsylvania.

[2] The shaft seal assembly used here is a "Type L Garlock Klosure," obtained from the Garlock Packing Company, Palmyra, New York.

Note on Constant Current Regulators

E. E. MINETT,* D. A. MACRAE,** AND J. TOWNSEND***
Carbide and Carbon Chemicals Corporation, Oak Ridge, Tennessee

October 21, 1948

NUMEROUS measurement and instrument problems require the establishment of a source of constant direct current. Current regulating circuits have been described in the literature[1] which are variations of the standard electronic voltage regulator. In the case of a constant current regulator, the controlling voltage is the difference between the potential drop across the load, or across a series resistor in the current output line, and a reference voltage derived from a gas regulator "*VR*" tube.

The above circuit works well in principle. However, in practice it is frequently difficult to obtain a potential drop-current relationship in the series resistor or load which will not change with time as the resistor heats up. The essential difficulty arises from the fact that the dropping resistor must carry the full regulated output current. Considerable wattage must be dissipated if large currents are to be handled and when a substantial voltage drop is desired. If ordinary wire-round resistors are used, it is found that ambient temperature control must be provided, even with resistance wire which has a low temperature coefficient. This is inconvenient and frequently expensive.

In the course of improving the current regulation in a mass spectrometer magnet supply, it has been found advantageous to use an incandescent lamp filament as the dropping resistor. The filament is operated at incandescence, so that the heat losses are very largely radiative and independent, within a few parts in ten thousand, of normal variations in room temperature. Because of the low heat capacity of the filament, equilibrium is reached within several seconds. Because of their non-linear voltage-current characteristic, for a given change of current tungsten lamps furnish approximately twice as much signal voltage to the regulating tubes as do linear resistors operating at the same voltage and current.

It has been found possible to regulate a 250-ma current to 2–3 parts in 10,000 over periods of many hours, using a 25-watt, inside-frosted, gas-filled, tungsten Mazda lamp as series resistor, a VR-90 to provide the reference voltage, a 6SJ7 as control tube, and parallel 807's as series regulator tubes.

A Lock-In *RC* Oscillator

W. C. ELMORE AND D. BANCROFT
Swarthmore College, Swarthmore, Pennsylvania

November 30, 1948

RECENTLY, in connection with the design of a laboratory time standard the problem occurred of converting a continuing sequence of regularly spaced pulses into a sinusoidal wave. At low audiofrequencies—for instance, 50 c.p.s.—inductors with high Q's are impracticable, so one cannot use tuned *LC* circuits for this purpose. It is possible, of course, to employ an electromechanical filter such as an electrically driven tuning fork. If one contemplates securing a series of frequencies in the low audio range, this solution to the problem does not appear attractive. We have found that a satisfactory way of converting pulses to sine waves is by means of an electronic oscillator whose frequency is locked to that of the non-sinusoidal wave form. The use of such a *lock-in* oscillator for this purpose is certainly not new. The circuit devised by us, however, possesses several novel features which make it worth describing here. It will be assumed that the oscillator has impressed on it a periodic signal consisting mostly of fundamental component. Since it turns out with the circuit devised that a signal of only one-tenth of a volt is satisfactory for a reliable frequency lock, one can remove a considerable fraction of the high frequency components by a simple *RC* filter, which also can serve as part of an attenuator.

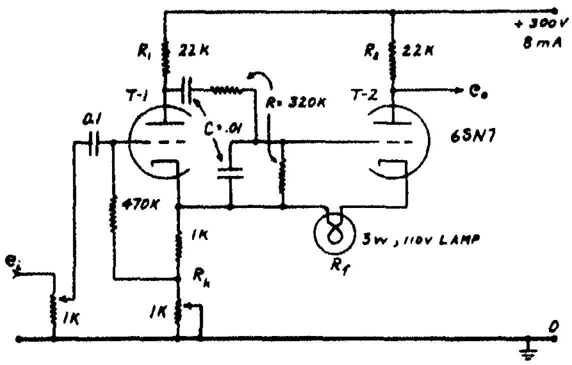

FIG. 1. Lock-in *RC* oscillator for 50-c.p.s. operation.

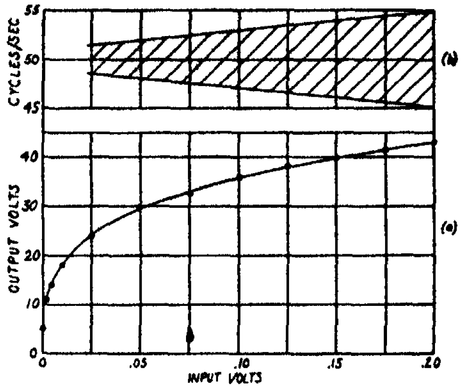

FIG. 2. Locking characteristics of oscillator.

The basic oscillator circuit is a modification of the much-used Wien-bridge circuit.[1] The present circuit, Fig. 1, differs from the conventional one in that the feed-back loop is completed by a regenerative connection between the cathodes of two triodes. The regenerative path consists of a 3-watt, 110-volt lamp that serves to stabilize the amplitude of oscillation within the range of linear (Class A) operation of the tubes. The arrangement adopted leaves the grid of one tube (*T*-1) free for the injection of the locking signal. In addition, the plate circuit of the other (*T*-2) has a considerable degree of isolation from the remainder of the circuit, and can serve as a source of the sinusoidal output signal. (The isolation would be nearly perfect if a pentode were used for *T*-2.) The variable portion of the cathode resistor R_k permits setting the regenerative feedback at a point where resistance changes in the lamp serve to stabilize the amplitude of oscillation. It is found expedient to set the amplitude of oscillation in the absence of an injected signal at a low level. The reason for this choice will become evident in subsequent discussion.

The resistors and capacitors in the Wien-bridge network (*R*, *C*) are so chosen that the frequency of oscillation is close to that of the input signal. Part of one or of both the resistors may be made adjustable to permit fine tuning of the oscillator. The resistance *R* should be high compared with the plate-load resistance R_1 to minimize the effect on frequency of changes in plate resistance. The values given in the figure have been found suitable for 50-c.p.s. operation.

Grid bias for *T*-1 is obtained from a tap on the cathode resistor R_k. Bias for *T*-2 is furnished by the *IR* drop across the lamp.

Let us now consider the operation of the circuit when a periodic signal of nearly the same frequency as the natural frequency of oscillation is applied to the grid of *T*-1. If the signal has sufficient amplitude—a tenth of one volt is sufficient if the injected signal has a more or less square wave form, the frequency of oscillation locks to that of the injected signal and the amplitude of oscillation increases. The increased signal amplitude has an important consequence in that *it causes the resistance of the lamp to increase beyond the value fulfilling the condition for oscillation.* The circuit becomes, in effect, a band-pass amplifier whose gain is greatly magnified by regenerative feedback. As long as the signal amplitude maintains the resistance of the lamp above the value required for spontaneous oscillation, the circuit responds chiefly to the fundamental frequency component of the injected signal. It is not possible for it to oscillate at its own natural frequency which may differ slightly from that of the input signal. In practice it is found that the breadth of the resonance curve (of the regenerative band-pass amplifier) is sufficient that the natural frequency of oscillation can depart several percent from that of a square-wave input signal before the circuit breaks into its own mode of oscillation. The loss of control is very definite when it occurs and results from a decrease in amplitude of the amplified signal which, in turn, reduces the resistance of the lamp to the value fulfilling the condition for oscillation.

When the magnitude of the input signal is held within suitable limits (0.05 to 0.2 volt), the output signal appears to be sinusoidal when viewed on a cathode-ray oscilloscope. No measurements have been made of the small amount of harmonic distortion that may be present.

The stabilizing action of the lamp tends to reduce variations in the amplitude of the output signal for small changes in input level and for small frequency deviations. This feature is illustrated in (*a*) of Fig. 2 which shows a plot of output voltage against input voltage when the input frequency and the natural frequency of oscillation (50 c.p.s.) coincide. For the purpose of this test the input signal was made sinusoidal. In (*b*) of the same figure are shown the frequency limits within which the output signal stayed within 70 percent (3 db) of the maximum occurring at 50 c.p.s. In these tests the r.m.s. amplitude of free oscillation was set at five volts. Definite failure of locking occurred when the frequency departed sufficiently from 50 c.p.s. for the amplitude to drop to about 5 volts.

It should be noted that the resistance of the lamp depends both on the direct current and the alternating current through it. For this reason the plate supply voltage should be stabilized.

D.C. Flat Card Resolver

R. G. Murdick
Aeronautics and Ordnance Systems Division, General Electric Company, Schenectady, New York

August 9, 1948

THE purpose of this paper is to introduce an accurate, compact, and inexpensive d.c. resolver. Methods of producing in d.c. computing networks voltages proportional to the sine and cosine of the input angle have frequently involved either the use of more equipment than is desirable or loss of accuracy. Of all known devices, the most compact is the flat card resolver with four brushes to give ±sine θ and

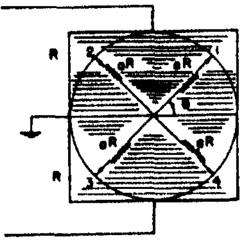

FIG. 1. Flat card resolver.

±cos θ where θ is the angle of rotation. (See Fig. 1.) The brushes are displaced 90° from each other. The amount of the resistance of R measured from ground that is subtended by the brush at 1 is proportional to sine θ and that subtended by 2 is proportional to cos θ. Similar relations hold for brushes 3 and 4.

If the total resistance of the resolver is $2R$, then the ratio of the resistance load on one brush to the resistance of the resolver between a terminal point and ground is a and is called the cascade ratio. If a is large, this device is excellent. However, in many computations a is necessarily restricted to values below ten. A plot of the errors for various cascade ratios is shown in Fig. 2. These errors were computed by usual loop analysis methods. Figure 3 shows the schematic form of the network on which the set of equations required to determine the output voltage was based.

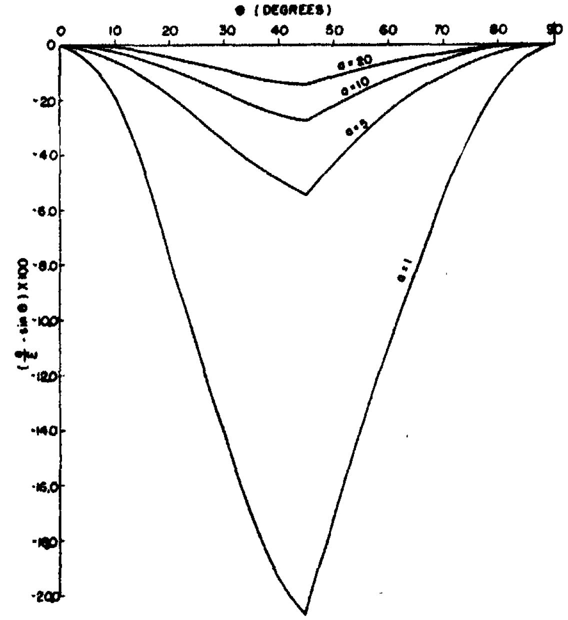

FIG. 2. Error for four-brush resolver. Cascade ratios of 1, 5, 10, and 20.

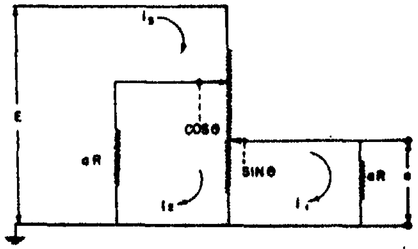

FIG. 3. Schematic diagram of section resolver used for loop analysis.

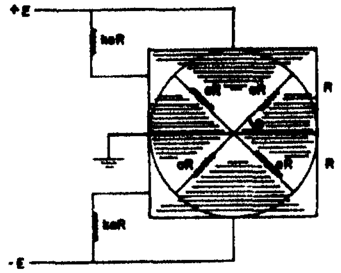

FIG. 4. Modified flat card resolver.

$$(aR+R\sin\theta)i_1-R\sin\theta i_2=0,$$

$$-R\sin\theta i_1+(aRR\cos\theta)i_2-aRi_3=0,$$

$$-aRi_2+[R(1-\cos\theta)+aR]i_3=E.$$

This set of equations is solved for i_1 and e is determined as i_1aR. Since it is desired that $e/E=\sin\theta$, the error plotted in Fig. 2 is obtained by plotting $[(e/E)-\sin\theta]$ *versus* θ. From these results, it is apparent that with a cascade ratio as high as ten, the error is of such magnitude as to preclude this type of resolver in the design of accurate computing nets.

In Fig. 4 a modified flat card resolver is shown that is approximately ten times as accurate as that in Fig. 1 when the cascade ratio is three in each case.

If $a=3$ and the resistances kaR are connected at the points $\theta=\pm 45°$ and k is chosen so the loading error is zero for $\theta=\pm 45°$, then the loading errors are shown in Fig. 5. These errors were computed by a loop analysis similar to that shown above for the resolver shown in Fig. 1. Thus k is determined by the relationship necessary to give the proper voltage division at $\theta=\pm 45°$, i.e.,

$$[a/2]/[(a/2)+ka]=\sqrt{2}/2,$$

$$k=(\sqrt{2}-1)/2.$$

A comparison of the errors shown in Fig. 5 to those shown in Fig. 2 for a cascade ratio of three indicate the great gain in accuracy through use of the modified flat card resolver. If only two of the trigonometric functions are desired, dummy resistor loads may be attached to the remaining brushes.

In Fig. 5 it is apparent that the positive error is numerically greater than the negative error. By varying k, the positive and the negative values of the error may be made equal, thus reducing the variation in output from the desired output still further.

Why was 45° chosen as the point to tie in the resistors? The 45° point was originally chosen since the error was maximum at that point in the simple type resolver (see Fig. 2). Although several other points were tried after this, the range of the error was not decreased. However, since the methods used here were numerical rather than analytical, it is not implied that the 45° point is the best.

The use of four resistors is a considerably more difficult problem to solve since it involves choosing values of the resistors and points of tie-in both. In addition, there is the design difficulty in making the additional taps on the resolver winding.

In the actual manufacture of the resolver, the wire is wound on a flat card of resin-bonded, glass cloth laminate. The wire is wound on the card by servo-controlled winding machines that are capable of winding wire with a diameter varying from 0.0015 inch to 0.0063 inch with resistance varying

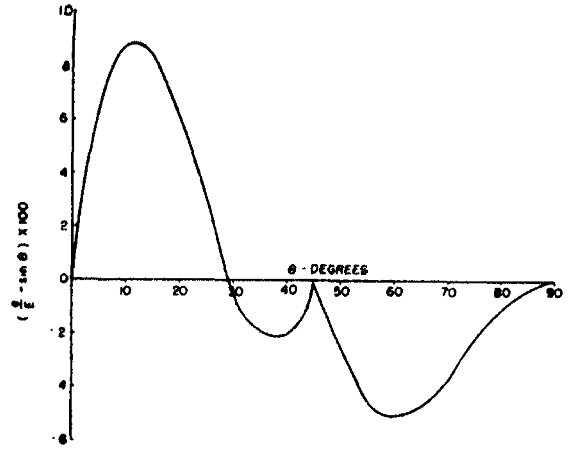

FIG. 5. D.c. resolver error.

from 290 ohms per foot to 7.4 ohms per foot. This wire is wound with turns as close together as practical; usually a space factor of 70 percent to 80 percent is obtained. A stencil exposing a circle for the brush track is laid against the wound card and the exposed insulation is buffed off. The brush at the end of a springlike arm is of a gold and platinum alloy, Paliney No. 7, with a rounded contact point. With present servo winding machines, the sides of the square cards may be varied from 1.5 inches to 2 inches.

Use of Characteristic Curves for Pump-Speed *vs.* Pressure

SAUL DUSHMAN
Research Laboratory, General Electric Company, Inc., Schenectady, New York

December 6, 1948

In many cases it is of interest to be able to derive from the speed characteristic of a pump the total period of time required to exhaust a system from atmospheric pressure to some very low value. The following discussion is intended to describe a method that may be used for this purpose.

Let V = volume of system, P = value of pressure in the system at any instant of time, t, and S = speed of pump. The latter is defined by the relation

$$-V(dP/dt) = S(P-P_f),$$

where P_f = ultimate pressure. Since this is usually much less than P, we can write the last relation in the form

$$-V(dP/dt) = SP. \tag{1}$$

This can be written in the form

$$dt = -(V/S)(dP/Pdt). \tag{2}$$

Hence

$$t_2 - t_1 = V\int_{P_2}^{P_1}(d\ln P/S), \tag{3}$$

where P_1 and P_2 denote the values of P at t_1 and t_2, respectively, and $t_2 > t_1$, $P_1 > P_2$, and *ln* denotes the natural logarithm.

In general, S is plotted on a linear scale *versus* log P and cannot be expressed as a simple function of P. But Eq. (3) indicates that if $1/S$ is plotted *versus* P on semilog cross-section paper, then $t_2 - t_1$ can be derived by merely measuring, or calculating in some approximate manner, the *area* under the curve for $1/S$ *versus* log P between the limits P_1 and P_2.

Obviously, the calculation becomes very simple for the range P_1 to P_2 for which S is constant. In that case

$$t_2 - t_1 = (2.30\,V/S)\log(P_1/P_2),$$

where log denotes logarithms to base 10.

For the other ranges of pressures, in which the value of S varies with the pressure, mechanical integration may be used, or an equivalent method.

The value of $(t_2 - t_1)/V$ gives the *time per unit volume*, and the units are the same as those used for expressing S. Thus, if the latter is given in cubic feet per minute, then $(t_2 - t_1)/V$ gives the period of pumping down in minutes per cubic foot.

A Method of Assessing Transient Stresses in Photoelastic Substances

JOHN S. STANTON
Naval Ordnance Test Station, Pasadena Annex, Pasadena, California

December 6, 1948

A NOVEL method has been found for measuring the transient stresses within photoelastic substances when the latter are subjected to dynamic loading forces of any type. The method consists essentially of combining techniques of the conventional static photoelasticity and of the spark shadowgraph as used in the study of air shock waves.

A photograph (Fig. 1) is obtained of the instantaneous photoelastic pattern by use of a critically damped spark which gives an exposure time of the order of 1/10 microsecond. The model is mounted in a conventional manner as for static photoelastograms. The photograph may be taken either by camera or shadow.

The model may be dynamically loaded in various ways as by transmitted shock, electrodynamic pulsing, collision, and so on. The model shown here was dynamically loaded at the left end of the "neck" (already shown deformed) by a steel ball having a velocity of some 400 feet/second. The stress wave has traveled down the neck as a nearly plane wave, spreading into the widened portion in the complicated fashion shown. This photograph is a shadow picture of the model, and plane polarized light was used to illuminate the model.*

A time delay, variable to alter the time between initiation of loading and exposure, is provided by a conventional multivibrator circuit built into the shadowgraph employed for this photography.**

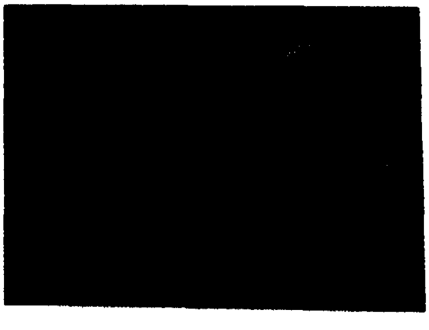

FIG. 1. Transient photoelastogram. Exposure: 10^{-7} second, taken 36 microseconds after collision with a steel ball at the left end of "neck." Model: Plexiglas, 9/16" thick by 3" high.

Any type of photoelastic substance is susceptible to the method here described. The author has employed gelatin models to detect air shock impinging on a photoelastic medium; the model used for the photograph shown here was Plexiglas. Non-photoelastic substances in the elastic region can be studied by the use of photoelastic models if a simple change of time scale is made. By the bonding of photoelastic elements to various points of a non-photoelastic structure, it is possible to extend the study beyond the elastic limit.

---

* Author desires to acknowledge the aid of Dr. D. S. Clark, California Institute of Technology, and of Dr. W. M. Cady of this station in suggesting this and other valuable experiments.

** The shadowgraph employed for this work was designed by Mr. D. G. Marlow and Mr. C. R. Nisewanger of this station and kindly loaned to the author for his use.

Kovar Glass Seals at Liquid Helium Temperatures

C. T. Lane
Sloane Physics Laboratory, Yale University, New Haven, Connecticut

November 22, 1948

In recent months several inquiries have been received by us concerning the problem of metal to glass seals usable at the temperature of liquid helium. A brief summary of current practice in this laboratory may therefore be of some use to other workers in the low temperature field.

We have found the Kovar to Pyrex glass type of seal very satisfactory for use in the liquid helium region, both above and below the λ-point, and we are now using this type of seal exclusively in all our work. Our chief source of supply for these seals has been the Stupakoff Ceramic Company, Latrobe, Pennsylvania, although, on occasion, we have made use of seals fabricated by our own glassblower with equally satisfactory results.

We have not had any experience with this type of seal in sizes much above ½-inch diameter, but there does not appear to be any reason why the larger sizes would not work equally well. In addition to single seals we have on occasion used double ones, i.e., a Kovar tube joined to glass at both ends and this latter form has proved equally successful.

The Kovar seal has shown itself to be exceptionally rugged, much more so than the copper-glass "Housekeeper" seal where, of necessity, the metal has to be very thin at the joint. The resistance of the Kovar seal to repeated thermal shock is also very good. Our current practice is always to have the apparatus in our helium Dewars at liquid nitrogen temperature (77°K) prior to filling with liquid helium at 4.2°K. In so doing the Kovar seal experiences a sudden drop in temperature of over 70°C in a minute or so and in some cases the same seal has been used a number of times without failure. We have used these seals in the helium II region without detecting any porosity to the superfluid, which is a very severe test.

We have also used these seals as "lead-ins" through the metal cap on the Dewar flask, the metal section being either soft soldered or silver soldered to the cap with the glass section then immediately inside the Dewar. This is a much more satisfactory procedure than bringing the glass tube directly through the cap and using a rubber washer, wax, or shellac. We have also found the small Kovar-glass terminals supplied by the Stupakoff Company invaluable for bringing electrical leads into the Dewar through the metal cap. Due to their small size a large number of separate wires may be introduced into even a small Dewar, with excellent insulation. Since these terminals are soldered directly to the cap, excellent vacuum tightness can be attained in the flask.

There is one drawback to the use of Kovar glass seals, namely, the fact that Kovar is ferromagnetic which would preclude the use of such seals in some work. There are, however, many more applications where the magnetic properties are unimportant. Also since Kovar copper produces large thermoelectric effects, it is preferable to use lead-in terminals of the hollow tube type* rather than of the solid rod type in measurements where thermoelectric effects are important. The copper wires can then pass through the Kovar tube into the flask and be sealed to the tube with a drop of solder.

---

* I am indebted to Dr. R. T. Webber for this suggestion.

New Instruments

W. A. Wildhack: Associate Editor
in Charge of this Section
National Bureau of Standards, Washington, D. C.

These descriptions are based on information supplied by the manufacturer and in some cases from independent sources. THE REVIEW *assumes no responsibility for their correctness.*

Ultrasonic Generators

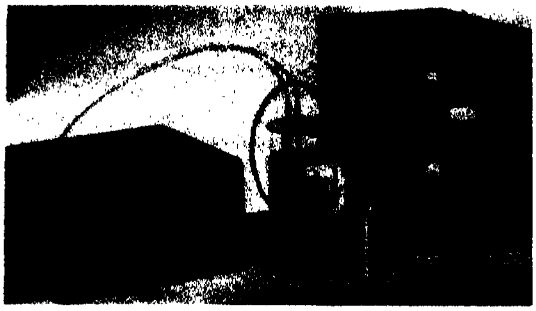
Central Scientific Company announce two new models of ultrasonic generators. They are portable, popularly priced, and generate high power.

These new ultrasonic generators are stable, efficient, and easy to operate for physical, chemical, biological, and industrial research or control.

The Ultrason generates mechanical energy in the crystal holder to vibrate solids, liquids, and gases.

Typical uses in chemical reactions and in other applications are:

to activate ozone to peroxide;
to remove fatty acids from semirefined oils;
to emulsify oils;
to disperse pigments;
to accelerate extractions;
to hasten or retard growth of bacteria, mold, and enzymes.



The U-300 Ultrason crystal delivers 300 watts of mechanical energy to the oil bath. A maximum of 10 watts of power per square centimeter of crystal area (a 76-mm crystal) is permissible without fracture of crystal. The crystal oscillating circuit is energized by 900 watts supplied by the low voltage, high frequency generator from a 115-volt, 60-cycle line. Model 100 Ultrason delivers a maximum of 6 watts at the crystal. Both units operate at 450 kc and provide instant and accurate reproduction of power and frequency conditions. The units are provided with built-in safety features and are designed for continuous operation and trouble-free service.—CENTRAL SCIENTIFIC COMPANY, *1700 Irving Park Road, Chicago, Illinois.*

Atomic Clock

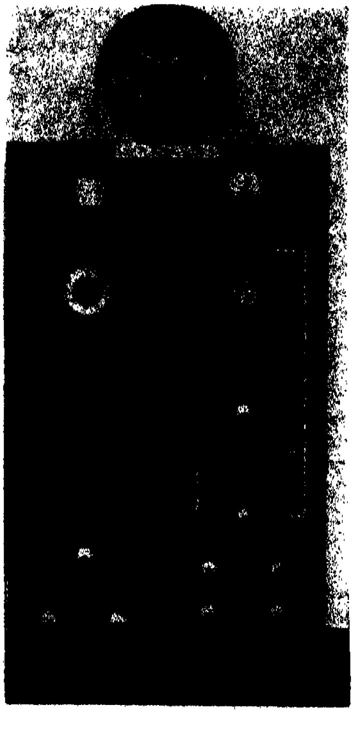
In a radical departure from all conventional methods of measuring time, an atomic clock—invariant with age and for the first time independent of astronomical observations—has been developed by the National Bureau of Standards. Based on a constant, natural vibration frequency of atoms in the ammonia molecule, the atomic clock is a scientific achievement which offers an entirely new primary standard of frequency and time. The principle of the atomic clock promises to free man from age-old methods of fixing time by the daily rotation of the earth on its axis as it revolves around the sun. Not only does the new clock promise to surpass in accuracy any time measurement heretofore known, but the primary standard, the earth, is very gradually slowing down. In addition, unaccountable fluctuations in the rate of rotation have sporadically lengthened and shortened the day by a few thousandths of a second. The new method offers an invariant master clock against which the variation in timekeeping of the earth could be measured.

This first atomic clock has run with a constancy of better than one part in 20 million and is already being improved. By use of the proper atomic system a potential accuracy of a part in ten billion is theoretically indicated.

Because it is a standard of frequency as well as of time, the new method may be applied to the precise control of radio-frequencies, eliminating the "drift" allowances in present band-width allocations, and thus providing additional room in the ultra high frequency bands. The maximum utilization of available space in the radio spectrum depends on the accuracy with which the frequency of an individual station can be controlled, especially at the higher frequencies where quartz-crystal control cannot be used. These higher frequencies, which are used by radar, television relays, and microwave equipment, could be controlled by atomic elements. Such control would also make possible the permanent establishment of radio channels on such an exact basis that tuning could be made as automatic as the dialing of a telephone number.

Based on a principle developed by Dr. Harold Lyons, Chief of the Microwave Standards Section of the Bureau's Central Radio Propagation Laboratory, the new clock was constructed under his direction and with the assistance of B. F. Husten and E. D. Heberling. According to Dr. E. U. Condon, Director of the National Bureau of Standards, the method should prove an invaluable tool for basic research and will affect every technical field where precise measurements of time and frequency are crucial.

In recent years, vibrations of atoms in molecules, giving rise to molecular spectrum lines, have been found in the very high frequency (microwave) region of the radio spectrum. Very precise measurements of these lines are now possible by using extremely sensitive radio methods. When it became evident that such spectrum lines could be used as new primary frequency standards, scientists at the National Bureau of Standards began seeking a means of utilizing one of these lines



to control an oscillator, which in turn could be used to drive a clock. Because the resulting equipment, the atomic clock, is controlled by the invariable molecular system of ammonia gas, it is independent of astronomical determinations of time and unaffected by temperature, pressure, and aging.

The National Bureau of Standards atomic clock consists essentially of a quartz crystal oscillator, a frequency multiplier, a frequency discriminator, and a frequency divider, all housed in two small cabinets on the top of which are mounted a special 50-cycle clock and a wave-guide absorption cell—a 30-foot copper tube wound in a compact spiral around the clock and filled with ammonia gas. The crystal oscillator generates a fundamental driving signal at a low radiofrequency. A frequency-multiplying chain transforms this into a microwave (very high frequency) signal, which is then compared with a natural vibration frequency of the ammonia molecule. If these two frequencies are different, an "error signal" adjusts the oscillator to bring them into agreement. The oscillator which is inclined to "drift" slightly with age—that is, change in frequency—is thus "locked" to the ammonia molecule. It can then control an electrically driven clock with extreme accuracy.

Present time and frequency standards are based on astronomical determination of the period of rotation of the period of rotation of the earth. Essentially, a telescope is pointed toward a star, and the interval between the exact moment it passes the cross hairs until the exact moment 24 hours later that the star reappears is taken as the standard of time. The "twinkling" of the star, which makes its position difficult to fix, affects the accuracy of such measurements. The atomic clock gives a time standard of high precision continuously available in any interval of time desired instead of every 24 hours, whether it is a millionth of a second or ten hours. Moreover, the atomic clock is invariable so that a given interval of time, whether measured today or a hundred years from now is truly reproducible. The atomic method automatically and continuously controls the rate of the clock without delay or human intervention and is independent of weather.

Another advantage of the atomic method is that if an atomic clock were run continuously over a period of a year, our knowledge of the length of the year could be improved. The time it takes the earth to travel around the sun (a year) is completely independent of the time it takes the earth to rotate once on its axis (a day). This independence causes all the trouble with the calendar, necessitating leap years so that the seasons will always come at the same time during the year. With an atomic clock measurements could determine whether the mean sideral year is more accurate than the mean solar day, as some astronomers believe may be the case.

In terms of the regular 24-hour-day broadcasts of time and frequency by the National Bureau of Standards, which serve the nation and much of the world for standards of radiofrequencies and time, an atomic clock means a precision of both time and radiofrequency standard signals hitherto impossible.

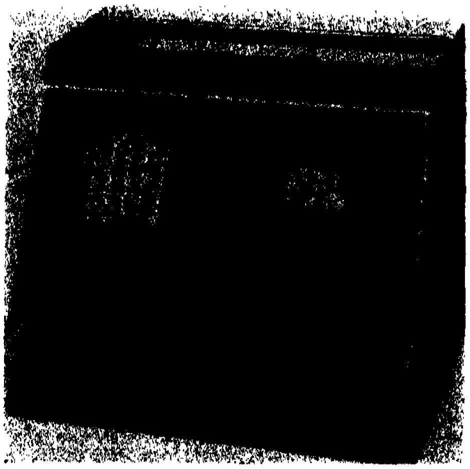
The atomic clock gives the Bureau a time standard analogous to the Bureau's new atomic standard of length furnished by the single isotope of mercury which, if adopted internationally, will provide man with the ultimate standard of length. Both of these recent developments stem from the application of atomic physics to practical problems.—NATIONAL BUREAU OF STANDARDS, *Washington 25, D. C.*

Hydrostatic Impulse Gauge

This mechanical, self-recording gauge may be lowered into a well or connected to a pressure chamber to measure directly the total impulse per unit area generated by pressure waves resulting from underground explosions or other high pressure sources. In operation, the hydrostatic impulse forces mercury through a capillary passage and into a collector; the weight of mercury discharged is proportional to the impulse per unit area in p.s.i.-sec., from 10 to 400 p.s.i. The gauge is entirely self-contained and of simple construction, for convenience in field use. Its applications include geophysics, internal combustion studies, blast damage determination, and water hammer research.—ENGINEERING RESEARCH ASSOCIATES, INC., *St Paul 4, Minnesota.*

Radioactivity Demonstrator

Tracerlab has developed its new radioactivity demonstrator in response to the need for an inexpensive instrument for teaching basic principles of radioactivity in high schools and colleges. Radiation is indicated by three different means: by loudspeaker, by a flashing neon light, and quantitatively with a counting rate meter. The meter reads in counts per minute and will indicate up to 2500 counts per minute. This instrument has sufficient accuracy to permit carrying out simple classroom and laboratory demonstrations of basic principles of radioactivity.



A removable shield is mounted in front of the Geiger tube, to completely eliminate beta-rays when it is desired to measure only gamma-radiation. A switch permits the meter also to indicate the voltage across the Geiger tube which can be varied from about 500 to 1100 volts. The instrument operates on 110 volts a.c.

Sources of beta- and gamma-activity are included at no extra charge, together with an instruction manual, experiments, and a discussion of radioactivity suitable for use in elementary lectures. With the radioactivity demonstrator it is possible to illustrate some of the properties of beta- and gamma-radiations, take background readings, plot the characteristic Geiger tube curve of counting rate *versus* applied voltage, and to make rough qualitative checks of the amount of radioactivity in various natural substances. For additional information and price, write for the Radioactivity Demonstrator Bulletin.—TRACERLAB, INC., *55 Oliver Street, Boston 10, Massachusetts.*

Selenium Rectifiers

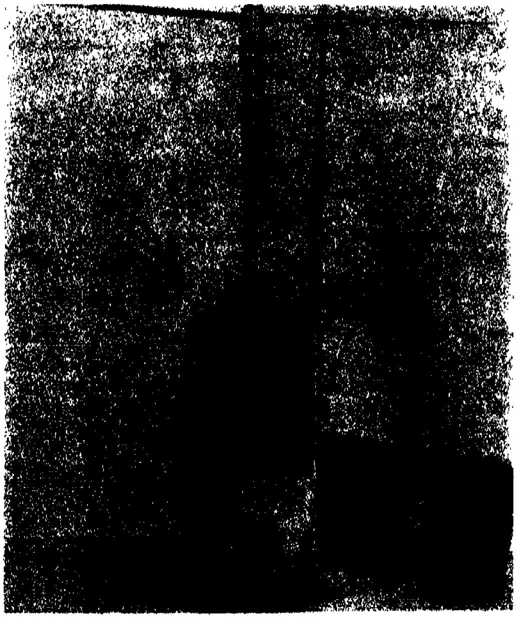
The International Rectifier Corporation has developed a complete new line of selenium rectifiers covering the range from 2 volts and 150 milliamperes to 5000 volts and 10,000 amperes. The individual plate sizes range from 1¼"×1¼" to 6¼"×7¼".

The individual selenium plates are capable of withstanding 24 volts r.m.s. maximum in the reverse direction and can be overloaded up to 10 times rated load for periods of 7 seconds or less. The characteristics are also extremely stable since the leakage is less than 1 ma/cm² at maximum reverse voltage. Efficiency varies from 65 percent to 85 percent depending upon the circuit employed, and the change in voltage is less than 5 percent after the first 10,000 hours of operation.—INTERNATIONAL RECTIFIER CORPORATION, *6809 S. Victoria Ave., Los Angeles 43, California.*

Civilian Walkie-Talkies

Portable radio transceivers for public use between homes, automobiles, offices, plants, farms, and many other person-to-person radio telephone applications are now in pilot plant production by the Citizens Radio Corporation which has received the first F.C.C. type approval for equipment to be used on the 465-megacycle band allocated for civilian use.

The equipment is one-fourth the size of the famous wartime walkie-talkie, and is the result of more than two years of research and engineering in which many new techniques, including subminiature tubes and the use of silver-on-ceramic circuits, have been perfected for practical push-button, person-to-person radio communication for public use.



The transceiver, two of which are required for person-to-person air contact, is housed in a tiny case measuring 6"×2¾"×1¼" topped by a small folding antenna. This pocket-sized radio station includes all necessary equipment except a tiny headphone and batteries carried in a separate case about the size of a miniature camera.

The model 100-B citizen's radio is a transceiver for Class B stations only; it operates at 465 mc, tolerance 0.4, input 3 watts, emission A-3 with 30 percent maximum modulation. The transmitting section uses a Sylvania 6K4 subminiature oscillator and the receiver is super-regenerative, using three Sylvania 1V5 subminiature tubes. The transceiver weighs 11 ounces, including antenna; total station equipment, including batteries, is only two and one-half pounds.—CITIZENS RADIO CORPORATION, *Cleveland, Ohio.*

Vibration Measurement Equipment

The new Massa Model GA-1006 vibration measurement equipment was developed to meet several recent demands for extending both the frequency and dynamic ranges of generally available vibration measurement instruments. This new apparatus employs an extremely rugged accelerometer which is designed to give a uniform electrical output for constant acceleration over the entire frequency range 10 cycles to 20 kc. Its output is linearly proportional to mechanical vibrations corresponding to accelerations ranging from less than 0.001 g to more than 100 g.

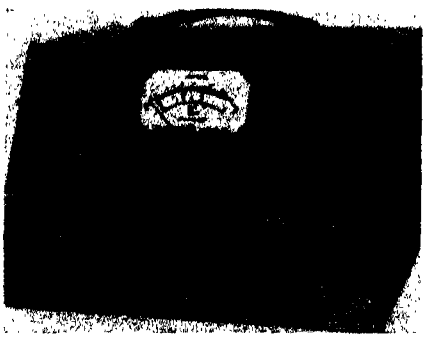
The accelerometer responds only to vibrations applied along its principal axis, and it can therefore be used to measure the absolute vector components of any vibration existing at any point on the structure under test. Because the phase shift between the mechanical vibration and the generated electrical voltage is independent of frequency over the entire frequency range to 20 kc, very accurate transient vibrations may be electrically reproduced without changes in wave shape of the vibrations. Remote electrical indications of the vibrations can be conveniently made. A self-contained power supply unit makes the equipment conveniently portable for field applications. The new equipment is designed so that it can also be used as a wide-range sound pressure measuring instrument for making both conventional low level measurements as well as for making blast wave analyses of gunfire or other intense sound fields or explosions.—MASSA LABORATORIES, INC., *3868 Carnegie Avenue, Cleveland 15, Ohio.*

Slotted Line and Standing Wave Indicator

A new type of slotted line section, –hp–805A, incorporating a radical departure from conventional design is in production by the Hewlett-Packard Company.

Slotted lines are a fundamental tool for measurements in microwave circuits. By determining the pattern of a standing wave in a transmission line, the character of the load may be calculated. Both magnitude and phase may be determined. In many cases, knowing the standing wave ratio and phase is more important than knowing the impedence itself.

Slotted Line



Standing Wave Indicator

The –hp–805A substitutes two parallel planes and a rigid central circular conductor for the conventional coaxial arrangement. This configuration has several important advantages over the standard slotted section.

First, parallel planes may be made mechanically rigid while also providing a rigid probe carriage. Second, the central conductor is proportionately larger and thus can be similarly rigid, eliminating tendency to bow. The depth of probe penetration is much less critical and carriage inaccuracies are all but eliminated.

This design also makes possible a very small effective slot opening. In the –hp–805A the slot opening is less than 0.001 inch referred to a coaxial system, and this serves to keep leakage very low. Residual VSWR can be held to less than 1.04.

Position of the probe is controlled with a cable system driven by a central stationary knob. The probe circuit is tunable over the entire frequency range, and the position may be read to 0.1 mm. Frequency range of the new slotted line is 500 to 4000 mc, and characteristic impedence is 50 ohms.

Hewlett-Packard Company has also in production the new –hp–415A Standing Wave Indicator to measure relative audio-voltages detected by a crystal rectifier or bolometer. It is designed for use with the –hp–805A Parallel-Plane Slotted Line, but may also be used with other slotted line systems. In conjunction with a slotted line it will determine flatness of a coaxial or wave-guide system, measure impedence, locate sources of reflection, and determine percentage of reflected power.

The new indicator consists of a high gain amplifier having a very low noise level and operating at a fixed audiofrequency. The output of the amplifier is measured with a square-law indicating vacuum tube voltmeter. The meter face of this voltmeter is calibrated both in decibels and in voltage standing wave ratio. Input circuits are provided for use with either a crystal or barreter. Equivalent "Q" of the over-all amplifier is 205.

The instrument is powered by any 115-volt a.c. source. The –hp–415A Standing Wave Indicator operates on a single fixed tuned frequency of 1000 cycles per second. However, other frequencies from 300 to 2000 cycles per second can be supplied on special order.—HEWLETT-PACKARD COMPANY, *395 Page Mill Road, Palo Alto, California.*

Manufacturers' Literature

Teledyne and Teleflight Instruments—Single sheet bulletins describe instruments of the electrical bridge type using bonded wire strain gauges, especially valuable in telemetering from aircraft and guided missiles. Teledyne pressure transmitters are available in ranges from 0–100 p.s.i. to 0–500 p.s.i. Teleflight pressure transmitters measure either positive or negative pressures, in ranges up to ±50 p.s.i., and are especially useful where small size is important. Teleflight accelerometers measure accelerations in ranges up to ±200 g.—ENGINEERING PHYSICS DIVISION, FREDRIC FLADER, INC., *North Tonawanda, New York.*

Type RV2 Precision Potentiometers—8-page bulletin includes specifications, photographs, drawings, and prices. Both linear and non-linear functional windings are available.—TECHNOLOGY INSTRUMENT CORPORATION, *1058 Main Street, Waltham 54, Massachusetts.*

Silicone Fluids—31-page booklet, *Dow Corning Silicone Note Book*, Fluid Series No. 3, presents a comprehensive body of information on the properties and behavior of DC200 Silicone Fluids. Charts and graphs of properties are presented. —DOW CORNING CORPORATION, *Midland, Michigan.*

Tubular Rheostats—Bulletin 41, 12 pages, describes various styles of standard, screw-drive, double, graded, switchboard, metal-caged, and non-inductive Jagabi "Lubri-tact" tubular rheostats. Diagrams and applications are shown in a "how to select" section.—JAMES G. BIDDLE COMPANY, *1316 Arch Street, Philadelphia 7, Pennsylvania.*

Decade Counter and Radiation Survey Instrument—Bulletin 485, 4 pages, describes decimal decade-scaling type instrument with built-in impulse register (recording clock), scale of 100 or scale of 1000 Higinbotham scaling circuit. Bulletin 486, 4 pages, describes Model SM3 portable battery-operated instrument for the measurement of radiation intensities.—EL-TRONICS, INC., *2647–67 N. Howard Street, Philadelphia 33, Pennsylvania.*

Phase Microscopy—24-page bulletin, *Phase Microscopes*, presents historical background, theory, and bibliography on phase microscopy and includes a catalog section on phase microscopes.—SCIENTIFIC INSTRUMENT DIVISION, AMERICAN OPTICAL COMPANY, *Buffalo 15, New York.*

New IRC Resistor—Bulletin B-1, 12 pages, gives comprehensive data on characteristics and specifications of new, advanced type BT insulated fixed composition resistors. Performance standards given for ¼-, ½-, 1-, and 2-watt types.—INTERNATIONAL RESISTANCE COMPANY, *401 N. Broad Street, Philadelphia 8, Pennsylvania.*

Accelerometers—Instrument Notes No. 6, December 1948, 8 pages, presents an article on "Calibration and test of accelerometers," illustrated with four figures.—STRATHAM LABORATORIES, *9328 Santa Monica Boulevard, Beverly Hills, California.*

Precision Electrical Instruments—Bulletin describing Muirhead precision instruments of the following types: miniature tuning fork, acoustic strain gauge, portable dark room, the Ipot (toroidal auto transformer), D'Arsonval galvanometer, and phonic motors.—MUIRHEAD AND COMPANY, LTD., *Beckenham, England.*

Radioactive Isotopes—12-page bulletin, *Tracerlog*, No. 14, December 1948, contains information on simulated phosphorus −32 and iodine −131 reference sources, including a procedure for standardizing with these simulated standards. Also presented is a list of uses for radioisotopes.—TRACERLAB, INC. *55 Oliver Street, Boston 10, Massachusetts.*

Instrumentation, Vol. 3, No. 5, fourth quarter, 1948, contains items of interest on applications of scientific instruments and automatic controls in industrial processes and in research laboratories.—MINNEAPOLIS-HONEYWELL REGULATOR COMPANY, *Brown Instruments Division, Wayne and Roberts Avenues, Philadelphia 44, Pennsylvania.*

Wire Wound Resistors—24-page catalog of high quality wire wound resistors, including both *non-inductive* and *inductive* types. Resistors with power ratings of ½ watt to 30 watts are listed.—INSTRUMENT RESISTORS COMPANY, *1036 Commerce Avenue, Union, New Jersey.*

Occupational Safety Posters—72-page 1949 Directory contains 744 illustrations and a convenient index for locating posters on specific accident hazards. Permission granted to reproduce posters. Price, 50 cents.—NATIONAL SAFETY COUNCIL, *20 North Wacker Drive, Chicago 6, Illinois.*

Television Components—4-page folder P-1 gives essential information on a line of television components.—TRANSVISION, INC., *460 North Avenue, New Rochelle, New York.*

Gas Analyzers—Bulletin No. 213, 8 pages, describes instruments for rapid control analysis of gas mixtures containing carbon monoxide, carbon dioxide, methane, oxygen, hydrogen, or nitrogen.—BURRELL TECHNICAL SUPPLY COMPANY, *1942 Fifth Avenue, Pittsburgh 19, Pennsylvania.*

Retaining Rings—8-page bulletin gives comprehensive specification data on Spirolox retaining rings.—SPIROLOX DIVISION, RAMSAY CORPORATION, *3693 Forest Park Boulevard, St. Louis 8, Missouri.*

New Materials

Forest K. Harris: Associate Editor
in Charge of this Section
National Bureau of Standards, Washington, D. C.

Ultra-Sensitive Photographic Emulsion

A new emulsion for nuclear track plates is so sensitive as to present a problem in preventing premature exposure by cosmic rays during shipment to research workers. Packing the emulsion in dry ice affords protection, because of the reduction of sensitivity at low temperatures. It must be continuously refrigerated and allowed to warm up just before exposure. The emulsion is characterized by high concentration of silver halides and by uniform sensitivity. It is approximately four times as sensitive as Eastman's present nuclear track plates and has successfully recorded electron tracks which are ten times as long as those previously recorded.

An additional suggested use is in precision autoradiography. In this application, sections of tissue containing radioactive isotopes are placed in contact with the emulsion so that radiation from the tissue exposes the emulsion. Examination of the developed plate permits identification of the location and amount of radioactive penetration in the tissue.

The new emulsion has been made so far only on an experimental basis and is not yet generally available.—EASTMAN KODAK COMPANY, *Rochester 4, New York.*

Synthetic Calcium Tungstate Crystals

Successful production of water-white single crystals of pure calcium tungstate in research quantities has been accomplished. Single crystals are now being grown in rods having a ⅜-inch square section and lengths up to 2 inches. Representative samples are colorless and their clarity varies from transparent to slightly cloudy. Development work is proceeding on the growing of uniformly clear crystals and on the production of other sizes and forms.

Indicated applications include the use of the material in scintillation counters in the detection and measurement of radioactivity and as screens in x-ray fluoroscopy. Crystals are available in research quantities in the square ⅜" rods, in lengths from ¼" to 2" in ¼" increments. The manufacturer has facilities for the fabrication of special windows or mosaica from the rod now available, and will be glad to consult with prospective users regarding possible applications and techniques of fabricating desired shapes.—NEW PRODUCTS DIVISION, THE LINDE AIR PRODUCTS COMPANY, UNIT OF UNION CARBIDE AND CARBON CORPORATION, *30 East 42 Street, New York 17, New York.*

Copper-Tungsten Contacts

Gibsiloy UW 6 is a powder-metal mixture of copper and tungsten made in various contact shapes and sizes. It is designed for handling heavy currents with minimum erosion. The units are molded to shape and one face is coated with silver solder for brazing in place. The cross strength is 135,000 p.s.i., and the hardness is 90 on the Rockwell B scale.—GIBSON ELECTRIC COMPANY, *8353 Frankstown Avenue, Pittsburgh 21, Pennsylvania.*

Flexible Copper Tubing

Vacuum-tight flexible tubing made of seamless copper may be obtained in lengths up to ten feet or in multiples of this length by welding end to end. The tubing measures $\frac{7}{32}$ inch i.d. and $\frac{11}{32}$ inch o.d. and has a pressure capacity up to 300 p.s.i. without requiring outside reinforcing braid. Fittings may be specified as well as lengths made up of corrugated and plain sections.—JOHNSON METAL HOSE, INC., *221 Mill Street, Waterbury 88, Connecticut.*

Sealed Terminal Bushings

A new line of tinned steatite-sealed terminals have been designed for use on metal enclosures. The terminals are made of glazed steatite that is resistant to rough handling and thermal shock. A tinned surface, permanently bonded to the steatite body, permits rapid and easy soldering to the enclosure after insertion in a hole of the proper size. Leads are brought through an axial hole in the bushing and soldered to the tinned lug provided at the end of the bushing. On special order terminals can be supplied which will operate at temperatures up to 200°C.—GENERAL CERAMICS AND STEATITE CORPORATION, *Keasbey, New Jersey.*

New Resin

Isopol is a hydrocarbon resin of moderately high molecular weight, made up of approximately three parts of styrene to one part isoprene, exactly the opposite proportions to those used in synthetic rubber. It is clear, hard, nearly water-white in appearance, possesses many of the chemical properties of rubber, and is completely soluble in petroleum naphtha. It is best described as a modified polystyrene in which the isoprene acts as an internal plasticizer. Thus the advantages of polystyrene have been retained while the disadvantage of brittleness has been partly eliminated.

In the solid state its use is suggested as a stiffener for both natural and synthetic rubber. Because of its chemical similarity it can be milled and cured in the same way. Because of its solubility in naphthas, aromatic hydrocarbons, chlorinated solvents, esters, and ketones, it offers possibilities in coating applications. In this field it has the advantages that solutions of the resin may be sprayed (in contrast to polystyrene) and that a film may be obtained without using a plasticizer. It shows some tack which may be of advantage in special applications where a finish coat of a different nature is contemplated and where an inert but mildly tacky base coat is desired. The resin may be readily emulsified and shows promise as an impregnant for cloth, paper, or wood. Technical data sheets and samples for laboratory investigation may be obtained from the manufacturer.—UNION BAY STATE CHEMICAL COMPANY, *50 Harvard Street, Cambridge, Massachusetts.*

Heat-Resistant Plastic Tubing

Templex 105 is a plastic tubing approved by the Underwriters Laboratories for continuous use at temperatures up to 105°C. In addition, manufacturer's tests show very favorable results in regard to retained elongation, tensile strength, flexibility, and dielectric strength after exposure to temperatures up to 150°C. 1000-hour exposure to transformer oil shows little effect. The tubing has continuous, abrasion-resistant identification marking. Complete information and samples may be secured from the manufacturer.—IRVINGTON VARNISH AND INSULATOR COMPANY, *Irvington, New Jersey.*

Instrument-Cleaning Solutions

Zenith solutions have been compounded specifically for the cleaning and rinsing of instrument and meter parts without leaving harmful residues. The manufacturer states that they are non-toxic and non-flammable, and they have been thoroughly laboratory and field tested. The cleaning solutions are stated to clean faster and brighter than any others on the market, and the rinses dry quickly without spotting. They are also low in cost, economical in use, and may be used with standard cleaning equipment. Samples will be furnished on request.—ZENITH MANUFACTURING AND CHEMICAL CORPORATION, *52 Beeckman Street, New York 7, New York.*

Anti-Fogging Cleaning Cloth

Specloth is a lens cloth impregnated with a synthetic detergent that coats the lens with a transparent film which prevents moisture from condensing on the surface of the glass. This film is non-greasy and is stated to fog-proof the lenses for as much as 24 hours. These lens cloths are inexpensive and remain effective for many weeks of daily use.—KLEER-VUE CLOTH PRODUCTS, *334 West 37 Street, New York 17, New York.*

Wetting Agent

Santomerse 30-X is a low cost liquid wetting agent and detergent of the alkyl aryl sulfonate type, which is expected to be of interest to the textile industry. It is a clear, light colored liquid containing 30 percent solids (85 percent active sulfonate, 15 percent sodium sulfate), and is resistant to decomposition by either strong acids or alkalis even under extreme conditions. It is suggested for the wet processing of textiles and for other applications where reduction of surface tension and quick wetting are desired. Its high detergent value and viscosity are said to make it also suited for liquid cleaners.—MONSANTO CHEMICAL COMPANY, *St. Louis 4, Missouri.*

Strippers for Organic Finishes.

Strippers S-17 and *S-19* are new room-temperature strippers for synthetic enamels. Stripper S-17 is stated to be a clear, quick-evaporating stripper used at room temperature for removal of all types of synthetic enamels, including heavy coatings of enamels that accumulate on work holders and hooks. For such cases the various layers of enamel exfoliate, leaving the work holders clean. It is particularly recommended for the removal of clear synthetic enamels from highly polished surfaces such as brass, gold plate, and silver. It does not tarnish metals and it has no significant odor. Stripper S-19 is similar to Stripper S-17 in its action and appearance except that it is slightly ammoniacal in composition and is used in certain special cases for removal of synthetic enamels where Stripper S-17 is not satisfactory. Both strippers are used with water seals to minimize evaporating losses, and rinsing is not necessary after their use. The work to be stripped is immersed in the strippers at room temperature. After a few seconds to several minutes, the enamel is completely removed from the surface of the metal and the parts can be removed. The stripper evaporates quickly and the part is ready for refinishing.—ENTHONE, INC., *442 Elm Street, New Haven, Connecticut.*

Self-Adhesive Wire Markers

Flag-It wire markers are designed for coding wires having diameters up to 0.2 inch. They may be wrapped around the wire to form an encircling marker, or the ends may be pinched together to form an upright, numbered flag. It adheres without moistening, is unaffected by moisture or heat, and may be removed without harming the wire surface. The fabric of the marker is coated to make it resistant to grease, dirt, and liquids. Standard cards are preprinted, black-on-white, in numbered or alphabet series, or can be printed to specification. They are attached to a 10-inch card, 40 to the card, from which they may be individually removed as needed.—FLAG-IT WIRE MARKER COMPANY, *320 Rose Street, Los Angeles, California.*

Counter Pulse Shape

C. D. Thomas
West Virginia University, Morgantown, West Virginia

(Received August 30, 1948)

The shape of the decay pulse from a self-quenching counter depends on the circuit constants as well as on the motion of the positive ion sheath. This is considered mathematically and a formula developed to take account of these factors in determining pulse height and form. In order to check this relation experimentally, data obtained from photographed single pulses are presented and compared to the calculated values. These curves cover a wide range of values of circuit resistance and capacity.

THE calculation of the voltage which develops on the wire of a self-quenching counter due to the motion of the positive sheath has been checked by schemes which permit a fairly accurate reproduction of the relation. However, if the series resistance, as well as wiring capacity, is not of negligible importance, the shape of the discharge pulse may be quite different, depending on the values of R and C_p (Fig. 1). It was thought desirable to extend the calculations to the case cited here, since in practice the shunting capacity (C_p) may exceed the capacity of the counter C_g by many times and since the value R used will also materially influence the shape. It is obvious that if R approaches zero the wire voltage will be held constant, while if R becomes very large the discharge will be very nearly that caused by the sheath's motion alone until the cylinder is reached.

If the wire is considered charged and isolated, at some instant after the electron avalanche has been collected, the space within the counter may be treated as a problem in electrostatics, and the relation obtained between the voltage across the counter (ϕ), the charge per unit length of wire (q_0), the radius of the positive sheath (r), and the charge per unit length of the sheath (q). The relation so obtained is

$$\phi=2q_0\ln(b/a)+2q\ln(b/r). \tag{1}$$

When the sheath has moved to the cylinder (b), the voltage on the wire will have returned almost to its original value V. The difference in voltage is due to the fact that q_0 has been reduced slightly because of the negative charge collected on the wire. Equation (1) may be put into time-dependent form by assuming a constant ion mobility, a constant wire charge, and that the sheath is located at position r_0 at time t equal zero:

$$r^2=r_0^2+4kt[q_0+(q/2)]. \tag{2}$$

This situation, however, will not fit the case of Fig. 1 where the supply voltage V tends to return the wire potential to its original value in time comparable to, or less than, the time of motion of the sheath. The equation which determines the wire potential is then given by:

$$R(dQ_t/dt)+\phi=V,$$

where Q_t is the total charge on the wire and the shunting capacity. Equation (1) relates the wire

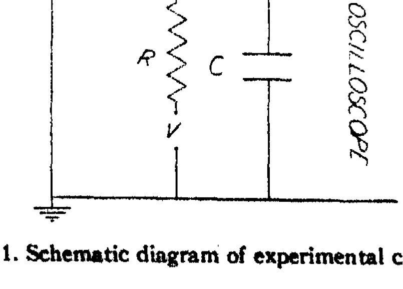

FIG. 1. Schematic diagram of experimental circuit.

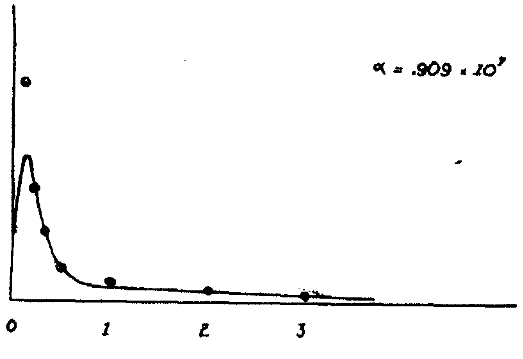

FIG. 2. Full line is the observed pulse height plotted to an arbitrary scale. Circled dots are calculated values. The curves are matched at 0.5 microsecond; $\alpha = 9.09 \times 10^6$ sec.$^{-1}$

charge to ϕ and, since the parallel capacity is constant, its charge also may be expressed in terms of ϕ, yielding

$$R(C_g+C_p)(d\phi/dt) \\ -2RC_gq[d/dt][\ln(b/r)]+\phi=V. \quad (3)$$

In order to solve this, Eq. (2) may be substituted in the second term. The coefficient of t in Eq. (2) is considered as a constant although this is no longer quite accurate, for the charge on the wire is no longer constant during the sheath motion. However, since q is much less than the total charge, the resultant inaccuracy in r (t dependence) may be expected to be slight, and the approximate field for determining the ions' motion may be found by use of q_g^0, the wire charge per unit length before the ionizing event occurs. Upon making this substitution, Eq. (3) becomes

$$[1/\alpha][d\phi/dt]+[qRC_g/(A+t)]+\phi=V, \quad (4)$$

where

$$\alpha=1/(R(C_g+C_p)), \quad A=r_0^2/4kq_g^0.$$

The boundary condition for this equation is obtained from the value of ϕ at time zero. Since the total charge on the wire and parallel capacity is reduced by the amount of the collected charge, its value at $t=0$ is

$$Q(0)=V(C_g+C_p)-qp,$$

where p is the length of the sheath. By use of Eq. (1) $q_g(=q_g^0-q)$, and hence $Q_t(0)$, may be evaluated in terms of the wire potential, $\phi(0)$, and r_0. By equating these two values of Q_t and solving for $\phi(0)$, the initial condition is found to be

$$\phi(0)=V-[2qC_g/(C_g+C_p)]\ln(r_0/a).$$

The solution of Eq. (4) is found to be

$$\phi=V-[qC_g/(C_g+C_p)]\{2\ln(r_0/a)E^{-\alpha t} \\ +E^{-\alpha(A+t)}[\langle Ei\rangle_M\alpha(A+t)-\langle Ei\rangle_M(\alpha A)]\}, \quad (5)$$

where $\langle Ei\rangle_M$ is the exponential integral function.

EXPERIMENTAL PROCEDURE

In order to check results of the above calculation, a circuit such as Fig. 1 was connected to an oscilloscope adapted to photographing single pulses. The capacity of the counter alone, and when in the circuit, was measured in order to get both C_g and C_p. In addition, the circuit was arranged to permit insertion of dummy capacity as well as for interchange of resistance values. Four different counter tubes whose characteristics and dimensions were quite different were used in the tests.

For comparing the photographs with the calculations based on Eq. (5), two schemes were used. For general shape, the photographs were projected onto cross-section paper, but for more accurate check, especially near the end of the pulse where differences were small, the height measurements were taken by use of a low power microscope with micrometer screw. The later device was also used for checking and correcting the time base.

In attempting to evaluate Eq. (5), all factors except q, r_0, and k (or A) may be obtained directly from the physical size of counter and electrical components. The charge q occurs as a multiplier in both terms which vary with time, and since no attempt was made to measure absolute pulse heights, this multiplier will not be needed. The ratio of radius of sheath origin to wire radius is not accurately known, but beaded wire experiments have shown that it is in the neighborhood of 2. The uncertainty in the value of A is still greater since it involves both r_0 and k. With the assumption that r_0 is equal to twice a, and that k is about 2 cm per sec. per volt per cm, the values of A for the counters used were of the order of 0.5 to 1.5×10^{-6} sec. As indicated in the discussion of the initial condition, the time origin is at the instant when the avalanche has been collected and the sheath has not appreciably moved. Experimental evidence on rise time, as well as calculation of the electron velocity in the field near the wire, indicates

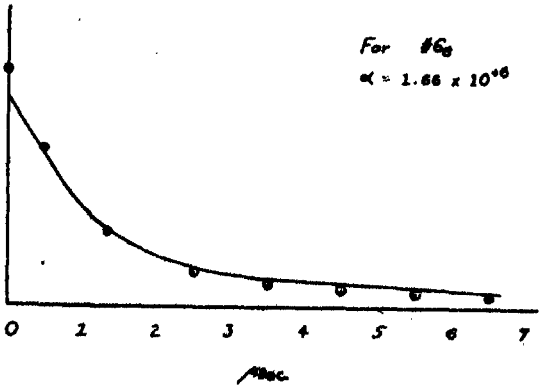

FIG. 3. Full line is the observed pulse height plotted to an arbitrary scale. Circled dots are calculated values. The curves are matched at 1.25 microseconds; $\alpha = 1.66 \times 10^6$ sec.$^{-1}$

that the error thus introduced in the time origin is a small fraction of a microsecond.

Since a great number of different values of α were used with each counter, only typical examples are shown here. Figures 2, 3, 4, and 5 are for a small counter with 5 mm of amyl acetate as the quench-in gas. The cylinder diameter of this counter is approximately 1.9 cm, its wire diameter 0.01 cm, and its length 8 cm. The curves shown are for a wire voltage of 1050, about 90 above threshold voltage. In each case the full line represents the photographed trace beyond peak value and the circles are calculated values which were matched to the experimental height at one point. In order to show most of the length and, at the same time, not to mask the departure from calculated value, as a logarithmic scale would do, the lower end appears very close to zero. The fit at this end is, however, very good. It is noticed that near the pulse peak there is considerable departure. This can be accounted for by the rough approximation made in estimating A, to which the curve is most sensitive for small times. It is also known that in this region of high field the mobility is not a constant as was assumed here.

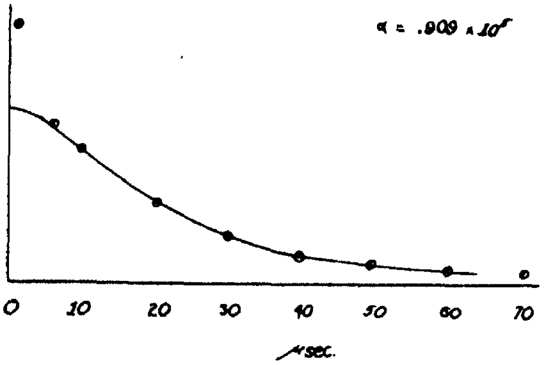

FIG. 4. Full line is the observed pulse height plotted to an arbitrary scale. Circled dots are calculated values. The curves are matched at 10 microseconds; $\alpha = 9.09 \times 10^4$ sec.$^{-1}$

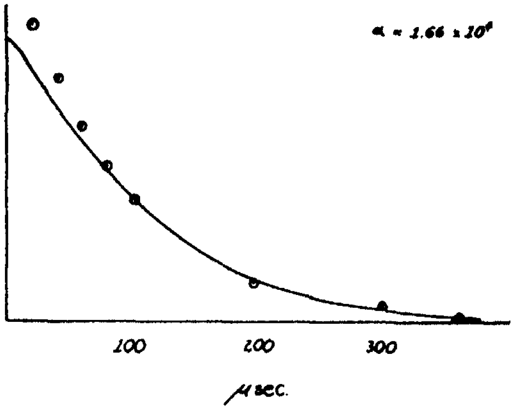

FIG. 5. Full line is the observed pulse height plotted to an arbitrary scale. Circled dots are calculated values. The curves are matched at 100 microseconds; $\alpha = 1.66 \times 10^4$ sec.$^{-1}$

It should be pointed out that while the resistance has a very great effect on the shape of the pulse, the motion of the sheath is not changed very much, and hence the field near the wire and the counter dead time are practically independent of R.

Developments in the Useful Circular Nomogram*

Douglas P. Adams and Howard T. Evans, Jr.
Section of Graphics, Massachusetts Institute of Technology, Cambridge, Massachusetts

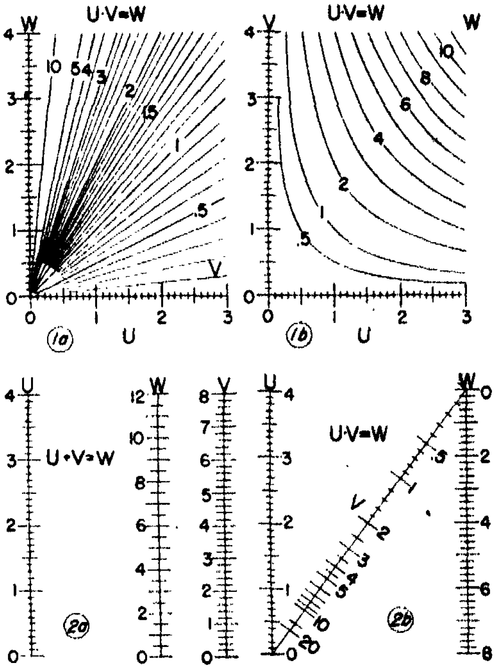
(Received August 30, 1948)

The particular type of alignment diagram for the function $U\cdot V=W$ in which the U and V scales lie on the circumference of the same circle and the W scale along a diameter is developed in detail. The forms of the diagram for which certain intervals on these scales are maximized in their spread are derived and described. Such maximized diagrams, it is found, have certain characteristic properties of symmetry. These developments are illustrated with examples.

BACKGROUND

A NOMOGRAM, or "law in graphical form," is a diagram designed to represent graphically a functional relationship between varying quantities. In particular, a nomogram consists of points, lines, or curves—each calibrated in one of the varying quantities of the relationship. When all the quantities but one have known values in a relationship for which a diagram has been prepared, the value of the unknown one can be found by reference to a point, line, or curve, characteristic of the solution, established by the known values. Extended use of the diagram can also often be made to determine compatible values of more unknowns than one.

The ordinary network chart is such a nomogram. Thus, for the equation $U\cdot V=W$, it might take the form of Fig. 1(a) or Fig. 1(b). On reference to the point P_j, characteristic of the solution established by known values U_j and W_j, the unknown value V_j can be read from the chart. The alignment diagram is likewise such a nomogram. It could take, for instance, either of the well-known forms of Fig. 2(a) or Fig. 2(b). On reference to the line K_j characteristic of the solution established by the known values U_j and W_j, the unknown value V_j can be read from the diagram.



Figs. 1a, 1b, 2a, and 2b. Elementary forms of network chart and alignment diagram.

The generalized alignment diagram for the three-variable equation,

$$F(U,V,W)=0,$$

can be schematically represented in the form of Fig. 3. The U, V, W curves may partake of any definable form. Thus, one of them might be circular (Fig. 4). This type of diagram is not especially rare in the literature. It is clearly distinguished from the type which is of special interest in this article.

THE CIRCULAR NOMOGRAM

The equation $U\cdot V=W$ can also be represented in alignment diagram form by the use of a pair of coincident, circular U and V scales and a third straight-line W scale lying along a diameter of the circle. The values $U, V, W=0$ coincide at one end of the diameter and the values $U, V, W=\infty$, $U, V, W=-\infty$ coincide at the other end (Fig. 5). This diagram, extremely useful for certain purposes, seems to be employed by current English nomographers, but to be practically unknown in this country. In a survey of seventeen hundred nomograms appearing in the technical periodical literature in this country for the years 1925–1947, only one, designed by an Englishman, was found which partook of this form.

Geometrical Relationships

In Fig. 6, let line ABC be a random line of collineation cutting proposed U, V, W scales at points A, C, and B, respectively. Draw lines OA and OC defining peripheral angles θ and ϕ, which vary directly with arcs EA and EC. Construct line

---

* The circular nomogram has been given a thorough introductory treatment in *Elements of Nomography* by R. D. Douglass and D. P. Adams (McGraw-Hill Book Company, Inc., New York, 1947). The present authors believe that treatment to be the first in American texts.

ED parallel to line AC and draw line DC. Since $DC = AE$,

$$\measuredangle DOC = \measuredangle AOE,$$
$$\measuredangle DOC = \theta,$$
$$\measuredangle OAC = \measuredangle ODC.$$

Triangles OAB and ODC are similar and

$$OB/OA = OC/OD,$$
$$OA = 2a\cos\theta,$$
$$OC = 2a\cos\phi,$$
$$OD = 2a\cos(\phi-\theta).$$

Let OB, the distance from O to the cutting point B along the proposed W scale, be called S_W. It is the scale distance measured from point O out along the diameter to the point of location of any particular value W.

$$S_W = 2a\cos\theta\cos\phi/(\cos\theta\cos\phi+\sin\theta\sin\phi),$$
$$S_W = 2a/(1+\tan\theta\tan\phi).$$

Let the U and V scales be defined upon their circular arcs by the relationships:

$$U = \tan\theta, \tag{1}$$

$$V = \tan\phi, \tag{2}$$

$$S_W = 2a/(1+U\cdot V),$$
$$S_W = 2a/(1+W). \tag{3}$$

Thus, the W scale equation is observed to be identical with that for the diagonal scale for the N-type diagram, Fig. 2(b), when the latter is measured from the $V=\infty$ end.[1] This makes it possible to compound the circular diagram with the N diagram. A completed circular diagram appears in Fig. 7.

DISCUSSION

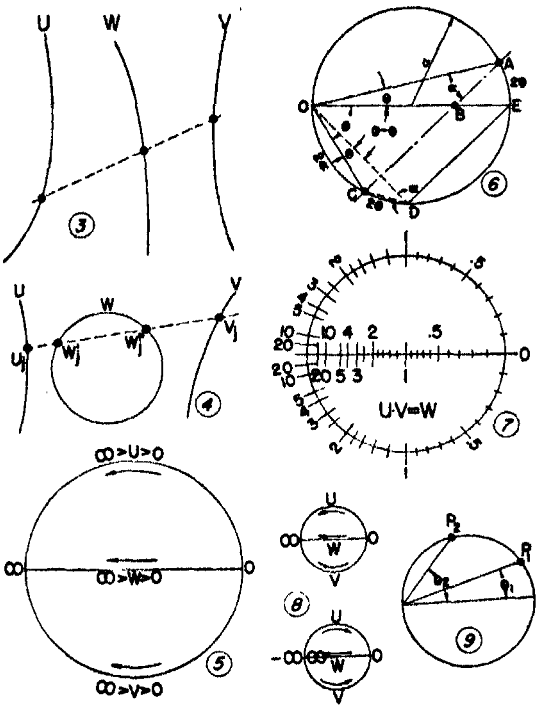
Range and Scope of the Circular Nomogram

The great advantage of the circular nomogram lies in its closure, which permits infinite ranges of all three variables to be present. This property is in contrast to the diagrams for the same basic formula for multiplication presented in Fig. 2(b). More generally, one can have the two arrangements presented schematically in Fig. 8. Any adaptable portion of such a diagram will be a valid alignment diagram.

Changing the Distribution of Graduations

Figure 7 shows the unit values of all three scales on a vertical line through the center of the circle. Fortunately, this distribution of values along the scale can be varied. Assume

$$P\cdot Q = R,$$
$$mP\cdot nQ = mnR.$$



FIGS. 3–9. Basic characteristics of the circular nomogram.

Let

$$U = mP,$$
$$V = nQ,$$
$$W = mnR;$$

then

$$U\cdot V = W.$$

A diagram in U, V, W can be drawn in the standard form of Fig. 7. However, the diagram graduated in the original variables P, Q, and R will be such that these variables along the vertical line through the center of the circle will be $P_0 = 1/m$, $Q_0 = 1/n$, and $R_0 = 1/mn$. Great freedom of distribution of values is thus achieved. The standard equations 1, 2, and 3 will now be

$$P = \tan\theta/m, \tag{4}$$

$$Q = \tan\phi/n, \tag{5}$$

$$S_R = 2a/(1+mnR). \tag{6}$$

Maximizing Intermediate Scale Intervals

If the lowest values of the more useful ranges of the variables P and Q are greater than zero and the highest values of these ranges are finite, the more useful range of the R scale will not contain $R=0$ or $R=\infty$. The *spread* of this useful range will vary with m and n. A preliminary plan of the diagram may show this more useful range to be embarrassingly small. However, it can be maximized as follows. Let R_1 and R_2 be the lowest and highest values in the more useful range of R. Let this R

---

[1] R. D. Douglass and D. P. Adams, *Elements of Nomography* (McGraw-Hill Book Company, Inc., New York, 1947), p. 100, Note 2.

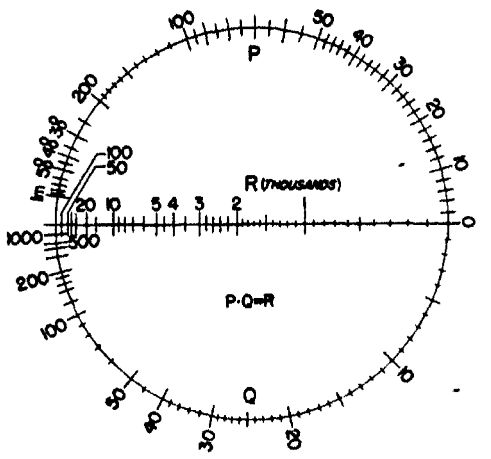


FIG. 10. A simple circular nomogram with maximized ranges.

range be maximized as a problem independent of the other scales. The R scale is characterized by the multiplier $l=mn$:

$$\begin{aligned} S_R&=2a/(1+lR),\\ S_{R_1}&=2a/(1+lR_1),\\ S_{R_2}&=2a/(1+lR_2),\\ T&=S_{R_1}-S_{R_2}. \end{aligned}$$

Then T, the spread of the most used range of R, is to be maximized with respect to the variable l:

$$T=2a\left(\frac{1}{1+lR_1}-\frac{1}{1+lR_2}\right),$$

$$\frac{dT}{dl}=2a\left(\frac{R_2}{(1+lR_2)^2}-\frac{R_1}{(1+lR_1)^2}\right).$$

For a maximum,

$$R_1(1+2lR_2+l^2R_2^2)=R_2(1+2lR_1+l^2R_1^2),$$

$$l=1/(R_1R_2)^{\frac{1}{2}},$$

$$\left.\begin{aligned} S_{R_1}&=2a/[1+(R_1/R_2)^{\frac{1}{2}}]\\ S_{R_2}&=2a/[1+(R_2/R_1)^{\frac{1}{2}}]\\ S_R&=2a/[1+[1/(R_1R_2)^{\frac{1}{2}}]R] \end{aligned}\right\}. \tag{7}$$

It is interesting to observe that the position of this spread upon the diameter is symmetric with respect to the center of the circle. Thus,

$$\frac{S_{R_1}+S_{R_2}}{2}=\frac{2a}{2}\left(\frac{1}{1+(R_1/R_2)^{\frac{1}{2}}}+\frac{1}{1+(R_2/R_1)^{\frac{1}{2}}}\right)$$
$$=a.$$

Maximizing the circular scale intervals, one has (Fig. 9):

$$\begin{aligned} \theta_1&=\tan^{-1}mP_1,\\ \theta_2&=\tan^{-1}mP_2,\\ A&=2(\theta_2-\theta_1). \end{aligned}$$

Then A is the spread of the most used range of P and is to be maximized with respect to m.

$$dA/dm=2[(P_1/(1+m^2P_1^2))-(P_2/(1+m^2P_2^2))].$$

For a maximum,

$$-P_1-m^2P_1P_2^2+m^2P_2P_1^2+P_2=0,$$
$$m=1/(P_1P_2)^{\frac{1}{2}}.$$

Correspondingly,

$$n=1/(Q_1Q_2)^{\frac{1}{2}}.$$

These ranges are also distributed symmetrically with respect to a vertical line on the circle, for

$$\begin{aligned} \tan\theta_1&=(P_1/P_2)^{\frac{1}{2}},\\ \tan\theta_2&=(P_2/P_1)^{\frac{1}{2}},\\ \tan\theta_1&=\cot\theta_2\\ &=\tan(90°-\theta_2),\\ (\theta_1+\theta_2)/2&=45°. \end{aligned}$$

Let the P and Q ranges be maximized independently and the R range be regarded as dependent.

$$\begin{aligned} P_1Q_1&=R_1,\\ P_2Q_2&=R_2,\\ l&=mn,\\ l&=1/(P_1Q_1P_2Q_2)^{\frac{1}{2}},\\ l&=1/(R_1R_2)^{\frac{1}{2}}. \end{aligned}$$

Thus, the R range is also maximized.

In this way, a circular diagram may be drawn with maximum dispersions for the most useful portions of all three scales. In addition, the maximization process, because of its symmetry with respect to the vertical diameter described above, produces a chart in which the index line (e.g., line ABC in Fig. 6) makes the greatest angle with the dependent scale on the diameter, thus allowing the most accurate measurement of R. Hence, the problem of optimum placement of scales for intermediate ranges of the variables in the circular nomogram achieves a pleasing and classical simplicity.

APPLICATIONS

Illustrative Problem 1

Figure 10. Design a circular nomogram six inches in diameter for the equation $P\cdot Q=R$ where infinite ranges of the variables are desirable but the ranges of P from $P_1=50$ to $P_2=100$, of Q from $Q_1=20$ to $Q_2=30$, and of R from $R_1=1000$ to $R_2=3000$ are subject to especially heavy use.

$$\begin{aligned} m&=1/(50\cdot 100)^{\frac{1}{2}}=0.01414,\\ n&=1/(20\cdot 30)^{\frac{1}{2}}=0.04082,\\ l&=1/(1000\cdot 3000)^{\frac{1}{2}}=0.0005773,\\ \theta&=\tan^{-1}0.01414P,\\ \phi&=\tan^{-1}0.04082Q,\\ S_R&=6/(1+0.000577R). \end{aligned}$$

Illustrative Problem 2

Figure 11.[2] Design a circular nomogram six inches in diameter for the equation

$$(\log \sin A)(B^3-4)=7\cos^2 C.$$

Place the B scale on the diameter of the circle. All first-quadrant values of the angles A and C are useful but the range of A from $A_2=10$ to $A_1=50$ and of C from $C_1=10$ to $C_2=50$ are heavily used.

Solution: Since the variable B is to be recorded upon the diameter, write the equation in the form

$$\begin{aligned}(\log \sin A)(1/7\cos^2 C)&=1/(B^3-4),\\ U'&=-\log \sin A,\\ V'&=1/7\cos^2 C,\\ W'&=-1/(B^3-4),\\ U_1'&=0.1158,\\ U_2'&=0.7603,\\ m&=3.37,\\ V_1'&=0.1473,\\ V_2'&=0.3457,\\ n&=4.44,\\ l&=14.95.\end{aligned}$$

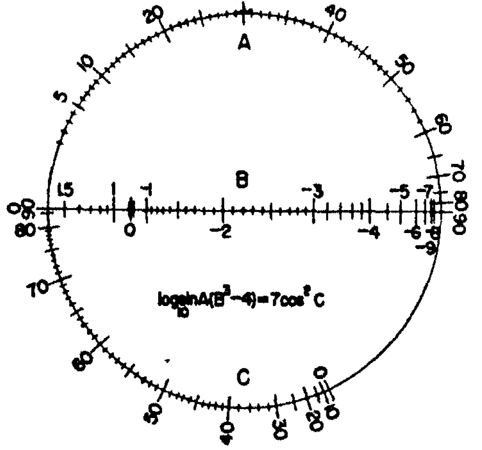

FIG. 11. An advanced circular nomogram with maximized ranges.

Then useful scale equations[3] for plotting this diagram are:

$$S_A=-6(3.37\log \sin A)\quad\text{or}\quad S_A=-6/3.37\log \sin A;$$
$$S_C=6(4.44/7\cos^2 C)\quad\text{or}\quad S_C=6(7\cos^2 C/4.44);$$
$$S_B=6/[1-(14.95/(B^3-4))].$$

Illustrative Problem 3

Figures 12 and 13.[4] Design a nomogram for the

$$s=r_s\cot\cos^{-1}(\cos\bar{\mu}-d^*),$$

equation where $\bar{\mu}$ ranges from 0° to 35°, d^* ranges from 0 to 1.0, s ranges from 10 to 70, r_s ranges from 15 to 40, in steps of 5. s is the dependent variable in practice. Experience indicates that it has a most heavily used interval from $s=25$ to $s=60$.

Analysis

The presence of four variables, three of them independent, precludes the possibility of a single alignment form for the diagram and requires a compounding of diagrams. Let

$$U=\cot\cos^{-1}(\cos\bar{\mu}-d^*).$$

Then,

$$s=r_s U.$$

Since U is given by $\tan\theta$ in the preceding theory, the presence of the cotangent function militates strongly in favor of the circular nomogram.

Let α be the complementary angle to θ, Fig. 12(a). Then $U=\tan\theta$ is properly recorded as $U=\cot\alpha$. Let

$$\begin{aligned}\alpha&=\cos^{-1}(\cos\bar{\mu}-d^*),\\ \cos\alpha&=\cos\bar{\mu}-d^*=x/2a,\\ x&=2a(\cos\bar{\mu}-d^*).\end{aligned}$$

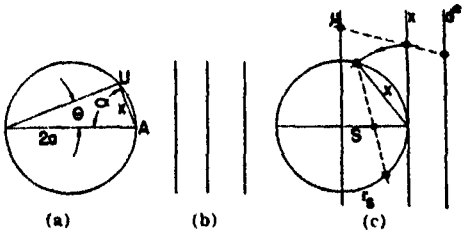
The problem of the last equation is easily solved by a diagram of the form of Fig. 12(b). Let the x scale be tangent to the circle at the vertex A of angle α, have zero value there and be $2a$ units long. Let the $\bar{\mu}$-scale be located pleasingly upon the vertical center line of the circle. Let the values $\bar{\mu}=0$ and $d^*=0$ be on a level with $x=2$. Distances along the x scale can be conveniently transferred to the U scale by concentric arcs about point A, particularly with the aid of corresponding arbitrary graduations on the x and U scales (Fig. 12(c)).

Derivation of the Scale Equations

s scale: To maximize the most favored s interval,

$$l=1/(25\cdot 60)^{\frac{1}{2}}=0.0258;$$
$$S_S=10/(1+0.0258s)$$

for a circle of ten inches diameter ($a=5$).



(a) (b) (c)

FIG. 12. Breakdown of parts for nomogram for camera.

---

[2] Compare with Fig. 88 in Douglass and Adams, reference 1, p. 156, where no interval has been maximized.

[3] For derivation and application of scale equations for the circular nomogram, see Douglass and Adams, reference 1, Chapter XVII.

[4] H. T. Evans, Jr., S. G. Tilden, Jr., and D. P. Adams. "New techniques applied to the Buerger precession camera for x-ray diffraction studies," Rev. Sci. Inst. 20, 155 (1949).

In practice, this diagram has been found to be practically indispensable to the efficient use of the equipment whose behavior is represented by this equation.

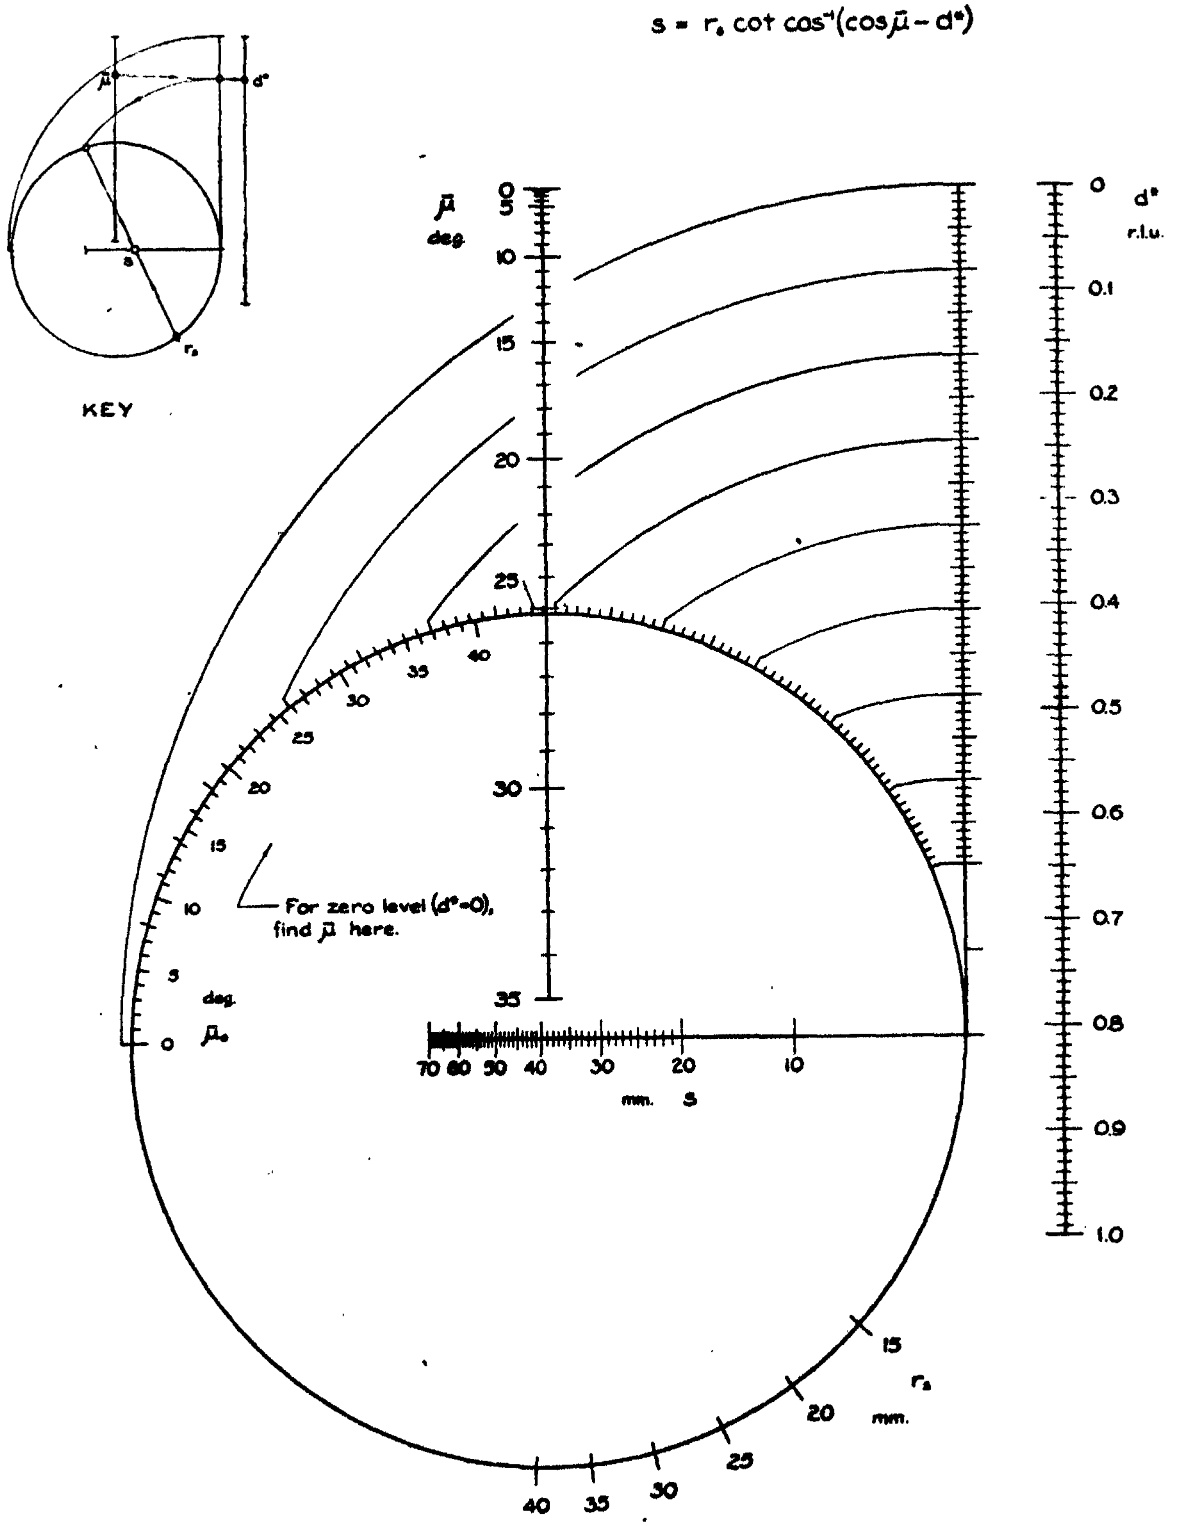


Fig. 13. Final Buerger precession camera nomogram.

r_s scale: The original equation now reads

$$ls=(nr_s)[m\cot\cos^{-1}(\cos\bar{\mu}-d^*)].$$

The device employed requires that

$$\cot\alpha=m\cot\cos^{-1}(\cos\bar{\mu}-d^*).$$

Hence $m=1$, $n=l$ in this scheme and neither of the circular scales can be varied for maximization. The value of r_s on the vertical center line will be

$$r_s=1/l=38.73.$$

The resulting r_s scale does lie in part to the left of the center line and has a satisfactory spread without maximization. A convenient scale equation for drafting the r_s scale will be

$$S_{r_s}=10r_s.$$

x scale: The scale factor of the x scale is unity. The sum of the scale factors of the d^* and $\bar{\mu}$ scales will equal their product and the distances of these scales from the x scale will be proportional to these scale factors.[5] Of these four quantities, only the distance of the $\bar{\mu}$ scale has been fixed (at five inches) by the present design.

$\bar{\mu}$ scale and d^* scale: The equations for these scales, reduced to scale measurement upward from the horizontal center line of the circle, can accordingly be

$$S_{\bar{\mu}}=52.6(\cos\bar{\mu}-0.810),$$
$$S_{d^*}=12.34(0.810-d^*).$$

The d^* scale is 1.17 inches from the x scale.

---

THE REVIEW OF SCIENTIFIC INSTRUMENTS VOLUME 20, NUMBER 3 MARCH, 1949

New Techniques Applied to the Buerger Precession Camera for X-Ray Diffraction Studies

HOWARD T. EVANS, JR.,* S. G. TILDEN, AND DOUGLAS P. ADAMS
Section of Graphics, Massachusetts Institute of Technology, Cambridge, Massachusetts

(Received August 30, 1948)

The usefulness of the Buerger precession method for single crystal x-ray diffraction studies is increased by the following techniques: (1) The use of a nomogram to facilitate the setting and operation of the instrument; (2) the simplification of orientation and lattice measurement techniques; and (3) the application of the Dawton photographic method to precession photographs for obtaining quantitative intensity data, together with a graphical method for determining Lorentz and polarization corrections.

IN 1944, a new method of obtaining x-ray diffraction data from single crystals was described by Buerger.[1] By use of a camera of novel design, aptly called the "precession" camera, layers of the reciprocal lattice were photographed directly without distortion. This instrument has since been made available commercially and has earned favor in several laboratories.[2] It seems apparent, however, that the full possibilities of this instrument have not been generally realized. Therefore, some of the techniques developed in this laboratory in connection with the precession method will perhaps be of interest.

INSTRUMENT SETTINGS

In preparing the instrument for a run, five separate adjustments must be made for each photograph, defined as follows: (1) F, the film-to-crystal distance; (2) $d^{*\prime}$, an adjustment of the film position for proper registration of the upper levels of the lattice; (3) $\bar{\mu}$, the angle between the direct beam and the normal to the plane being photographed; (4) r_s, the radius of the layer-line screen; (5) s, the screen-to-crystal distance.

F is an independent adjustment determined by the desired magnification of the lattice image, and $d^{*\prime}$ is simply the product of F and d^* the reciprocal lattice spacing normal to the planes being photographed. $\bar{\mu}$, r_s, s, and d^* are, on the other hand, related in a rather complex way, as shown by Buerger, thus: $s=r_s \cot\cos^{-1}(\cos\bar{\mu}-d^*)$.

s is usually the last adjustment made and, hence, may be regarded as the dependent variable of the equation. In his monograph, Buerger gives a chart permitting rapid determination of s over a range of d^* (0 to 1.0 reciprocal lattice units) for two values of r_s (15 and 30 mm) and a fixed value of $\bar{\mu}$ (20°). Although these restrictions on r_s and $\bar{\mu}$ are not inconvenient in a majority of cases, there are many times when a greater flexibility of these variables is desirable.

It is possible to present the behavior of the variables in the equation in an alignment diagram which will give the value of s for all useful values of r_s, $\bar{\mu}$, and d^*. By using this diagram, reproduced in Fig. 1, it is an easy matter quickly and accurately to arrive at an optimum value for each of the settings involved. The key to the diagram shows the general scheme to be the employment of two elementary types of alignment diagrams. The first of these is the familiar three-parallel-line diagram; the second is the less familiar circular nomogram. The further adaptation of the latter to the special needs of the

equation at hand appears to the writers to be new, and is described in detail elsewhere.[8] Also, its form has accurately maximized along the circle's diameter the spread of the most useful range of the dependent variable, s (25 to 60 mm).

ORIENTATION OF CRYSTALS

The use of the Buerger precession camera in the orientation of crystals has been described in detail by Buerger.[1] If the crystal has a zone of faces parallel to the dial axis, which carries the goniometer head, the optical autocollimator attached to the standard x-ray collimator may usually be used to align the crystal without any trial photographs. Alternatively, the crystal may be brought into orientation by means of a series of trial photographs from which the setting errors are estimated by observing the traces of the zero level reflections on the film.

---

[8] D. P. Adams and H. T. Evans, Jr., "Developments in the Useful Circular Nomogram," Rev. Sci. Inst. 20, 150 (1949).

We have found that another very convenient method is provided by drilling two very small holes (No. 80 drill) in the back of the film holder under the spring clip. These holes admit just enough light to mark the film. A line is thus determined which is accurately located parallel to the dial axis. The angle between this line and a lattice row line thus can be measured accurately to find directly the error of setting of the goniometer head arc parallel to the film. Two such photographs taken 90° apart on the dial supply the data necessary to bring a roughly oriented crystal into perfect alignment. In Fig. 2, which shows such a photograph, two sharp spots are visible near the extreme ends of the horizontal central lattice line. The arc error, measured between the line of these spots and the adjacent lattice line, in this case is 2° 20′. (The orientation of the film is indicated by a cut in the upper right corner, which corresponds with a mark on the film holder.)

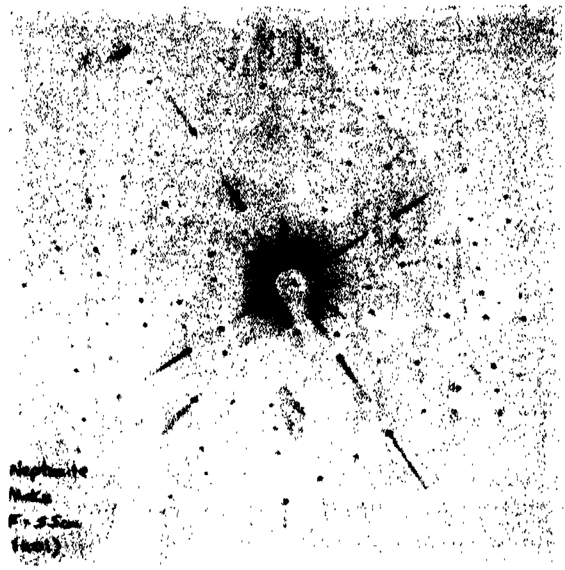

FIG. 2. Zero level precession photograph, showing orientation marks (neptunite, monoclinic).

This method, combined with those described by Buerger, makes the instrument extremely valuable for the purpose of orienting crystals, especially when only anhedral fragments are available. The ease with which the lattice of a crystal may be located, oriented, and explored with the precession instrument makes the latter a very fitting adjunct to the Weissenberg camera with its far-reaching range.

LATTICE MEASUREMENTS

The Buerger precession camera has been found to provide measurements of lattice spacings of considerable accuracy. Our instrument has been calibrated with a quartz crystal, as suggested by Bradley and Jay.[4] The (*h*0*l*) reciprocal net plane of the crystal was photographed with the film-to-crystal distance, F, set as closely as possible with the vernier to 6.000 cm. Two values of F were measured from the spacings on the film, as follows: 5.998 cm; 6.002 cm. The accuracy apparent from these measurements, better than 4 parts in 10,000, has been confirmed by comparative measurements on other crystals. Such precision can be obtained with the Weissenberg only with some trouble involving extrapolations and corrections. One advantage of the precession method is that the spacings of a whole row of spots on a film may be averaged simultaneously bv alignment with a hair-line. Thus, two settings of the hair-line are usually sufficient to provide data of the quality indicated, without any further corrections. The performance of this instrument testifies not only for the nature of the method, but also for the skill of the machinist who built it.[5]

INTENSITY MEASUREMENTS

The precession method has been found to be well suited to the recording of intensity data over a limited range, which, for many cases, is adequate. The Dawton photographic technique[6] is readily adapted to precession photographs. The spots on the film are round and uniform and very con-

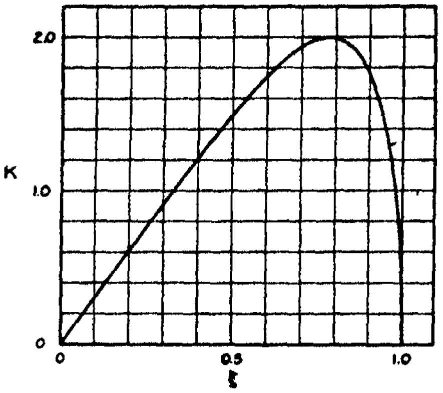

FIG. 4. Lorentz-polarization correction, K, for zero level.

veniently arranged, lending themselves to rapid and straightforward photometric measurement. The maximum range is obtained by using an inclination angle of $\bar{\mu}=30°$, and a film-to-crystal distance of $F=5.5$ cm. With this setting, a circular area of the zero level 11 cm in diameter is recorded on the 5 inch square film. This corresponds to a diameter of 2.0 reciprocal lattice units, and, if molybdenum radiation is used, covers a range just greater than that recorded by the Weissenberg camera using copper radiation. Actually, it has been found that, for most purposes, efficient application of the Buerger precession camera depends on the use of molybdenum radiation.

The form of the Lorentz factor for the precession method has been described by Buerger.[1] Figure 3 is a view normal to the zero level of the reciprocal lattice. One lattice point and the origin are shown. The circle is the intersection of the lattice plane and the unit sphere of reflection. With the quantity w defined as shown in Fig. 3, Buerger derived the following expression for the Lorentz factor:

$$1/L=w\sin\bar{\mu}\cos\bar{\mu}. \tag{1}$$

For the zero level, it appeared that a more convenient expression would combine both the Lorentz and polarization corrections, in terms of $\bar{\mu}$ and the radial coordinate ξ (in r.l.u.; see Fig. 3), the latter being readily measured directly from precession films. Such an expression may be derived as follows:

$$\begin{aligned}\sin^2\alpha&=w^2/\xi^2,\\ \cos^2\alpha&=\xi^2/4\sin^2\bar{\mu},\\ 1&=w^2/\xi^2+\xi^2/4\sin^2\bar{\mu},\\ w&=[\xi(4\sin\bar{\mu}^2-\xi^2)^{\frac{1}{2}}/2\sin\bar{\mu}].\end{aligned} \tag{2}$$

Substituting (2) into (1), there results:

$$1/L\doteq 1/2\xi\cos\bar{\mu}(4\sin^2\bar{\mu}-\xi^2)^{\frac{1}{2}}. \tag{3}$$

The polarization factor is readily derived from the classic formula:

$$1/p=(2/1+\cos^2 2\theta). \tag{4}$$

For the zero level,

$$\begin{aligned}\xi&=\lambda/d=2\sin\theta,\\ 2\sin^2\theta&=1-\cos 2\theta,\\ \cos^2 2\theta&=[1-(\xi^2/2)]^2.\end{aligned}$$

Substituting in (4) gives:

$$1/p=4/(8-4\xi^2+\xi^4). \tag{5}$$

Combining (5) with (3), we obtain:

$$\frac{1}{Lp}=\frac{4\xi\cos\bar{\mu}(4\sin^2\bar{\mu}-\xi^2)^{\frac{1}{2}}}{8-4\xi^2+\xi^4}. \tag{6}$$

If we adopt the settings suggested above ($\bar{\mu}=30°$, $F=5.5$ cm) universally for the taking of zero level quantitative Dawton photographs, this correction is very easily determined for all reflections by means of a simple graphical device. This consists of a template with a set of rings graduated according to $1/Lp$, and whose positions are determined by Eq. (6). By superposing the template directly on the precession film, the correction may be read off directly for each spot by its position with respect to the rings. When $\bar{\mu}=30°$, Eq. (6) may be written:

$$\frac{1}{Lp}\sim K=24.34\frac{\xi(1-\xi^2)^{\frac{1}{2}}}{8-4\xi^2+\xi^4}. \tag{7}$$

This function is scaled arbitrarily to allow $1/Lp$ to range between 0 and 2.00, as shown by the graph illustrated in Fig. 4. In Fig. 5, a chart made from Eq. (7) is shown in place on a precession photo-

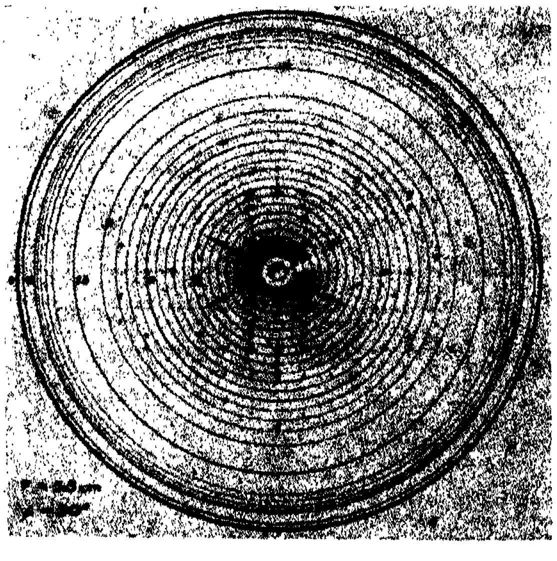

FIG. 5. Template for Lorentz-polarization correction in place on zero level photograph ($K_6TeMo_6O_{24}\cdot 7H_2O$, orthorhombic).

graph. The chart is best prepared photographically from an original drawing, which may be easily made from the data given in Table I.

The precession method is not well adapted to the quantitative photography of upper levels, for several reasons. The range recorded for upper levels is much smaller; the central blind area increases very rapidly with the distance of the lattice plane from the origin (d^*); and the Lorentz-polarization correction is much more awkward to evaluate. Thus, the precession method is practically limited to two-dimensional Fourier studies of crystal structures at present. For three-dimensional studies, the equi-inclination Weissenberg method will maintain its superiority.

SUMMARY

New techniques and aspects of the Buerger precession method for single crystal x-ray studies have been described. The utility of the instrument is greatly increased by the use of a nomogram which quickly solves the rather awkward setting relationships for any case. Other aspects of the method that have been dealt with are the following:

(1) A new method of measuring orientation errors, together with earlier known techniques, speeds the process of locating and aligning the lattice of a crystal, even when crystal faces are totally lacking.

(2) The Buerger precession camera has been found to give reliable measurements of lattice dimensions, accurate to better than 4 parts in 10,000, directly without corrections or extrapolations.

(3) The precession method is convenient for making intensity measurements by the Dawton photographic technique, for zero level reflections. Its range, when molybdenum radiation is used, is comparable with that of the Weissenberg method used with copper radiation. The Lorentz-polarization correction is easily measured by the use of simple graphical methods.

ACKNOWLEDGMENT

The observations described in this paper were made in the Laboratory for Insulation Research, at the Massachusetts Institute of Technology. We wish to express our appreciation to Professor Arthur R. von Hippel, director of the laboratory, for his encouragement of the work.

THE REVIEW OF SCIENTIFIC INSTRUMENTS VOLUME 20, NUMBER 3 MARCH, 1949

Conditions for Optimum Luminosity and Energy Resolution in an Axial β-Ray Spectrometer with Homogeneous Magnetic Field

JESSE W. M. DUMOND
California Institute of Technology, Pasadena, California

(Received October 18, 1948)

In a β-ray spectrometer with axial homogeneous magnetic field, it is shown that optimum energy resolution and luminosity are obtained when the trajectories make an angle close to 45° with the field and that an annular resolving slit should be provided at a determined radial and axial location relative to the source. The combined effect of three independent sources of instrumental energy line width is analyzed for the optimum condition. Formulas are given for the optimum dimensions, the energy resolution and the luminosity.

THE improvement recently obtained in the precision of absolute measurement of nuclear energy levels by the direct crystal diffraction of short wave-length nuclear gamma-rays[1] makes it a matter of considerable interest to develop a β-ray spectrometer of high resolving power and high precision comparable to that obtainable in the crystal diffraction method. The low reflecting power of crystals for wave-lengths of order 30 x.u. and less necessitates the use of extremely strong gamma-ray sources and hence practically eliminates this method as an exploratory technique. Its great advantage on the other hand, lies in the high absolute precision which it affords. It thus complements very satisfactorily the qualities of the β-ray spectrometer since the latter instrument has high luminosity but is very difficult to calibrate with absolute precision. The thought here is that if a β-ray spectrometer of sufficiently high resolving power and reproducibility can be designed, its calibration in terms of absolute β-ray energies can be accomplished by utilizing a number of nuclear gamma-ray lines (precisely standardized by the crystal diffraction method) to eject photoelectrons from known and precisely measured electronic energy levels in appropriately selected secondary radiators. The β-ray spectrometer, so calibrated, can then be used for the accurate measurement of both β-ray and gamma-ray energies from a wide variety of sources and the high absolute precision of the crystal diffraction method can thus be propagated over a much wider domain of measurements.

Many types of the β-ray spectrometer exist or have been proposed. Under the auspices of the Office of Naval Research[2] S. Frankel and E. C. Nelson have very recently made a valuable survey of many of these and have discussed their properties. They fall into three general classes.

(*1.*) *Spectrometers in which the central ray of an electron beam or pencil lies in a plane essentially perpendicular to the magnetic field.*—The electrons execute circular orbits which may consist of arcs greater or less than 180° and the field may be uniform or tapered in various ways to obtain various types of focusing. Notable among these is the Siegbahn-Svartholm[3] so-called double-focusing type.

(*2.*) *Spectrometers of the helical focusing type.*—The magnetic field may be approximately uniform (utilizing the field from a long solenoid) or it may be set up by a more-or-less concentrated coil and may merely have axial symmetry. Electrons leave a more or less concentrated source point on the axis at one end and execute paths more or less helical in form passing through various restricting stops and returning to the axis at the other end where they enter the window of a counter. First suggested by Kapitza in 1923 this type, in various modifications, has been used and described by Tricker,[4] Klemperer,[5] Witcher,[6] K. Siegbahn,[7] Deutsch, Elliot and Evans,[8] and T. Lauritsen and R. F. Christy.[9]

(*3.*) *Spectrometers utilizing electrostatic deflection of the β-rays.*—It is pointed out by Frankel and Nelson[2] that for a fast electron whose velocity nearly equals that of light the same curvature may be produced by a magnetic field of 1000 gauss (which is conveniently small) as by an electric field of 300,000 volts per cm (which is uncomfortably large). Such instruments, which possibly have some importance for the formation of images in electron microscopy have therefore not played an important role in β-spectrometry.[10]

[9] T. Lauritsen and R. F. Christy, Phys. Rev. **73**, 536 (1948).

The helical focusing type seems so obviously advantageous as regards the utilizable solid angle of β-rays emanating from the source that this was chosen as the object of the first analysis (the one herein presented) to determine the optimum conditions for simultaneous high resolving power and high luminosity. It is not entirely certain, however, that other and radically different types cannot be devised which will be superior to this one and a program of analysis of other types is now being planned.

The choice of a homogeneous magnetic field (rather than the more complicated field from a concentrated coil) for the β-ray spectrometer here described was based on the following considerations. (1) The analysis is considerably simplified. (2) A homogeneous field is not difficult to realize with a high degree of precision by means of a long solenoid. (3) Small geometrical distortions of such a field by external magnetic influences are more readily detected than they would be in the case of more complicated fields. (4) Since the applied magnetic field is everywhere uniformly strong over the useful region, errors from external magnetic effects are everywhere at a minimum. (5) The adjustment of the spectrometer relative to the field coil is less critical since it depends in first approximation only on the orientation and not on the position. This is a consideration which becomes important because of the high accuracy sought. As Frankel and Nelson[2] point out the thin lens β-spectrometer is more efficient as regards the cost for copper and for power than the solenoid type with uniform magnetic field, but Lauritsen and Christy[9] have shown it to have a poorer resolution for the same range of angles within which the β-rays emanate from the source. The thick lens spectrometer is a compromise between the superior resolving power of the solenoid type and the cheaper thin lens type.

It is a rather surprising fact that the use of a ring shaped annular resolving slit in this type of spectrometer was not suggested until rather recently[11] although the existence of a ring-shaped focus for the bundle of β-rays appears to have been clearly apparent in earlier papers. In a homogeneous magnetic field (solenoid) a bundle of β-rays *of specified energy* leaving a source point on the axis of the spectrometer at colatitude-angles θ in the range $\theta_1<\theta<\theta_1+d\theta$ will focus in a ring whose plane is normal to the axis and whose radius and distance from the source can be readily calculated. It is this type of focusing with which we shall be concerned in this paper.

The trajectory of an electron in a uniform magnetic field is a helix. Let us consider a point source S from which electrons of definite kinetic energy, T, emanate with equal probability in all directions in space. Let us measure the kinetic energy of these electrons in terms of the dimensionless parameter, $\epsilon=T/(m_0c^2)$ (ratio of the kinetic energy to the electron rest-energy, 0.5108 Mev). As x-axis we take a line through the point source S in the direction of the magnetic field whose intensity is H. Let the angle between the helical trajectory and the magnetic field be θ. After one complete turn of the helix the trajectory will once more intersect the x axis in a point S'. Let the diameter of the helical trajectory be R and the distance SS' be L. Then, if e is the electronic charge it is easy to show by elementary considerations that

$$R=2(m_0c/He)[(\epsilon+1)^2-1]^{\frac{1}{2}}\sin\theta, \tag{1}$$

$$L=2\pi(m_0c/He)[(\epsilon+1)^2-1]^{\frac{1}{2}}\cos\theta. \tag{2}$$

For brevity let $K=2(m_0c/He)$ and $Q=K[(\epsilon+1)^2-1]^{\frac{1}{2}}$. The assemblage of helical trajectories emanating from S form a triply infinite family of helices characterized by the three parameters; (1.) the azimuth angle of the trajectory at S, (2.) the colatitude angle θ at S, and (3.) the parameter Q depending on the kinetic energy ϵ and the field strength H.

If we consider the entire sub-class of trajectories having a specified value $\theta=\theta_1$ and $Q=Q_1$ but all values of the azimuth angle at S, these helices will all be found to lie on a cigar shaped surface of revolution having the x axis as axis of revolution and having a sinusoidal profile or trace on a plane through the x axis. Figure 1 illustrates a side view of this surface of revolution with a few of the individual helices traced upon it. Only the part of each helix on the side of the surface of revolution toward the observer is drawn, to avoid confusion. The trace or intersection of this surface of revolution with a plane through the x axis will henceforth be designated simply by the word "trace," and the cartesian coordinates x and y describing the equation of a trace will be taken in a plane through the x axis at any arbitrary azimuth angle. Clearly the angle made by the trace at the origin S with the x axis is equal to θ, since there is one of the helical trajectories which is tangent to the trace at S. We shall henceforth be much more concerned

---

[10] Relatively little attention, however, has been paid to the possibilities of combining electrostatic and magnetic deflections for β-spectrometry.

[11] The suggestion appears to have been first made by Witcher, (see reference 6) who did not, however, make the most of this very ingenious idea. In a letter to the editor of the Physical Review by S. Frankel, Phys. Rev. 73, 804 (1948) the large gain in solid angular luminosity for a specified high resolution obtainable by this ring focus is explained and emphasized. In a still more recent letter to the Physical Review, E. Persico gives his conclusions as to the optimum finite source size and angle of electron departure from the source. E. Persico, Phys. Rev. 73, 1475 (1948).

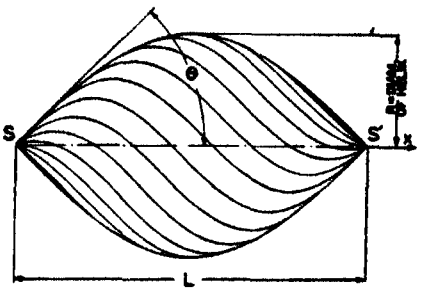

FIG. 1. Illustrating that a family of helical trajectories of specified θ and Q lie on a sinusoidal surface of revolution. L is one full turn of the helix.

with the traces than with the helices. The general equation of a trace is

$$y = Q\sin\theta\sin[x/(Q\cos\theta)]. \tag{3}$$

The traces starting from the origin S form a doubly infinite family of sinusoids characterized by the parameters Q and θ. Now suppose we hold the kinetic energy of the particles and the magnetic field intensity constant (i.e., Q constant) and impose a slight variation on θ. Two closely adjacent traces for a slight variation of θ will be found to have an ultimate intersection point P which will not be situated at S' but somewhere between S' and the summit of the sinusoidal trace. Figure 2 shows the geometry of two such adjacent traces. Let us compute the coordinates x_i and y_i of this ultimate intersection point, by equating

$$Q\sin(\theta+d\theta)\sin\frac{x_i}{Q\cos(\theta+d\theta)} = Q\sin\theta\sin\frac{x_i}{Q\cos\theta}.$$

A straightforward calculation rejecting terms of higher order than the first gives

$$x_i = (Q_1\cos\theta_1)\psi_i, \tag{4}$$

$$y_i = (Q_1\sin\theta_1)\sin\psi_i. \tag{5}$$

Here Q_1 and θ_1 are the particular values of Q and θ which characterize the traces having the ultimate intersection at x_i, y_i, while ψ_i is an angle related to θ_1 by the transcendental equation

$$-\psi_i\tan^2\theta_1 = \tan\psi_i. \tag{6}$$

In Fig. 3 we plot the various branches of the curve $\tan\psi_i$ and also the straight locus $-\psi_i\tan^2\theta_1$. The intersections of these two loci give the solutions for ψ_i, the solution of interest to us being that one which lies in the range $\pi/2 < \psi_i < \pi$. Clearly when

$$\theta = 0, \quad \psi_i = \pi,$$

and when

$$\theta = \pi/2, \quad \psi_i = \pi/2.$$

By substituting a series of values of ψ_i between these limits it is an easy matter to calculate the corresponding values of θ, from the equation

$$\tan^2\theta_1 = -(\tan\psi_i/\psi_i), \tag{7}$$

and the curve of Fig. 4 has been traced in this way. Table I gives the relation between ψ_i and θ_1 numerically.

Geometrically ψ_i is the abscissa coordinate *in angular measure* of P the ultimate intersection point, that is

$$\psi_i = x_i/(Q_1\cos\theta_1). \tag{8}$$

(The half-wave-length L of the sinusoidal trace is $\pi Q_1\cos\theta_1$.)

The ultimate intersection point P on the sinusoidal trace is obviously the focal place where the ring focus defining slit should be located in order to select a specified small band of kinetic energies. Clearly this slit must be an annular opening defined by a pair of diaphragms normal to the x-axis of the instrument.[12] We shall return later to a more careful consideration of the choice of the width of this opening. Its mean radius is given by y_i (Eq. (5)). In Fig. 5 we show a family of different sinusoidal trace-pairs for one and the same initial angle θ_1 but different values of Q_1 (i.e., different kinetic energies or magnetic field intensities). The ultimate intersection points are seen to lie along a straight line which also passes through the origin S.[13]

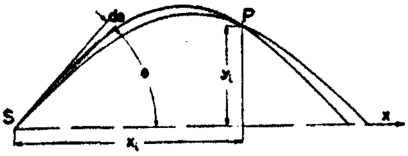

FIG. 2. Showing how two adjacent traces of constant Q but slightly different θ determine an ultimate intersection point P.

We now attack the problem of selecting the best value of θ_1, the colatitude angle at which the β-rays to be used in the instrument are to issue from the source S. If we fix the two points S and P on a certain sinusoidal trace T_1 characterized by the parameters Q_1 and θ_1, P being the ultimate intersection point for T_1 with coordinates x_i, y_i given in Eqs. (4) and (5), and then consider the family of other sinusoidal traces which also pass through S and P in the neighborhood of the trace T_1, these will be characterized by parameters θ and Q in such a way as to establish a functional dependence between these two parameters. For these neighboring traces, as θ departs from θ_1 Q will depart from Q_1, but since the point P *was purposely selected as an ultimate intersection* for the trace T_1 (with its immediate neighbors) we have good reason to expect that the departure of Q from Q_1 corresponding to a specified departure of θ from θ_1 *will be a smaller order of infinitesimal quantity than the latter.* Now what we aim to do is to select θ_1 in such a way that, for small deviations $d\theta$ on either side thereof, the largest possible solid angle at the source S results in the smallest possible inhomogeneity of kinetic energy. To do this we substitute the coordinates x_i, y_i of the ultimate intersection point into the general equation of the sinusoidal trace. This gives us

---

[12] S. Frankel (see reference 11) recommends that the defining edges of the diaphragms lie on a cone with vertex at the source and axis parallel to the magnetic field.

[13] This line is an element of the cone referred to by Frankel (see references 11 and 12).

$$\frac{Q_1 \sin\theta_1}{Q \sin\theta} \sin\psi_i = \sin\left(\frac{Q_1 \cos\theta_1}{Q \cos\theta} \cdot \psi_i\right). \tag{9}$$

Equation (9) is the implicit expression of the above mentioned relationship between Q and θ which obtains for the family of traces passing through the points S and P. We must remember that ψ_i is a function of θ_1 but not of θ. The *solid angle* of β-rays emanating from the source point S is what we wish to maximize or more significantly still *the fraction of the total sphere* into which the β-rays can be projected. Let us define $d\phi$ as this fraction of the total sphere. Then

$$d\phi = \tfrac{1}{2} \sin\theta d\theta. \tag{10}$$

Since we are only interested in small deviations of θ away from θ_1 and of Q away from Q_1 we define two small dimensionless quantities r and δ as follows:

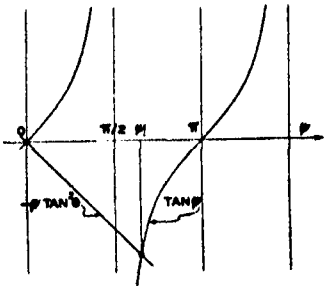

FIG. 3. Graphical solution of the equation relating ψ_i and θ.

$$\frac{Q-Q_1}{Q_1} = r \ll 1; \quad \frac{\cos\theta - \cos\theta_1}{\cos\theta_1} = \delta \ll 1.$$

We may confidently expect r to be an infinitesimal, at least one order of magnitude smaller than δ for the reason explained previously. Rejecting infinitesimals of higher order than the second, one obtains

$$\frac{Q_1}{Q}\frac{\sin\theta_1}{\sin\theta} = 1 + \frac{\delta}{\tan^2\theta_1} + \frac{1}{2}\frac{\delta^2}{\tan^2\theta_1} + \frac{5}{4}\frac{\delta^2}{\tan^4\theta_1} - r,$$

and $(Q_1/Q)(\cos\theta_1/\cos\theta) = 1 - \delta + \delta^2 - r$.

Substituting these values into Eq. (9) and solving for r one obtains

$$r = \tfrac{1}{4} \cos^2\theta_1 [6 + (5/\tan^2\theta_1) + 2\psi_i^2 \tan^2\theta_1]\delta^2; \tag{11}$$

now since

$$\delta = \frac{\cos\theta - \cos\theta_1}{\cos\theta_1} \cong \left[\frac{d(\cos\theta)}{\cos\theta_1}\right]_{\theta_1},$$

and $d\phi = \frac{1}{2}\sin\theta d\theta$, we obtain $d\phi^2 = \frac{1}{4}(\cos^2\theta_1)\delta^2$. So that Eq. (11) becomes

$$r = \left[6 + \frac{5}{\tan^2\theta_1} + 2\psi_i^2 \tan^2\theta_1\right](d\phi)^2. \tag{12}$$

This shows that our prediction was correct, i.e., that r is indeed a smaller order of infinitesimal than δ or than $d\phi$.

Clearly if we are to minimize the inhomogeneity of kinetic energy we must minimize r. In fact calculation shows that for constant field H

$$d\epsilon/\epsilon = [(\epsilon+2)/(\epsilon+1)]r. \tag{13}$$

Our problem is thus reduced to the evaluation of the bracket of Eq. (12),

$$B(\theta_1) = 6 + 5\cot^2\theta_1 + 2\psi_i^2 \tan^2\theta_1$$

which is a function of θ_1 only (since ψ_i is a function of θ_1 see Eq. (6). Figure 6 shows the value of this bracket $B(\theta_1)$ plotted as a function of θ_1 and

FIG. 4. Graph of ψ_i as function of θ. See also Table I.

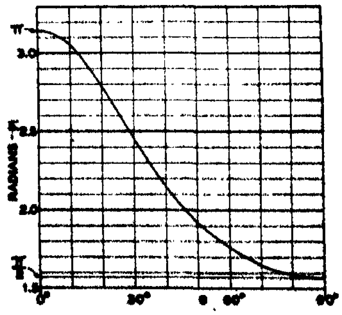

Table II gives the numerical values. It was a matter of considerable surprise to the author to discover that $B(\theta_1)$ is very nearly symmetrical about its minimum point and that this latter appears to occur very nearly at $\theta_1 = 45°$. Neither of the preceding statements is rigorously correct[14] but clearly from the numerical calculations the minimum in B is sufficiently flat to insure that there will be no significant loss of energy resolution if θ_1 is chosen anywhere within the range $40° < \theta_1 < 50°$. For $\theta_1 = 45°$ the value of B is about 19. At 40° and 50° it is about 20.

We now pass to the discussion of the appropriate shape and finite extension to give to the source and the appropriate width and disposition of the annular resolving slit. It appears to the author that when an extended source is necessary symmetry considerations dictate a source in the shape of a small very thin flat disk at S normal to and concentric with the x axis since this is the only shape for which all β-particles emerge at the same angle with the surface (45°). The small but unavoidable retardation of those particles which traverse the active layer from different depths will thus be minimized.

It is clear that the β-ray energy spectrum given by the spectrometer will have three[15] independent instrumental sources of line broadening, (1) the "spherical aberration" coming from the use of a finite angular aperture $\theta_1 < \theta < \theta_2$, (2) the finite spectral width of the selected energy band determined by the width of the resolving slit at the ring focus, (3) the radius of the source disk which we shall denote by ρ. Each of these sources of broadening alone would, if the effect of the other two were reduced to negligible proportions, yield its own characteristic spectral line profile (corresponding to a sharp line in the true energy spectrum). Figure 7 shows the shapes of these three profiles. With all three sources of broadening operating simultaneously the instrumental spectral line profile will be the *fold* of the three characteristic profiles, each with its own peculiar width parameter (determined by the stops and the source radius ρ selected). This resultant (folded) profile will have a resultant width parameter which will determine the resolving power of the instrument. At the same time, each of the three above mentioned sources of broadening contributes its factor to the counting rate of the instrument. The counting rate is in fact jointly proportional to the area of the source disk (ρ^2), to the width of the energy band selected at the ring focus (we assume, sufficiently high resolution so that all the spectral distributions studied can be regarded as continua) and to the solid angle defined by the aperture stops.[16]

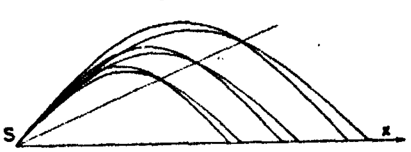

FIG. 5. A family of different trace pairs for the same initial angle θ_1 but different Q, i.e., different energies or magnetic intensities.

TABLE II.

θ_1 Degrees	B
0	∞
10°	167.6
20°	45.8
30°	25.0
40°	19.62
50°	20.0
60°	26.5
70°	48.2
80°	169.2
90°	∞

The problem we must pose is how to apportion the line broadening effects of the above mentioned three causes so as to minimize the resultant line breadth while maximizing the counting rate. The problem is complicated by the curious way in which the width parameter of the resultant folded profile is related to the width parameters of each of the three components.

A brief discussion and justification of the three component profiles of Fig. 7 is first in order. The profile I coming from the finite aperture angle has an infinite ordinate at $\epsilon = \epsilon_0$ but a finite area under the curve since the curve follows an inverse half-power dependence on $\epsilon - \epsilon_0$. This last may be shown as follows: Equation (12) implies that, for angles θ (of β-ray departure) differing slightly from θ_1, the energy ϵ selected by an infinitesimally small ring focus slit (of appropriate position and radius to focus an infinitesimal bundle of rays of angle θ_1)

---

[14] The value of θ_1 which makes $B(\theta_1)$ a minimum can be easily obtained by expressing B as a function of ψ_i,

$$B = 6 - \psi_i(5\cot\psi_i + 2\tan\psi_i).$$

The minimum of this function occurs at $\psi_i = 117.5$ degrees and substituting this value into Eq. (7) one obtains the corresponding value of $\theta_1 = 44°4'$ as the minimum point of $B(\theta_1)$. This differs slightly but not significantly, from the value 42°20′ given by Persico (see reference 11). It is so close to 45° that we shall use the latter value in design calculations since there is a gain in simplicity by this choice.

How nearly the function $B(\theta_1)$ is symmetric can be appreciated from the fact that even where B is enormous near $\theta = 0$ and again near $\theta = \pi/2$, i.e., for vanishingly small angles η, $B(\eta):B(\pi/2-\eta) = 5:\pi^2/2$.

[15] A fourth source of broadening coming from the finite *thickness* of the source is here ignored.

[16] The radius of the source disk has an important influence on the counting rate chiefly *in the case of direct sources of β-rays.* It is to such cases that the remainder of the discussion in this article primarily applies. When the primary source is a gamma-ray source which is to eject secondary β-rays from a converter it may be that the counting rate will not increase with the size of the secondary β-ray source. Then only the causes I and II (of line broadening) enter into the discussion.

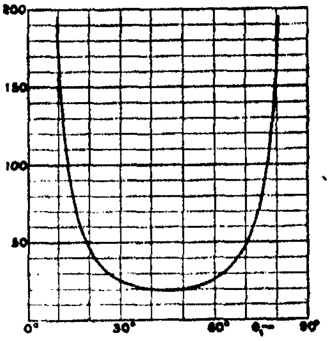

FIG. 6. The bracket $[6+5\cot^2\theta_1+2\psi_i^2\tan^2\theta_1]$ plotted as a function of θ_1. See also Table II.

will differ from ϵ_0 in first approximation by an amount proportional to $(\theta-\theta_1)^2$. This is illustrated by the parabolic characteristic of Fig. 8. If k_1 is a positive constant

$$(\epsilon-\epsilon_0)=k_1(\theta-\theta_1)^2. \qquad (14)$$

Now dj the flux of β-particles for small deviations of θ away from θ_1 will be proportional to the zone width $d\theta$ inside of which they are emitted. Differentiating Eq. (14) gives

$$d\theta=\tfrac{1}{2}k_1(\epsilon-\epsilon_0)^{-\frac{1}{2}}d\epsilon \qquad (15)$$

which proves the asserted inverse half power dependence of β-particle intensity j on $\epsilon-\epsilon_0$. The base width A_1 in Fig. 7 over which this distribution extends is fixed by the finite range of angle $2\Delta\theta$ for which the angular aperture stop is set. From Eq. (12) it is easy to show that to first-order this base width is given by,

$$A_1=(\Delta\epsilon)_1=[\epsilon(\epsilon+2)/(\epsilon+1)]B(\theta_1)\tfrac{1}{2}\sin^2\theta_1(\Delta\theta)^2. \qquad (16)$$

The origin of the profile *II* of Fig. 7 is obvious. If we consider β-rays emanating from a fixed point in the source, say the center, at a fixed sharply defined angle θ_1, then a ring focus slit of narrow but finite width can be considered divided into adjacent infinitesimal elementary rings by each of which slightly different β-ray energies are selected. Energy and position in the slit are linearly related. Because of the narrowness of the entire slit the β-ray flux per unit width of ring and per unit small energy domain will thus be constant across the slit opening yielding the rectangular characteristic shown. The following formula may be readily derived from Eq. (4) and (5) to give the base width A_2 of the rectangular characteristic in terms of the ring focus slit geometry

$$A_2=(\Delta\epsilon)_2=K^{-1}(\sin\psi_i\sin\theta_1)^{-1}\times(\epsilon+1)^{-1}\epsilon^{\frac{1}{2}}(\epsilon+2)^{\frac{1}{2}}\Delta y_i; \qquad (17)$$

$$=K^{-1}(\psi_i\cos\theta_1)^{-1}(\epsilon+1)^{-1}\epsilon^{\frac{1}{2}}(\epsilon+2)^{\frac{1}{2}}\Delta x_i. \qquad (18)$$

$$K=2(m_0c/He)$$

Δy_i and Δx_i are, respectively, the radial and axial widths of the ring focus slit which in formulas 17 and 18 is assumed to have its outer and inner edges lying on the cone whose vertex is at the source in the way first suggested by Frankel,[11] see Fig. 9.

The finite size of the source disk yields the semi-elliptical line profile shown in Fig. 7 at *III*. This conclusion is arrived at as follows: Consider for the moment the trajectories of β-rays which pass through a single point P in the ring focus slit and which take off from the source under a well defined angle θ. Set up cartesian coordinates ξ and η on the source disk with origin at the center such that the η-axis lies in the axial plane through P and the ξ-axis is perpendicular thereto. If now we displace the source point over the source in the η-direction holding θ and P fixed the energy selected will vary for, small displacements, substantially linearly with the displacement because a radial displacement η at the source with P fixed produces the same result as holding the source point fixed and executing a radial displacement $-\eta$ of the point P. On the other hand small displacements of the source point along the ξ-axis will result in no first-order variation whatever of the energy selected because such displacements are equivalent to holding the source point fixed and displacing P tangentially in the ring focus slit. Thus if the source disk is explored holding the point P and the angle θ constant a contour map of lines of constant selected energy can be plotted on the disk and these will simply be a set of equidistant straight lines parallel to the ξ-axis. If ϵ_0 is the energy selected when the source point is at the center of the disk, then each differential energy domain will have associated with it a flux of β-rays proportional to the area between two of the adjacent parallel contours, that is to say proportional to the length of one of the chords of the circle while the distance of the chord from the center is proportional to $\epsilon-\epsilon_0$ as indicated in Fig. 10. Thus, the flux of β-rays per unit spectral energy interval will obey a law

$$y=k_3[A_3^2-(\epsilon-\epsilon_0)^2]^{\frac{1}{2}} \qquad (19)$$

which is in general the elliptical profile shown at *III* in Fig. 7. The half-width of this profile at the base is A_3 and is given in terms of the radius ρ of the source disk by the formula

$$A_3=(\Delta\epsilon)_3=K^{-1}(\epsilon+1)^{-1}\epsilon^{\frac{1}{2}}(\epsilon+2)^{\frac{1}{2}}\times(\sin\psi_i-\psi_i\cos\psi_i)^{-1}(\sin\theta_1)^{-1}\rho. \qquad (20)$$

A few remarks are now in order regarding the validity of *folding* the three profiles of Fig. 7 to obtain the resultant instrumental line profile. For this to be a strictly valid procedure the shape of each profile must be completely independent of changes in the variables upon which the other two profiles depend. Thus, for example, as we vary ξ and η in our exploration over the surface of the source disk

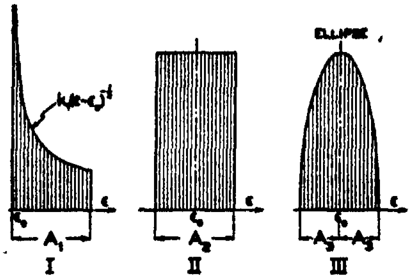

FIG. 7. Illustrating the three spectral profiles introduced by, (I) Finite angular aperture, (II) Finite width of ring focus slit, and (III) Finite size of source disk.

holding the point P in the ring focus slit stationary, is it possible by means of appropriate stops to insure that θ will also remain essentially constant as we have supposed it does in the above derivation of the elliptical profile? The answer is affirmative to a first approximation from the following reasoning. We suppose, to simplify the argument, that the diaphragm opening which selects the range of values, $\theta=\theta_1\pm\Delta\theta$, is placed at such a point along the axis of the instrument that the helical β-ray trajectories shall execute just *one-half of a turn*[17] in going from this diaphragm to the ring focus slit. (For a spectrometer in which $\theta_1=45°$ this situates it at about 0.15 the distance from S to S'.) If this is done then displacements of the source point on the source disk along the η direction (direction of greatest rate of change of energy) *produce tangential displacements* of the trajectory in the θ-selecting slit so that θ remains constant to the first order. Furthermore, displacements of the source point over the source disk along the ξ-direction produce changes in the limiting values of θ which can also be shown to affect the value of the energy only to the second order. This arises from the fact that the maximum displacement ρ over the source disk turns out to be small in comparison to the width of the θ-selecting slit for an instrument of reasonably high resolving power such as $\Delta\epsilon/\epsilon=1/1000$. Thus, we are reassured that the instrument affords a means essentially equivalent to holding ρ and the point P fixed while varying ξ and η over the source disk. The other two cases are much more easily perceived and need hardly be discussed beyond a mere statement of each. They are: Hold θ and the source point ξ, η fixed while varying the point P in the ring focus slit. Hold P and the source point ξ, η, fixed while varying θ.

We must now decide what width parameter (of the folded resultant of profiles *I*, *II*, *III*) to choose as a measure of the instrumental resolving power. If we choose *the base width* W_B of the resultant line for this measure, this will be given very simply by summing the base widths of the components, i.e., $W_B=A_1+A_2+A_3$. Now since the counting rate is proportional to the product $A_1^{\frac{1}{2}}A_2A_3^2$, if we wish to maximize this rate while holding $W_B=A_1+A_2+A_3$ at some specified constant value it is a simple matter to show that we must make $A_1=W_B/7$, $A_2=2W_B/7$ and $A_3=4W_B/7$. To the writer, W_B does not seem to be a satisfactory measure of resolving power however. It is too conservative a choice. A much better measure is the *width at half-maximum height* which we shall designate simply as W. To get this we must actually fold profiles *I*, *II*, and *III* together.

It is a well-known fact that the operation of folding several functions together gives a resultant whose shape is independent of the *order* in which the folding operations were performed. Let us fold profiles *I* and *II* together first. We shall call the half-maximum width of the resultant, W_{12}. Because of the discontinuous nature of the functions it is necessary to distinguish two cases corresponding, respectively, to $A_1<A_2$ and $A_2<A_1$. Perhaps the easiest way to obtain the fold is to decompose profile *II* into two step functions, one positive the other negative, with a displacement A_2 between the discontinuities. The fold of each step function into the inverse half-power curve then gives a parabola with horizontal axis. By such reasoning we obtain the results shown in Fig. 11. The case $A_2<A_1$ breaks into two sub-cases according to whether $A_2<(16/25)A_1$ or $(16/25)A_1<A_2<A_1$. For the latter sub-case the half-maximum width becomes $W_{12}=A_2+A_1-(A_2A_1)^{\frac{1}{2}}$. This then is the sub-case within which the half-maximum width makes the transition from its lower boundary value A_2 to its upper boundary value $21A_2/16$. The important thing to notice about this bizarre behavior of the half-maximum width W_{12} is that it remains within the very narrow range, $A_2<W_{12}<21A_2/16$, *both upper and lower bounds of which are independent of* A_1 *no matter how large* A_1 *may become.* Since the counting rate is proportional to $A_1^{\frac{1}{2}}$ one might at first be tempted, by greatly increasing the half aperture angle $\Delta\theta$, to make A_1 very large indeed since it will not result in any increase in the half maximum width W_{12}. This however would be unwise because such an increase in A_1 merely *adds intensity by lengthening the tail* of the line to the

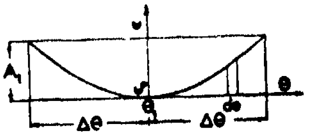

FIG. 8. Dependence of $\epsilon-\epsilon_0$ on $\theta-\theta_1$ from which profile *I* is derived.

---

[17] One-half turn of the helical trajectory corresponds to one-quarter turn round the principal axis of the instrument since the latter is on the circumference, not on the axis of the helix. This choice of position for the θ-selecting slit simplifies the discussion but is not to be regarded as imperative. The point where the two extreme traces of the pencil are radially farthest apart might be an even better place to locate it.

right (Fig. 11). That part of the line which is useful in resolving it from other lines is the core or essentially the part inside the two half-maximum points and as A_1 increases (A_2 constant) there is no gain in the intensity associated with this core beyond the point $A_1=A_2$. Increasing A_1 beyond the value A_2 therefore merely adds to the background distortion in an objectionable way without usefully increasing the intensity of the core of the line. On the other hand as A_1 is decreased below A_2 the intensity associated with the core of the line diminishes. We conclude therefore that the optimum is probably achieved if $A_1=A_2$ in which case the line assumes the simple form shown in the second diagram from the top of Fig. 11. It is this profile then which we shall fold with the elliptical profile *III* of Fig. 7.[18]

Four values of the ratio A_3/W_{12} have been selected for plotting namely, $A_3/W_{12}=0.5$, 0.75, 1.00, 1.25. In each case the folded profile has been plotted and W the width at half-maximum has been determined in terms of $W_{12}=A_1=A_2$. If we think of the half maximum width W as held constant we can thus express the three width parameters A_1, A_2, A_3, of Fig. 7 as multiples of W for the case of each of the four ratios A_3/W_{12} chosen. Now the total counting rate will be proportional to the product $A_1^{\frac{1}{2}}A_2A_3^2$ as we have already stated so that it is possible to compute a number which will be proportional to the total counting rate for constant W as a function of various ratios A_3/W_{12}. Table III shows the data with which this has been done.

In Fig. 12 we show the numbers (proportional to counting rate) in the last column of Table III plotted as a function of A_3/W_{12}. It seems clear that the optimum value occurs somewhere very close to $A_3/W_{12}=1$ or in other words the condition $A_1=A_2=A_3$ in all probability comes very close to giving the greatest counting rate for the least resultant width at half maximum. In Fig. 13 we show the resultant optimum line profile to be expected under this condition. Note that this profile has a width at half maximum which is 1.62 times each of the three equal parameters A_1, A_2, or A_3. Only a slight vestige of the asymmetry which results from the influence of the profile *I* can be detected when we examine Fig. 13. The width parameter $A_1=A_2=A_3$ is shown to scale in the figure.

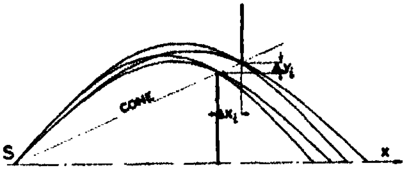

FIG. 9. Showing geometry of ring focus slit with its edges lying on a conical surface with vertex at *S*.

The author makes no claim that the above analysis for the optimum relationship between the parameters A_1, A_2, and A_3 is highly rigorous. He is well aware that the procedure of first choosing the optimum condition $A_1=A_2$ using the width W_{12} as a criterion *before* folding *I* and *II* into *III* is strictly open to criticism. The condition $A_1=A_2=A_3$ is not here laid down as giving *accurately* the greatest intensity for a specified resolving power. It seems likely however that it defines the optimum condition so closely that no significant gain in intensity would be effected by modifying it.

The radius ρ of the source disk should obviously then be chosen so that the loss of energy resolution A_3 from this cause alone shall be equal to A_1 the loss of energy resolution from the solid angle $d\phi$ (or from the range $\Delta\theta$) given in Eq. (16) also the width of the ring focus slit should be chosen to make $A_2=A_1$ using Eqs. (17) and (18) to proportion the radial and axial spread of the slit. The condition $A_3=A_1$ gives the following formula for the radius of the source disk

$$\rho=K\epsilon^{\frac{1}{2}}(\epsilon+2)^{\frac{1}{2}}B(\theta_1)(\sin\theta_1)$$
$$\times(\sin\psi_i-\psi_i\cos\psi_i)(d\phi)^2;\quad K=\frac{2m_0c}{He}. \tag{21}$$

For the optimum design with $\theta_1=45°$ and $\psi_i=2.03$ rad., this gives

$$\rho=36R(d\phi)^2 \tag{22}$$

in which

$$R=\sqrt{2}(m_0c/He)[(\epsilon+1)^2-1]^{\frac{1}{2}}. \tag{23}$$

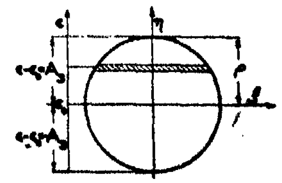
R is the maximum radial distance of the median traces from the axis of the instrument. We shall take it as a convenient geometrical unit in terms of which all the other linear dimensions are to be expressed.

The condition $A_2=A_1$ leads to the following formulas for the dimensions of the ring focus slit,

$$\Delta y_i=K\epsilon^{\frac{1}{2}}(\epsilon+2)^{\frac{1}{2}}\sin\psi_i\sin\theta_1B(\theta_1)(d\phi)^2, \tag{24}$$

$$\Delta x_i=K\epsilon^{\frac{1}{2}}(\epsilon+2)^{\frac{1}{2}}\psi_i\cos\theta_1B(\theta_1)(d\phi)^2. \tag{25}$$

FIG. 10. Iso-energy bands and coordinates ξ, η on the source disk. To illustrate derivation of profile *III*.



---

[18] If the case in point is one in which the finite radius of the source disk plays no part in giving an increased counting rate (γ-ray sources for example) so that the loss of resolving power from cause III can be kept small in comparison to that from causes I and II without any sacrifice of counting rate, then the discussion from this point on concerning the effect of folding in the elliptical profile *III* should be ignored and the final profile will be essentially the second one from the top in Fig. 11 with the width at half maximum height $W=W_{12}=A_1=A_2$.

For the optimum design with $\theta_1=45°$ and $\psi_i=2.03$ radians these become

$$\Delta y_i=18R(d\phi)^2, \qquad (26)$$

$$\Delta x_i=41R(d\phi)^2. \qquad (27)$$

Clearly, for a given energy ϵ, Eq. (23) shows that we may take R as large as we please provided we can make H small in inverse proportion. There is an advantage in large dimensions because by Eq. (22) ρ is proportional to R and hence the utilizable area and strength of source increases as ρ^2 and R^2. The practical limit to this occurs either when the cost becomes prohibitive or when H must be made so small that uncontrollable outside magnetic influences disturb the field distribution intolerably.

Figure 14 is a schematic axial section through the instrument showing its geometry and the nomenclature of its principal dimensions. We append below a list of the principal useful formulae and relations for the optimum case of $\theta_1=45°$, the nomenclature being that indicated in Fig. 14. Attention is called to the θ-selecting stop that is required to define the two extreme traces on either side of the median trace ($\theta_1=45°$). This is placed one-half turn of the helical β-ray trajectory nearer to the source than the ring focus slit.[17] Other stops which do not define the beam but serve merely to reduce scattering will doubtless be found advantageous. A heavy lead core to protect the counter from gamma rays is also commonly provided. These are omitted however in Fig. 14.

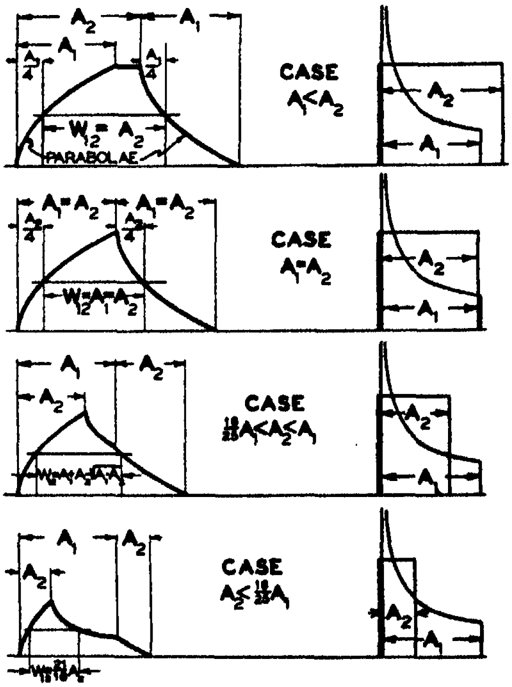


FIG. 11. Illustrating the various cases which arise when profiles I and II of Fig. 7 are folded together. In the above figure A_2 has been progressively diminished holding A_1 constant. The component profiles are shown in each case on the right, the folded resultant on the left. Note that the half-maximum width W_{12} of the folded resultant never becomes less than A_2 or greater than $(21/16)A_2$.

In a magnetic β-ray spectrometer of the type here described if the resolving power is very high the geometrical axis defined by the source and stops must be very accurately aligned parallel with the magnetic field, otherwise the ray traces will not register correctly and simultaneously all around the annular defining slit. For this reason it will be wise to provide for a slight amount of angular adjustment so that the orientation of the vacuum chamber with its source holder, stops and counter can be slightly varied relative to the solenoid which furnishes the magnetic field.

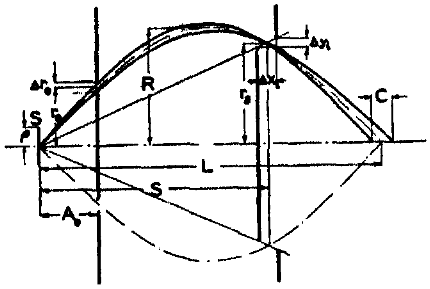

FIG. 14. Schematic axial section through β-ray spectrometer giving nomenclature of optimum dimensions.

It appears from the present analysis that by adhering to the optimum proportions as indicated above it should be possible to design a β-ray spectrometer with a direct β-ray source in which the utilized fraction of the total sphere around the source is $d\phi=0.01$ and in which for the three cases, $\epsilon\ll 1$, $\epsilon=1$, $\epsilon\gg 1$, the resolution is given respectively by $\Delta\epsilon/\epsilon=0.0065$, 0.0049, 0.0032 wherein $\Delta\epsilon$ is the full instrumental line width at half maximum in ϵ-energy units and ϵ is the energy at which the line occurs expressed as a fraction of the electron rest energy. The radius of the source disk should be for such a case $\rho=0.004R$ where R is the fundamental radius of the instrument (or the maximum radial distance from the central axis attained by the median ray of the pencil of electron trajectories). If the source disk can be made indefinitely small without loss of intensity (case of γ-ray source with converter) then $\Delta\epsilon/\epsilon=0.004$, 0.003, 0.002 for the above three cases.

The author wishes to acknowledge with gratitude very helpful criticisms and discussions of this paper by E. R. Cohen and by Professor R. F. Christy.

(Received October 18, 1948)

Voltages of arbitrary wave forms, such as those employed for stimulating biological tissues, are normally obtained from "grounded" signal generators. Isolation of such signals from ground can be accomplished by utilizing radiofrequency transmission of energy. The signal generator voltage serves as the source of plate power for a midget radiofrequency oscillator which converts the signal to amplitude-modulated carrier energy. This radiofrequency energy is then transmitted across a small air gap to a receiving circuit where it is demodulated and filtered. The voltage thus recovered is a faithful reproduction of the original signal but is isolated from the input circuit as well as from ground. One model of this radiofrequency link which was developed for nerve stimulation and which has performed well in the laboratory is described in detail.

DURING recent years many excellent designs for electronic tissue stimulators have appeared in the literature of biophysics. As the need for special forms of stimulus has arisen, e.g., step wave, square wave, pulse, double pulse, modulated tetanus, etc., electronic circuits have been evolved in various laboratories which adequately meet each of these special requirements, and it is economical, wherever possible, to utilize these developments instead of devising new but essentially similar apparatus.

A shortcoming of all usual stimulators is the electrical return path to ground, either conductive or capacitive, which they invariably exhibit. This return path greatly reduces the flexibility with which multiple stimuli can be combined and practically requires the use of a differential amplifier except in the simple cases where miniature transformers can be tolerated. Even the best of such transformers have considerable interwinding capacitance, and none can deliver unidirectional wave forms.

By utilizing a radiofrequency link as described in a preliminary note,[1] it is possible to use the pulse, step wave, d.c., or other stimulating wave form or combination wave form as obtained from conventional "grounded" stimulator systems and still retain electrical isolation. The stimulus itself becomes the source of plate power for a midget radiofrequency oscillator, and this radio power is transmitted across a small air gap to be received and demodulated by a tiny coil and varistor type rectifier system. The output voltage now faithfully reflects the wave form of the input but is electrically isolated from it and from ground.

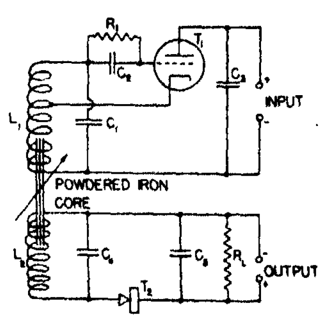

FIG. 1. Basic stimulator circuit. C_1, C_4, 20 μμf; C_2, C_5, 100 μμf; C_3, 25 μμf; R_1, 2200 ohms; R_L, 22,000 ohms; T_1, 6J6; T_2, 1N34; L_1, L_2, 17 turns No. 24 heavy Formvar wire; cathode tap on L_1 4 turns from grid end of coil. Tubular ceramic condensers and ½-watt resistors are used throughout.

Voltage generated in this manner can be treated as though it originated from a completely isolated power source, and several different stimuli similarly generated can be mixed at will or applied to different points on the tissue without reference to grounds. Since the radiofrequency link actually derives its plate power from the stimulus source, it can be used with any standard stimulator.

While there is nothing intrinsically difficult in the design of a unit embodying these principles, it will be found that considerable engineering design effort is required to develop a unit which is physically compact, electrically stable, efficient, and linear in output. One form of this stimulator has been standardized in this laboratory and for some months has given dependable satisfactory service. This stimulator together with its performance characteristics will be described in some detail so that it can be duplicated conveniently. It is hoped that this design will serve as a basis for further development.

The essential circuit of the stimulator is shown in Fig. 1. A small tank circuit together with a 6J6 miniature type tube with both triode sections connected in parallel constitute a Hartley grounded-plate oscillator. An inductively coupled tuned secondary or receiving circuit terminates in a 1N34 germanium crystal diode and filter. The oscillator

---

[1] O. H. Schmitt, "A radiofrequency coupled tissue stimulator," Science 107, 432 (1948).

is plate modulated, the necessary plate power being furnished by the stimulating voltage generator. The only additional source of power required is 6.3 volts at 0.45 ampere for the filament of the 6J6. This power may be d.c. or a.c. and may be grounded or ungrounded. Condensers C_1 and C_4 constitute the primary and secondary tank capacitances, respectively. Approximate tuning of the oscillator and receiver circuits depends upon the choice of these capacitances while the fine tuning is accomplished by adjusting a powdered iron core which can be moved axially inside the coil form by means of a threaded shaft. Since increased inductance in one coil is accompanied by decreased inductance in the other, adjustment for double-tuned resonance is easily found.

The grid leak resistor R_1 is adjusted for proper bias to give maximum efficiency consistent with stability of operation. The grid condenser should not be so large as to encourage intermittent oscillations nor so small as to decrease oscillator efficiency greatly. In addition, the reactance of this condenser at the highest frequency component of the modulating voltage should be at least twice the grid leak resistance in order to preserve linearity of modulation. The by-pass condenser at the input to the oscillator must have low reactance at the oscillator operating frequency but must offer a high impedance to the modulating voltage. If a shielded input cable is used, its distributed capacitance will usually suffice for this capacitance.

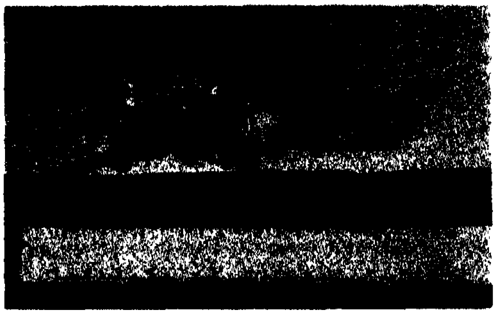

FIG. 2. Side view of complete stimulator.

The resistive load across the oscillator coil for maximum efficiency is easily determined experimentally and the receiver circuit is then designed to reflect this load into the oscillator circuit. It has been shown both experimentally and analytically that the equivalent input impedance to the rectifier filter circuit is approximately one-half the load resistance R_L and is essentially resistive. Thus the turns ratio of the primary to the secondary coil windings can be determined once the load resistance is established or the reverse.

Analysis of the rectifier and filter circuit using actual experimental characteristic curves for the 1N34 germanium diode instead of assuming ideal characteristics shows that a 20 percent loss of power in the crystal is inevitable. The maximum output voltage which the stimulator can produce with reasonable linearity is determined by the peak inverse voltage rating of the crystal diode rectifier. Theoretically, the rectifier should be able to produce an output voltage about one-half the inverse peak rating of the diode. With the 1N34 this rating is 60 volts and, consequently, 30 volts of output should be available. Usually at least 30 volts output can be obtained and with selected 1N34 units as much as 40 volts can be realized linearly. If very high voltages are required, several 1N34 units can be used in series, raising the output to 60, 90, or more volts and special rectifiers such as the 1N38 and 1N39 with higher inverse ratings up to 200 volts are obtainable.

FIG. 3. View of stimulator showing receiver section.

The filter section of the receiver circuit is designed so that its time constant RC is large compared with the time for one carrier oscillation but small compared with the period of the highest important frequency component in the stimulating voltage. Consequently, the ratio of carrier frequency to highest signal frequency should be at least 100. For normal requirements, carrier frequencies between one and twenty megacycles per second prove satisfactory. Design is simplest in the vicinity of five megacycles per second.

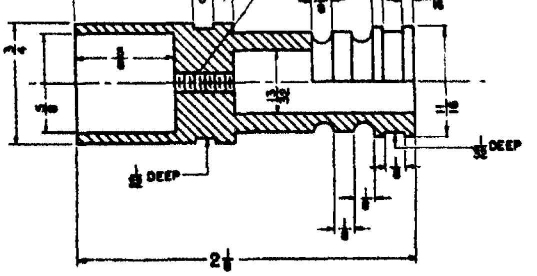

FIG. 4. Dimensional sketch of plastic frame for stimulator.

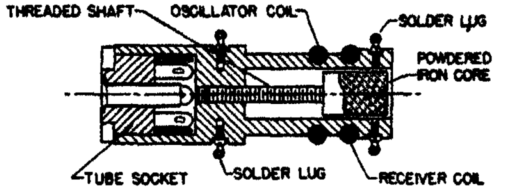

FIG. 5. Section view of plastic frame showing general placement of components.

Figures 2 and 3 show two detailed views of one completed form of the stimulator. The stimulator proper takes the rough form of a cylinder about 1″ in diameter and 4″ over-all including the tube. It is often convenient to mount the unit in a small Lucite stand as shown. It may be detached from this stand in a moment by loosening a single setscrew. As the pictures indicate, the unit is physically small and is thus easily installed in existing equipment close to the tissue to be stimulated. All the components including the miniature tube socket are mounted on a cylindrical frame machined from 1422 Textolite. A dimensional sketch of this frame is given in Fig. 4, and the general placement of components is shown in Fig. 5. The oscillator and secondary coils each consist of 17 turns of No. 24 heavy Formvar wire wound in grooves on the frame. The coils are approximately circular in section. The inductance of each coil is 6 microhenries with a Q of about 65. The presence of the powdered iron core increases this inductance by a factor of about 2 thus giving an adequate tuning range without changing the Q appreciably. The cathode tap of the oscillator coil is 4 turns from the grid end of the coil. The values of the remaining components are included in Fig. 1. Maximum output and best efficiency are achieved when the two coils are tuned for operation at around 7.5 megacycles per second. Tiny solder lugs fastened to the plastic frame by 0–80 machine screws aid in mounting the individual components and a coat of polystyrene based coil dope protects the coils and holds them rigidly in place.

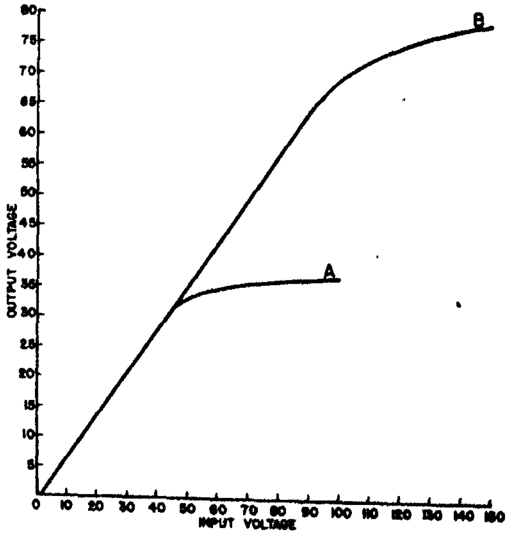

FIG. 6. Stimulator transfer characteristics. Curve *A* shows output *versus* input voltage when the receiving circuit utilizes a single 1N34 germanium crystal diode rectifier. Curve *B* shows the transfer characteristic using two 1N34 units connected in series. In each case the load resistance is 22,000 ohms.

Linearity of the stimulator response is shown in Fig. 6 where output voltage is plotted against input voltage. The rectifiers used in the receiving circuit for these cases consisted either of a single 1N34 crystal diode or of two diodes connected in series. These crystals were not specially chosen to give best results but represent better than average diodes of this type. As one might expect, linearity with a single crystal extends to about 30 volts and with two crystals to over 60 volts. In each case, however, the output in the linear region is roughly ⅔ of the input voltage when working into a load of 22,000 ohms. It will be noted that an initial signal of about 1.3 volts is required to set the oscillator into operation. Where extreme linearity is required even to very small output levels, a d.c. bias of this value may inserted in the input circuit.

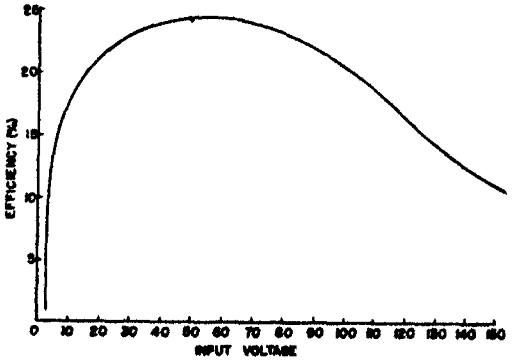

FIG. 7. Over-all stimulator efficiency curve (operating conditions corresponding to curve *B*, Fig. 6).

Figure 7 illustrates a typical stimulator efficiency curve. The oscillator itself has an efficiency of approximately 50 percent. Efficiency of the stimulator without the rectifier and filter circuits is between 30 percent and 40 percent and, as the figure shows, the over-all efficiency of operation has a maximum value of approximately 25 percent remaining fairly constant over the useful operating range.

Measurements with a sensitive capacitometer indicate a capacitance from output to input of approximately 5 micromicrofarads. If shielding is used to prevent direct transfer of residual radiofrequency signal to the tissue circuit, this capacitance may be slightly greater. Ordinary tissue amplifiers have little response at radiofrequencies and it is necessary only to hold down r-f pick-up to a level where the amplifier is not driven beyond its linear characteristic.

Although the r-f coupled stimulator was specifically designed to provide voltages isolated from ground to be used in connection with single nerve fiber studies, there appear to be several other applications where the basic principle is equally useful. Wherever a control or signal voltage appearing at some d.c. voltage level must be applied to circuits at a different voltage level, it is a simple and compact device for providing the transition.

Absorption Corrections in X-Ray Studies of Preferred Orientation*

R. Smoluchowski and R. W. Turner
Carnegie Institute of Technology, Pittsburgh, Pennsylvania

(Received October 18, 1948)

A general formula is derived for the evaluation of correction factors in the study of preferred orientations in flat specimens. These factors depend on orientation of the sample, angles of diffraction, thickness of specimen, etc. In practical applications a graphical presentation of the absorption correction proves to be particularly useful.

MOST of the qualitative investigations of preferred orientation in flat specimens are limited to comparison of x-ray patterns obtained with the direction of the x-ray beam perpendicular to the specimen. The various factors affecting the intensity of the x-ray diffraction in that case are well known and easy to take into account.

For accurate investigations, however, patterns obtained with the x-ray beam inclined to the surface of the specimen are necessary, and the correction for absorption becomes rather complicated. Recently formulas for this corrective factor applicable to pole figure work with a Geiger counter x-ray spectrometer have been published.[1] They are, however, not general enough for the standard photographic method, and thus it seemed advisable to report on formulas and graphs used for some time in our laboratory in the study of preferred orientation.

Let us consider a flat specimen as shown in Fig. 1, which also illustrates the quantities used: t—thickness of sample; α—angle between beam and normal to surface of sample; $c=(t/\cos\alpha)$—sample thickness in the direction of the beam; x—distance along c traversed by beam before a given individual reflection occurs; β—angle around the reflection ring on the film; the point at which $\beta=0°$ is determined by the intersection of the film and the plane containing both the x-ray beam and the surface normal of the sample.

For a reflection which strikes the film at β, the thickness of sample traversed after reflection is given by

$$[(c-x)\cos\alpha]/A$$

where $A=\cos\alpha\cos 2\theta+\sin\alpha\sin 2\theta\cos\beta$. Hence, the intensity as the beam reflected between x and $x+dx$

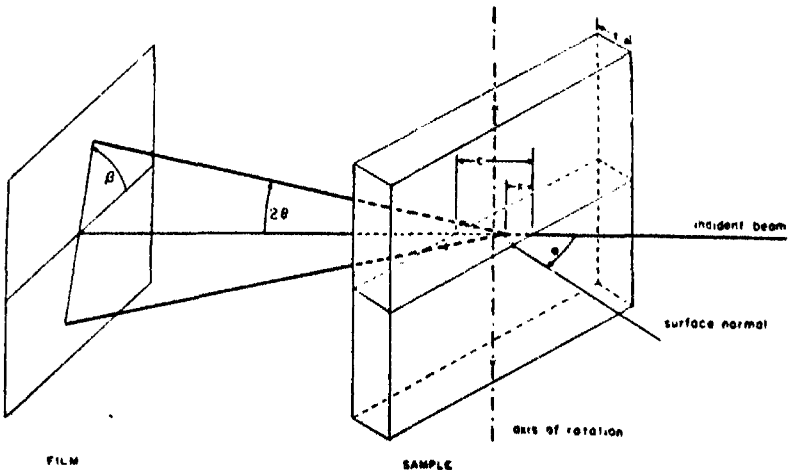

FIG. 1. Diffraction of x-rays in a sample inclined to the beam.

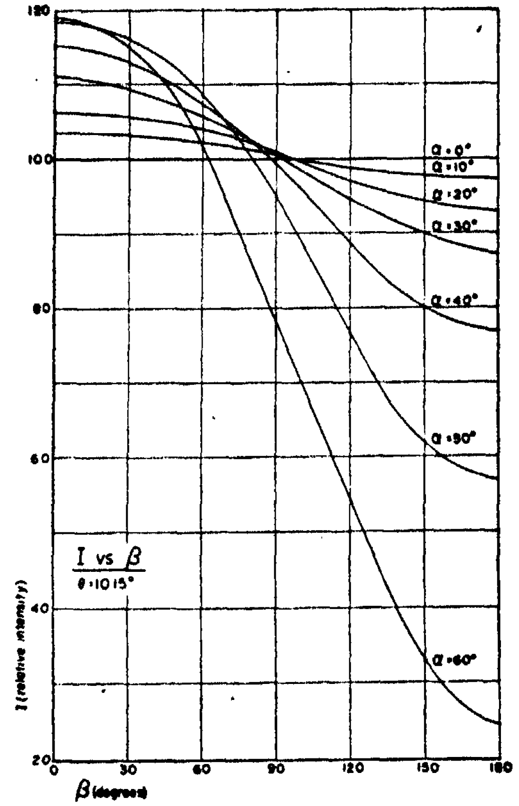

FIG. 2. Relative intensity around reflection ring. For various sample positions. (50% Fe—50% Co alloy. 0.025 mm thick, (110) reflection, Mo$-K\alpha$ radiation.)

leaves the sample is

$$dI = I_0 e^{-\mu x} \exp\{-\mu[(c-x)\cos\alpha/A]\}dx. \quad (1)$$

(All constant factors, such as the structure factor for the reflection, which will be cancelled by taking the ratio of two intensities about one reflection ring, have been dropped.) The total intensity of the given reflection is found by integrating (1) from $x=0$ to $x=c$, and the final result is

$$I = (A/A - \cos\alpha)[e^{-\mu t/\cos\alpha} - e^{-\mu t/A}]. \quad (2)$$

It is most convenient to express this as a graph of I *vs.* β for each of a series of values of α, θ being held constant. For simplicity and accuracy in making such plots, it is best to transform Eq. (2) by converting the exponentials to hyperbolic functions. By this method, the equation can be reduced to the form

$$I = Ke^{-K(1+m)}\left[\frac{\sinh K(1-m)}{K(1-m)}\right] \quad (3)$$

where

$$K = (\mu t/2\cos\alpha), \quad m = 1/(\cos 2\theta + \sin 2\theta \tan\alpha \cos\beta).$$

Figure 2 shows a typical plot of Eq. (3) obtained for the (110) reflections of an alloy of 50 percent Fe and 50 percent Co, in a sample 0.001-inch thick. The values of I have been adjusted to a value of 100 for $\alpha = 0°$. Plots of this type were made in this laboratory and proved to be of great value in quantitative evaluation of photographic measurements. In certain cases formula (3) can be greatly simplified. If $|K(1-m)| \leqslant 0.25$ then the expression $I = Ke^{-K(1+m)}$ represents the correct intensity to within one percent, and if $|K(1-m)| \leqslant 0.5$, to within less than five percent.

It should be emphasized that these plots give only relative intensities; any one point in a reflection ring may be selected as unity, with other points expressed as fractions or multiples of that. One may then correct observed intensities accordingly and determine the true relative intensities reflected in the various directions.

The corrective factor derived by Decker, Asp, and Harker is a particular case of our formula (2) for $\beta = 0$ and with zero value of α taken at the point at which $\alpha = \theta$.

The authors wish to thank Mr. R. Louis Bright for his help in evaluating the formulas, and Mr. Albert Kimmel for his careful work in plotting the graphs and figures.

A Rapid Infra-Red Gas Analyzer

RICHARD C. FOWLER
Department of Physiology and Vital Economics, School of Medicine and Dentistry,
University of Rochester, Rochester, New York

(Received October 28, 1948)

A brief description of an apparatus, together with a few representative curves, is presented, suitable for measuring the composition of very small amounts of any gas having at least one near infra-red absorption band or, if measured in the presence of other gases, at least one unique absorption band. With the bolometers used, 90 percent full scale response is obtained in 0.15 seconds on a 0.5 cc sample, permitting a 0.4 cm optical path and a very nearly linear response over the range usually found in physiological concentrations and anesthesia.

IN connection with many problems in physiology, cardio-respiratory disease, anesthesia, etc., an instantaneous means for analyzing quantitatively and continuously the respired gas during the respiratory cycle is desirable. Various ingenious methods have been devised to accomplish this, each with a particular limitation. Some of these schemes, together with their outstanding features follow:

(a) The classical fractional sampling of a single expired volume of gas[1,2] lacks time or volume-composition "resolution," involves laborious chemical analysis and is not instantaneous.

(b) The thermal conductivity method again is not instantaneous, with a minimum time lag of 15 to 30 seconds,[3–6] but is commercially available in reliable form.

(c) The acoustic methods[7] are now largely in the developmental stage. They are operable for some gases including oxygen, but have not proven satisfactory for carbon dioxide and some other gases. Since some interfering gases must be removed, and because of the electrical circuit used, they will have an appreciable delay.

(d) The mass spectrometers[8,9] have a small delay, largely in the sampling device, are quite cumbersome and expensive, but have the particular advantage of multiple simultaneous analyses. There is still some question of accuracy, however, as a result of the relative velocity of gases of different characteristics.

(e) The "spectrophotometric" method, developed by Dr. Lilly[10,11] involving the continuous sampling, subsequent ionization and photoelectric measurement is relatively expensive and cumbersome and

FIG. 3.

will have a time lag of the same order as the mass spectrograph and many of the same criticisms apply, but it is quite versatile and should be capable of considerable accuracy.

(f) The interferometric method,[12] while reportedly very accurate, requires constant manual adjustment and has a response lag of the order of 25 seconds.

(g) The paramagnetic oxygen analyzer[13,14] has proven to be a highly satisfactory device and is available commercially in a very reliable form[15] but is limited in usefulness and has a time lag of the order of 15 seconds.

(h) The optical gas analyzers, principally infrared,[16] depend on the unique absorption bands of the various gases, and consequently are limited in their usefulness to those having sufficiently strong absorption in a useful range. In addition, their time response is limited to the rate of response of available infra-red detectors. The instruments on the market at present require a considerable volume of sample[17,18,19] resulting in a poor volume-composition "resolution," and are relatively slow. An infrared "acoustic" device has been described, but has not been developed commercially.[20] A new instrument, developed by Phillips Laboratories, seems to have eliminated most of the objectionable features, but is expected to be quite expensive and is not available commercially as yet. British devices utilize a similar method and are available.[21] A further exposition of the problem is adequately covered by Fastie and Pfund[22] and Williams.[23]

An infra-red gas analyzer has been developed in this laboratory which has been found useful for a number of gases of physiological importance, including carbon dioxide, ether, carbon monoxide, acetylene, and others, and no trouble has been encountered with interference including that from water vapor. The principle features which make this instrument useful are: (a) the use of crossed beams from a common source to keep the sample as small as possible and to reduce the effect of variations of source temperature, (b) the use of inert mica windows (wave-length-transmission curve, Fig. 1) which allow the passage of near infra-red energy without hygroscopic or chemical action, and (c) the use of a rapid, sensitive detector made possible by Western Electric's "SETT" element, a "thermistor" bolometer. The use of selective filters may prove useful but have not been found to be essential.

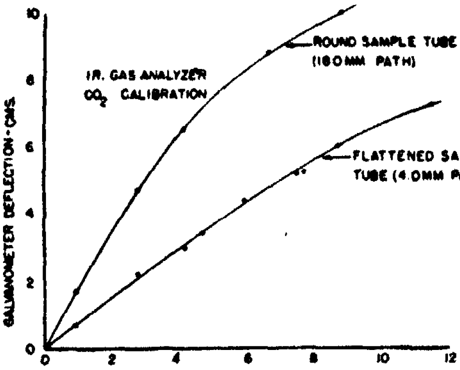

FIG. 4.

The apparatus is shown schematically in Fig. 2, and as built in Fig. 3. The source (S) is a helix of nichrome wire heated electrically (40 watts) and operated at a bright red heat, and the supports and box are water cooled to reduce temperature effects. The two spherical concave front surfaced aluminized or evaporated gold mirrors of 10-cm focal length (M_1, M_2), focus slightly enlarged superimposed images of the source at the center of the sample or breathing tube (T), which, for carbon dioxide, was constricted at this point to give a path length of about 4 mm in order to operate on the straighter first portion of the exponential concentration-absorption curve in the physiological range (0–9 percent). The two beams then continue through the 5.0-cm gas filter cells (F_1, F_2) one of which contains a mixture of all interfering gases in the test sample and the other contains all but the gas to be measured. Since the path through the filter cell is so long, all interfering radiation is filtered out before reaching the detectors. The second pair of mirrors, also of 10-cm focal length, (M_1', M_2'), similar to the first but larger in diameter, refocus a considerably reduced image of the source on the sensitive area (0.2×2.0 mm) of the detectors (D_1, D_2). The size of the source and optical components are so chosen that this reduced image just a little more than covers the active area of the bolometers. The two adjustable opaque flags (B) following the filter cells are essential for balancing the radiant energy in the two beams or spurious deflections will result. The chamber containing the mirrors and bolometers was constructed so that an additional filter gas might be introduced here also.

[23] VanZ. Williams, "Infra-red instrumentation and techniques," Rev. Sci. Inst. 19, 135 (1948).

Considerable attention was given to a suitable source, and while other means such as glass, oligoclase, etc.[24] might peak more energy at a particular absorption band, a considerable decrease in sensitivity would be experienced for another absorption band and furthermore, the high voltage and auxiliary heater made these cumbersome and dangerous. The Nernst glower proved quite fragile and short lived. Nichrome wire, operated at bright red heat, has a very broad peak at about 4 microns which extends relatively little into the visible and so is a good and convenient source.[25] No reason for replacement of the unit was noted after several hundred hours of severe operation.

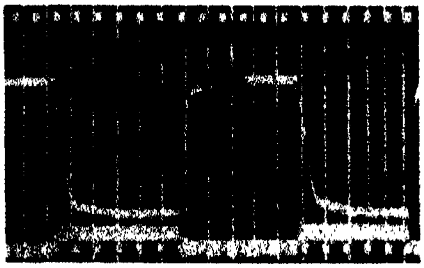

FIG. 5.

The detectors were chosen for their sensitivity and their relatively high speed of response. Other detectors, considerably less expensive may be used at the sacrifice of speed. For a gas having an absorption band in the near infra-red, considerably cheaper and faster detectors may be used (lead sulfide, thalofide cell).

The recorder consists simply of an electrocardiograph string galvanometer, sens. 1 mv per cm, 1500 ohm, with its associated camera, coupled to the high impedance bolometer bridge (each arm 3.0 megohms) through a single coupling vacuum tube with its steady state plate current bucked out. A more rugged pen recorder has been used in conjunction with a breaker type amplifier at the sacrifice of speed, but with greatly increased sensitivity. An indicating meter may thus be used for static measurements of isolated samples.

The calibration curve (Fig. 4) shows the effect obtained by decreasing the optical path through the breathing tube from 18 to 4 mm. The cylindrical tube first used, while quite simple, did not provide sufficiently linear response without extensive electrical compensation, and the short path (0.4 cm) flattened tube, proved quite satisfactory.

Figure 5 is included to indicate the electrical response (bolometer, circuit and galvanometer) obtained by blocking a very small portion of the radiation to one bolometer by means of a small signal magnet, thereby unbalancing the circuit to simulate blocked radiation. Simultaneously another signal magnet interrupted the beam to the camera. The two magnets were interchanged in order to rule out possibility of variations in response and similar results were obtained. The vertical time markers are 0.2 second apart. This shows a 90 percent electrical response in about 0.1 sec. and a slow rise for about 0.4 sec. The over-all response is very nearly the same. The irregularity on the descending portion of one record was due to chattering of the signal magnet.

A record of CO_2 of the respired air during a normal and complete expiration of a normal person is shown in Fig. 6 together with the expired velocity. The over-all speed of response is shown on inspiration where the CO_2 curve drops quickly to the base line. The inspiratory phase is designated by the flat portion of the velocity curve. The lag between the onset of expiration and rise of the CO_2 curve corresponds very closely to the volume of air trapped in the portions of the respiratory tree where gaseous exchange does not take place, the so called "dead space." The continued rise during expiration has

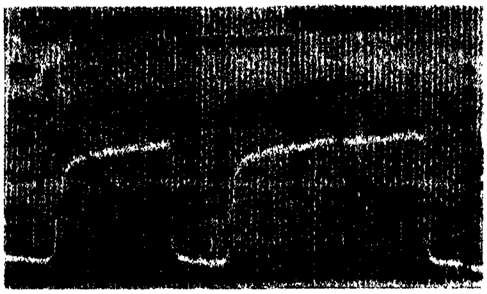

FIG. 6.

[25] General Electric Company, Lamp Bulletin.

been explained by the continuous diffusion of CO_2 into the lungs from the blood. Variations in this pattern have been found.

This device is believed to have a number of advantages over those existing. These are: (a) relatively low cost, (b) rapidity of response, (90 percent of maximum in 0.15 second over-all), (c) ease of recording, (d) full scale sensitivity obtained with fairly linear response from 0–9 percent CO_2, and (e) insensitiveness to normal pressure and temperature variations. The unit may be used with a number of gases mentioned and with proper alignment and construction, simultaneous measurements may be made of a number of gases.

The need and basic idea for such an analyzer was first brought to our attention by Professor W. O. Fenn, Department of Physiology. In addition to acknowledged sources of information, further material help and suggestions have been made by Dr. B. O'Brian, Colonel A. Gee, Dr. F. Paul, and Mr. W. Klinkert of the University of Rochester, Department of Optics; Dr. A. F. Turner and Staff of the Bausch and Lomb Optical Co.; and Dr. H. Rahn, Dr. A. B. Otis, Dr. H. A. Blair, Dr. W. S. McCann, and Mr. G. Rosenworth and numerous others at the University of Rochester Medical Center. The work was made possible by a fellowship from the John and Mary R. Markle Foundation and was supported in part by the Air Materiel Command at Wright Field.

THE REVIEW OF SCIENTIFIC INSTRUMENTS VOLUME 20, NUMBER 3 MARCH, 1949

The Scintillation Counter as a Proportional Device*

Rosalie C. Hoyt**
The University of Rochester, Rochester, New York

(Received November 2, 1948)

The statistical distribution of fluctuations in the gain of a 1P21 photo-multiplier tube has been investigated and standard deviations of 36 percent to 48 percent have been found. The distribution in photo-multiplier output pulse heights obtained with Po alphas incident on a ZnS screen has also been investigated and standard deviations of 27 percent to 80 percent found. The importance of the contribution from the fluctuations in gain is shown to be small in this case.

I. INTRODUCTION

It has been hoped that the phosphor-photomultiplier counter may be useful as a proportional device, giving output pulses whose sizes are a measure of the energy lost by the incident particle in the phosphor. For particles of short range that are stopped in the phosphor the output pulse heights should be a measure of the energy of the particles, while for particles of large range that pass through the phosphor the pulse heights should be a measure of the energy they lost in the phosphor and thus of their specific ionization. Thus, two particles of differing specific ionization should be distinguishable.

However, for particles losing the same amount of energy in the phosphor there will be a statistical spread of pulse heights, and the width of this spread will determine the degree to which such a counter may be used to distinguish between particles. Therefore, a preliminary investigation has been made of the statistical distribution in pulse heights from a monoenergetic source of particles, and an attempt has been made to determine the relative importance of some of the various factors that contribute to the spread of this distribution.

II. STATISTICAL DISCUSSION

The statistical spread in output pulse heights will be due to several causes, of which the following may be mentioned: (a) statistical fluctuations in the over-all gain (multiplication factor) of the multiplier tube, (b) fluctuations in the efficiency of the photo-cathode of the multiplier tube, (c) fluctuations in the number of light quanta emitted by the phosphor per particle passing through it, and (d) fluctuations in the fraction of these quanta that are collected by the optical system and fall on the photo-surface.

The larger the number of photoelectrons starting out from the first stage of the photo-multiplier tube the smaller will be the relative effect due to cause *a* above on the over-all spread of pulse heights. Likewise, the larger the number of quanta emitted in the phosphor, the smaller will be the effects due to causes *b*, *c*, and *d*, as well as that due to cause *a*.

The purpose of this investigation was to determine the magnitudes of the contribution due to *a* and to the other three taken together and, in addition, to determine the average number of photoelectrons necessary to make the contribution due to *a* negligibly small.

---

* This work was carried out with the support of the Office of Naval Research.

** Now at Bryn Mawr College, Bryn Mawr, Pennsylvania.

Let X = multiplier gain, Y = number of photoelectrons produced by an incident particle, Z = number of output electrons produced by an incident particle. It is then obvious that

$$\bar{Z}=\bar{X}\bar{Y}, \tag{1}$$

where $\bar{Z}$, etc. represent average values. H S. Snyder,[1] of the Brookhaven National Laboratory, has analyzed the statistical problem of the photomultiplier tube, assuming no specific shape for the distributions, and in particular has shown that

$$\langle Z(Z-1)\rangle_{Av}=\langle Y(Y-1)\rangle_{Av}\bar{X}^2+\bar{Y}\langle X(X-1)\rangle_{Av}. \tag{2}$$

Now, $X\sim 10^6$, and therefore $X-1\sim X$. Also, $\bar{Y}\geqslant 1$, therefore $Z-1\sim Z$. Thus Eq. (2) becomes

$$\langle Z^2\rangle=(\langle Y^2\rangle-\bar{Y})\bar{X}^2+\bar{Y}\langle X^2\rangle. \tag{3}$$

From (1) and (3) it is easy to show that

$$(\langle Z^2\rangle-\bar{Z}^2)/\bar{Z}^2=[1/\bar{Y}][(\langle X^2\rangle-\bar{X}^2)/\bar{X}^2] \\ +[(\langle Y^2\rangle-\bar{Y}^2)/\bar{Y}^2] \tag{4}$$

or

$$\sigma_z^2=(1/\bar{Y})\sigma_x^2+\sigma_y^2. \tag{5}$$

Where σ_z^2, etc., are the fractional mean square deviations of the distributions.

From the experimental data to be presented, σ_z^2, $\bar{Y}$, and σ_x^2 were obtained, and from these σ_y^2 was calculated. Thus the relative contributions of σ_x^2 (cause *a*) and σ_y^2 (causes *b*, *c*, and *d*) to the over-all σ_z^2 were determined. (Snyder has also derived relationships from which the higher moments of the distribution for Y can be determined; these, however, have not been experimentally determined in the following).

From Eq. (5) it can be seen that the smaller is $\bar{Y}$, the larger is the contribution of the first term of Eq. (5) (cause *a*) to the over-all distribution. However, it must be remembered that a smaller $\bar{Y}$ means a smaller number of photoelectrons per incident particle and thus a smaller number of quanta emitted per incident particle. The second term of Eq. (5) (causes *b*, *c*, and *d*) will be affected by the smaller number of quanta in the same way that the first term is affected by a smaller number of photoelectrons, although Eq. (5) does not show this explicitly. Thus, as $\bar{Y}$ decreases, not only will the contribution of the first term increase, but that of the second term will increase also.

III. EXPERIMENTAL METHODS AND RESULTS

While the organic phosphors have been found to be very efficient detectors of weakly ionizing radiation, they apparently are not as efficient as some of the inorganic phosphors for detecting heavily ionizing radiation such as alpha-particles. Thus, since the most convenient source of monoenergetic particles to use was a thin polonium alpha-source, activated zinc sulfide was employed as the phosphor throughout this investigation.

The ZnS in the form of commercial x-ray screen (Patterson *D*) was placed directly on the envelope of a 1P21 photo-multiplier tube. (*Note:* The same 1P21 tube, operated at 1230 volts, was used throughout, and thus the results presented below refer only to the *one* tube studied.) A hemispherical mirror was placed over the tube and phosphor, and the polonium source was inserted through a hole at the top of the mirror to within 1 cm of the phosphor screen. The whole assembly was placed in a container which was kept in a bath of liquid nitrogen.

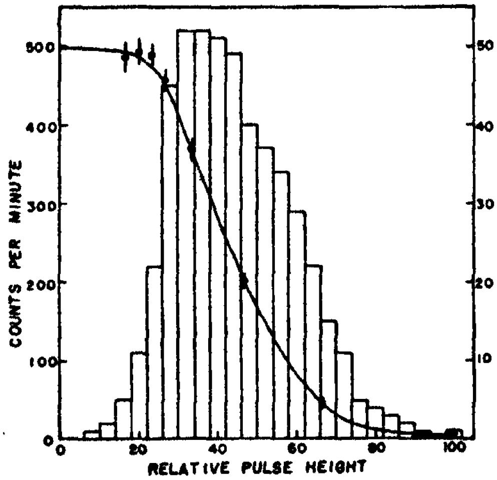

FIG. 1. Integral bias and distribution curves of the photomultiplier output pulse height when a weak light flux is incident on the photo-surface. The ordinates on the left refer to the integral bias curve and are in counts per minute. The ordinates on the right refer to the histogram and are in counts per minute per pulse height interval.

The ordinates on the left refer to the integral bias curve and are in counts per minute. The ordinates on the right refer to the histogram and are in counts per minute per pulse height interval.

---

[1] Private communication.

The output from the photo-multiplier tube passed through a cathode follower stage into a model A-1 amplifier.[2] The discriminated output from this amplifier was fed into a Tracerlab Autoscaler.

The distribution in multiplier gain (the X distribution in the notation of the previous section) was obtained by taking an integral bias curve (counting rate against discriminator bias setting) with a weak light flux falling on the tube. The light flux was made weak enough so that the probability of observing multiple primary electron pulses rather than pulses from single primary electrons was small. A second integral bias curve of dark noise pulses was obtained and subtracted from the first, yielding a resultant integral bias curve due to single photoelectrons. Such a resultant curve is shown in Fig. 1. From the smooth curve drawn through the experimental points the step distribution curve was obtained. The fractional mean square deviation obtained from the data of this curve was $\sigma_x^2=0.13$. Only one tube was tested; however, it is reasonable to expect that other 1P21 tubes should show standard deviations of the same order of magnitude. A second set of data for the same 1P21 tube gave a distribution curve for which the value of σ_x^2 was 0.23. Most bias curves do not approach as constant a value with decreasing bias as that shown in Fig. 1.

To obtain the pulse height distribution from alpha-particles two integral bias curves were obtained, with and without a 1.5-mil foil of aluminum (sufficient to stop Po alphas) surrounding the polonium source. By subtracting the first bias curve from the second, the effects resulting from the dark noise output and any possible α- and β-ray contamination in the source, mirror, etc., could be subtracted out. In this way the typical integral bias curve and distribution histogram for alpha-particles alone, shown in Fig. 2, was obtained. Analysis of this data gave a mean square deviation of $\sigma_z^2=0.084$. (Other sets of data gave values of σ_z^2 ranging from 0.07 to 0.64).

In order to apply Eq. (5), it is necessary to know the actual numerical value of $\bar{Y}$ rather than the relative pulse heights, H, as measured on the dial of a bias potentiometer. This was done by determining

$$\bar{Y}=\bar{Z}/\bar{X}=[(\bar{H}_z)/(G_z)C]/[(\bar{H}_x)/(G_x)C],$$

where G is the amplifier gain setting and C is a constant conversion factor. In this way $\bar{Y}$ was found to be 35 for the curve of Fig. 2.[3]

Application of Eq. (5) then gives

$$\sigma_y^2=\sigma_z^2-(1/\bar{Y})\sigma_x^2=0.084-0.004=0.080,$$

indicating that the contribution of σ_x^2 to σ_z^2 is practically negligible compared to that of σ_y^2.

It is thus seen that in the above case where $\bar{Y}=35$, the main contribution to the over-all distribution comes from the spread in number of photoelectrons starting out from the photo-cathode, rather than from the spread in distribution caused by the multiplication stages. If however, $\bar{Y}$ had been smaller, this latter effect would have been more serious. However, a smaller value of $\bar{Y}$ would also probably mean a larger value of σ_y^2 (as indicated earlier).

IV. DISCUSSION

From Fig. 2 it can be seen that if $Y>35$, then two particles losing differing amounts of energy in the phosphor can be distinguished to a fair degree of accuracy if both distribution curves have been obtained. If, however, it is desired to distinguish between single particles whose distribution curves cannot be obtained, then from the distribution curve of Fig. 2 an estimate can be made of the probable error of any one pulse height from the mean. Since Fig. 2 agrees in a qualitative way with a Gaussian distribution (as also does Fig. 1), it is reasonable to assume that the probable error of any single measurement from the mean will be of the order of σ_z, and thus, for Fig. 2, of the order of $(0.084)^{\frac{1}{2}}=29$ percent. This figure then gives an idea of the degree to which this counter as operated could distinguish between individual alpha-particles of differing energy.

The zinc sulfide used in this investigation was obtainable only in powders and screens of small grain size, and it is reasonable to expect that the statistical spread in the Y distribution (σ_y) would, if anything, be narrowed if a large transparent phosphor were used.

It is thus seen that this device can be used to give an indication of the energy or specific ionization of the particle, but with a precision that is poor unless the number of quanta emerging from the phosphor is fairly large. This means that for weakly ionizing particles of long range, large transparent phosphor samples must be used, so that a large fraction of the light quanta emitted over the long path may be collected.

---

[2] W. H. Jordan and P. R. Bell, Rev. Sci. Inst. 18, 703 (1947).

[3] A number of other curves were obtained for which the value of $\bar{Y}$ varied up to a maximum of 92. The low value of 35 obtained for the data of Fig. 2 may have been due to improper positioning of the mirror resulting in poor focusing.

THE REVIEW OF SCIENTIFIC INSTRUMENTS VOLUME 20, NUMBER 3 MARCH, 1949

A Pulse Amplitude Analyzer for Nuclear Research Using Pretreated Pulses[*]

C. H. WESTCOTT[**] AND G. C. HANNA
Division of Atomic Energy Research, National Research Council, Chalk River, Ontario, Canada

(Received November 2, 1948)

A pulse analyzer is an instrument used to record the number of pulses occurring in a given time whose amplitudes lie between certain limits. In the present equipment records are obtained from 30 "channels" simultaneously, the upper amplitude limit for any one channel being the lower amplitude limit of the next. Used in conjunction with an ionization chamber and linear amplifier of suitable design, the equipment gives detailed information of the frequency of occurrence of ionization pulses of various amplitudes.

The present equipment is an advance over previous designs in several respects. It is designed to deal with relatively fast counting rates and with pulses having a wide variety of shapes and durations. In order to avoid having to change the circuits of each of the 30 channel units to suit the pulse shape, the pulses are "pretreated" to yield signals of standard form before being passed to the channels for analysis. Further advantages of the present equipment concern the ease of calibration and of monitoring the behavior of the circuits. The whole is built into a console of convenient shape and reasonable mobility. Interchangeable plug-in channel units are employed.

I. INTRODUCTION

THE use of a pulse amplitude analyzer in the investigation of particle energy spectra has been discussed by Freundlich, Hincks, and Ozeroff.[1] In such an analyzer the pulses are divided into groups according to amplitude, and the number of pulses in all the groups are counted simultaneously. The equipment has a number of "channels" corresponding to the number of groups, each group comprising those pulses which are large enough to operate one channel but not large enough to operate the next. The whole of the amplitude spectrum is therefore covered without gaps, and if, as is usually the case, the channel thresholds are uniformly spaced, the spectrum is obtained directly. In this way results can be obtained much more quickly than from bias curve measurements. Consider, for example, the case when there are in time t a number n of counts in a particular group, and a number N of counts of greater amplitude. Then, using the pulse analyzer, the statistical error of the determination of n is $(n)^{\frac{1}{2}}$, whereas from a bias curve, counting for a time t on each setting, counts of $N+n\pm(N+n)^{\frac{1}{2}}$ and $N\pm(N)^{\frac{1}{2}}$ are obtained, so that the determination of n by difference is subject to the error $(2N+n)^{\frac{1}{2}}$. This is always greater, and may indeed be much greater, than $(n)^{\frac{1}{2}}$, and a time $2t$ is required for the determination.

The instrument described by Freundlich *et al.*[1] is, as they pointed out, somewhat limited in scope since the acceptable counting rate is rather low and special attention must be paid to the shape of the input pulses. A desire to improve the flexibility of such a device led to the development of the present instrument. In its design we have departed from the simple system where each "channel" receives a replica of the original signal. The incoming

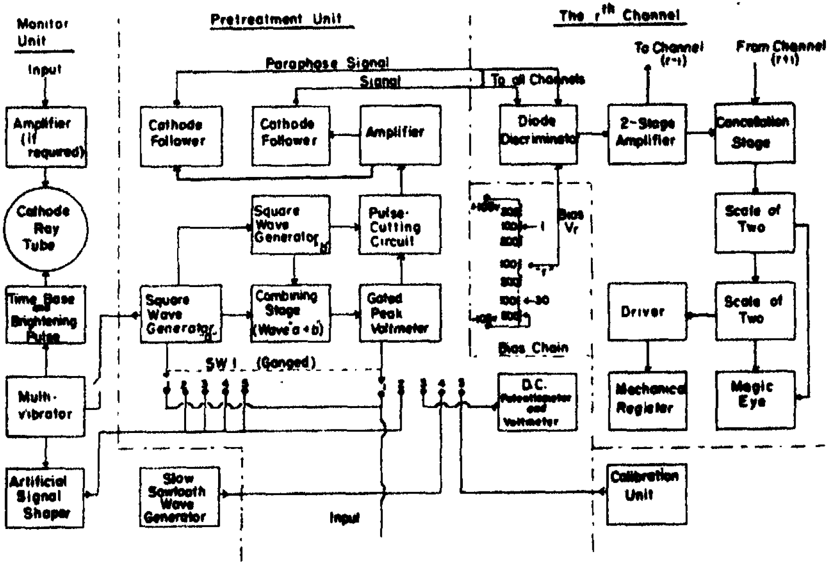

FIG. 3. General schematic diagram.

signal is fed into a "pretreatment unit" where a square wave signal of standard duration is manufactured having the same amplitude as the peak of the incoming signal. This square wave is then passed to the channel units for analysis. It is now possible to accept a wide variety of types of input signal by a simple adjustment to the pretreatment circuit without having to make changes in all the channels.

II. PHYSICAL FORM OF THE EQUIPMENT

The pulse analyzer is built in the form of a console (Fig. 1) for convenience in operation. The channels are interchangeable plug-in units accessible by removing the three rear panels (Fig. 2). Each channel is so arranged that its wiring is accessible for monitoring purposes even when plugged in the rack. The channels are 3½″ wide and are arranged in two rows of 15 alternately above and below a 3″ strip of panel on which are mounted, in a single row, the 30 mechanical registers, each with a "magic eye" underneath, which are used to record the count in each channel. The bias adjusting potentiometers associated with each channel are staggered alternately above and below the registers to indicate whether a particular register is driven from a channel in the upper or lower row. The space at the rear of the lower part of the console, and above the kneehole, is occupied by filament transformers and a large power supply: arrangements are made to deflect the hot air rising from this unit away from the channels above it. The space on either side of the kneehole is used for the pretreatment and monitor units. Each of these has a triangular control panel which fits into a recess in the console table.

III. GENERAL MODE OF OPERATION

Figure 3 shows a schematic arrangement of the equipment. Neglecting for the moment the monitoring circuits shown on the left of the diagram, we may follow the incoming signal from the bottom of the figure, through *SW*1, in its normal position (position 1) into two parallel chains of circuits. In the left-hand chain the arrival of any signal above a preset threshold initiates two successive square waves of duration "*a*" and "*b*," respectively. In the right-hand chain a peak voltmeter circuit records the maximum amplitude reached by the incoming signal and stores this information until the end of the period "$a+b$." A pulse cutting circuit forms a pulse during the period "*b*" only, of amplitude given by the peak voltmeter circuit, and this square pulse, after amplification, is passed to the channels. A smaller paraphase pulse is also fed to the channels for capacity neutralizing purposes.

A biased diode controls the channel operating level, each successive channel being biased more heavily. Two stages of amplification follow the diode discriminator, to provide a large voltage swing for the next ("cancellation") stage. The cancellation stage will only pass a pulse provided that the channel "above" has not operated; in this way each channel records only pulses with an amplitude lying between its own operating threshold level and that of the next channel above. The output from the cancellation stage drives a scale-of-four circuit which in turn feeds an impulsing pair driving a mechanical register.

A feature of the equipment is the section devoted to monitoring operations. This consists essentially of a unit providing artificial pulses of adjustable repetition frequency, and controllable shape and amplitude, synchronized with a time-base on a cathode-ray tube. This basic arrangement can be altered to allow the incoming pulses from the counting system to fire a single sweep time base. Another arrangement allows for accurate calibration of the system.

As shown in Fig. 3 the equipment sorts pulses of sizes between 1.5- and 100-volt amplitude into 30 equi-spaced channels. If it is desired to examine the amplitude spectrum in more detail, a narrower range of pulse amplitudes may be selected. A separate unit is used in this case which cuts a fixed amount from the size of each pulse and amplifies what remains until the desired range extends over 100 volts in amplitude. This unit, developed by Cranshaw and Harvey, is described elsewhere.[2]

IV. THE PRETREATMENT UNIT

The purpose of this circuit is to convert the input pulses, which may have any rise time between 1 μsec. and 3 msec., into square pulses 80 μsec. long of amplitude accurately proportional to the input amplitude.

The input pulse (+100-v max.) triggers a square wave generator *V*1, 2, 3 (see Fig. 4). The duration "*a*" of this square wave is adjustable in steps from 0.2 to 15 msec., and is made just greater than the time the input pulse takes to decay to the triggering threshold level. This threshold, controlled by the bias on the grid of *V*3, is normally set to 1.5 volts.

From the back edge of wave "*a*" *V*4 produces another square wave of duration "*b*" (80 μsec.). *V*6 combines these two into a single wave of duration "*a*+*b*"; there is necessarily a sharp crevasse in this wave but the response of *V*4 is fast enough to ensure that it does not drop below +110 v (see Fig. 5). Thus whenever this chain is triggered the discharging diode *V*7 is cut off for a time "*a*+*b*," during which the input pulse, fed in via a buffer stage *V*8, charges the 0.002 μf reservoir condenser through *V*8*A*. The isolating cathode follower *V*9 imposes a negligible load on the condenser. This then holds the full peak-amplitude charge for the time "*a*+*b*," after which it is rapidly discharged through *V*7 to a level controlled by the bias applied to *V*6 ("d.c. level 1"). The cathode of *V*9 therefore follows the rise of the input signal up to its peak amplitude and remains there until the end of the period "*a*+*b*."

The grid of *V*12 is held by the diode *V*11 at a potential set by "d.c. level 2," except during period "*b*" when the positive square wave from *V*4, applied through the 0.25-megohm resistance, pulls it up to the level of *V*9 cathode, further travel being arrested by conduction of *V*10. Here then we have a square pulse of duration "*b*" and amplitude equal to the input (less the losses in the cathode followers *V*8, 9) plus an adjustable "zero control" voltage set by d.c. level 2. It is necessary for the correct operation of this diode circuit that the quiescent level of *V*9 cathode, set by d.c. level 1, be more positive than the quiescent level of *V*12 grid, set by d.c. level 2.

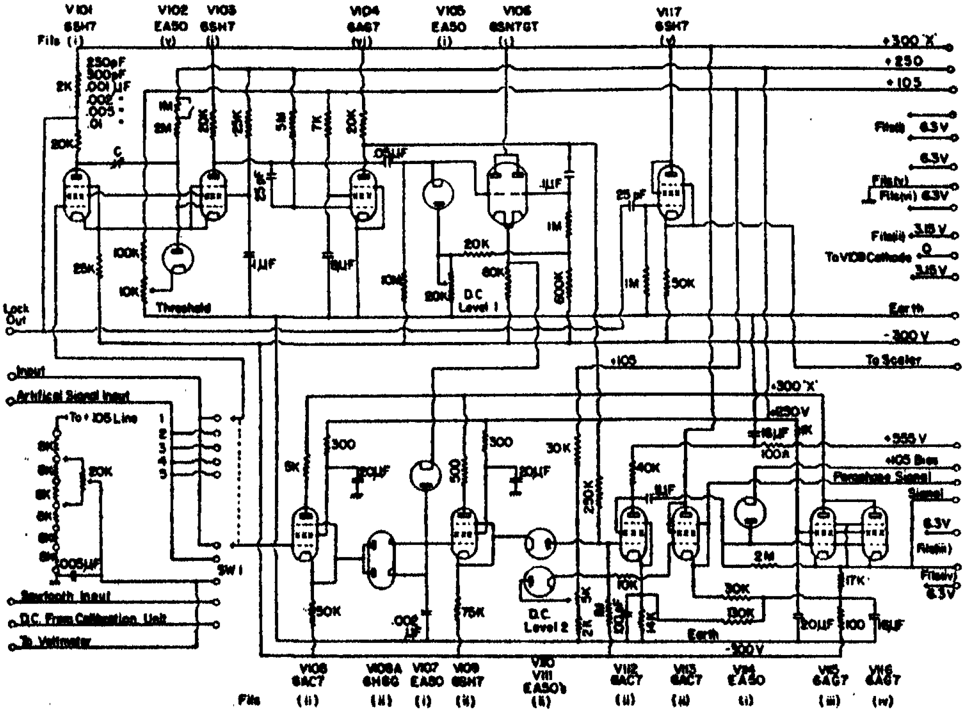

FIG. 4. Pretreatment—circuit. For *V*101, *V*102 ··· *V*117 read *V*1, *V*2 ··· *V*17.

---

[2] T. E. Cranshaw and J. A. Harvey, Can. J. Research A26, 243 (1948).

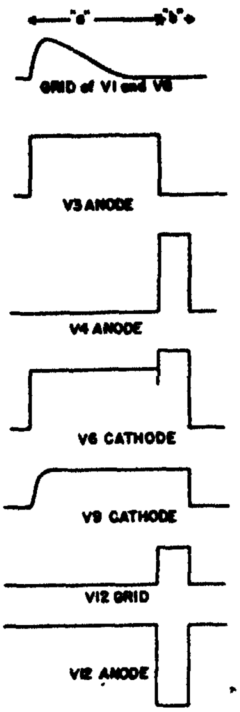

FIG. 5. Pretreatment—wave forms.

The gain of $V12$ is 2.5; consequently there appears on its anode a 220-v (max.) negative going signal of duration "b," which is "d.c. restored" in $V14$ against the +105-v bias line, that is, against the positive end of the resistor chain from which the discriminator diodes in the channels are biased. It is then fed out through the high power cathode-follower stage $V15$, 16 to operate the channels.

From the cathode of $V12$ the positive 80-v (max.) wave is fed out to the channels through the cathode follower $V13$ to act as a capacity-neutralizing paraphase signal. For efficient neutralizing the wave forms at $V15$, 16, and $V13$ cathodes, both of which work into highly capacitative loads, should be identical. This cannot be realized in practice, but the shapes have been made sufficiently similar by shunting the cathode load of $V12$ with a small condenser and smoothing slightly the pulse applied to the grid of $V13$.

Subsidiary features of the circuit include a negative "lock" pulse for driving the monitor unit from the input signals (from $V1$ anode circuit) and short pulses fed out through $V17$ suitable for driving a scaler to check the total number of counts.

The above applies during normal operation, when the monitor unit is driven from the input pulses (arriving at random) and provides a single-sweep time base for studying the operation of the equipment on the oscilloscope. As an alternative, however, the pretreatment unit can be driven from the monitor unit; this arrangement is particularly useful for calibration and fault-finding. Artificial pulses of adjustable amplitude, shape, and repetition frequency from the monitor unit can be fed in directly (position 2 of the input selector switch), and can also be used to trigger the square wave generator ($V1$, 2, 3) while a constant voltage, obtained from a built-in potentiometer system, is applied to $V8$ (position 3). In this case pulses are generated with an amplitude corresponding to the level of $V8$ grid. That is, if $V8$ grid is connected to a source of +50 v (say), which can be measured accurately with a precision voltmeter, the output of the pretreatment unit is the same as though pulses of peak amplitude 50 v were applied to $V8$. This equality is maintained provided the pulse rise time to maximum is less than 10 μsec. Input pulses with a rise time of 2.5 μsec. will record at a level about 5 percent below that of a steady voltage of the same amplitude, but the input/output characteristic of the system is still linear to 1 percent. The equivalence of d.c. and pulse input is not, however, quite exact due to the imperfect cut-off of the diode $V8A$. When a steady voltage is fed in, the reservoir condenser continues to charge up very slowly over the whole of the period "$a+b$." The net effect is a zero shift, the magnitude of which increases with period "a" up to about ¼ volt for "a" equal to 10 msec. This behavior is discussed in greater detail in the report CRP-291.

Fast rising pulses are in general of short duration: consequently period "a" may be shortened and the size of the reservoir condenser reduced, since it need not hold its charge so long. This will increase the accuracy of response to fast pulses and reduce the difference between d.c. and pulse input. In fact the instrument has recently been operated with a 200-$\mu\mu f$ reservoir condenser which permits rise times of less than 1 μsec. to be used. A single switching wave 80 μsec. long derived from a slightly modified square wave generator circuit was employed, gating the peak voltmeter circuit as before and driving $V12$ to produce the channel operating pulse directly. The rise time of this pulse was of course the same as that of the input pulse; provided this is less than about 10 μsec., the channel operation is not affected.

Position 4 of the input selector switch connects $V8$ grid to the slow sawtooth wave provided by the monitor unit (see Section VI), and position 5 to the calibration unit. This unit consists of 30 100-ohm precision resistances connected across a stabilized 100-v line monitored with a standard voltmeter. The junctions of these resistances are, clearly, at potentials corresponding to the transitions between successive channels. A selector switch enables these potentials to be applied in turn to $V8$ for setting up the channels. This unit was found more convenient in use than the potentiometer and voltmeter arrangement available in position 3.

Several power supply voltages are used in the pretreatment unit. The 300-v "*X*" line (semi-stabilized—see Section VII) provides most of the h.t. current. Where high stability is required—for example for screen supplies to ensure constancy of valve characteristics-stabilized +250-v and +105-v lines are available. The large anode swing of *V*12 necessitates the provision of a stabilized +550-v supply. The negative h.t. lines are both stabilized.

The filaments of *V*15, 16 (iii and iv) are heated from a 12.6-v center-tapped, low capacity screened transformer winding, the center wire being driven by the cathode. This supply also feeds all the channel diodes (*V*101 Fig. 6). Filament supply (i) is biased to +90 v (in the main power supply) so that the cathodes of the valves it feeds may rise to +180 v without exceeding the insulation rating. The cathode insulation of the charging diode *V*8*A* is important since it determines the rate of discharge of the reservoir condenser. Consequently this valve is heated from a low capacity transformer winding, the center-tap of which is driven by *V*9. *V*8 and *V*10–13 are also fed from this supply (ii). The other valves are heated by the main 12.6-v system with earthed center-tap (v and vi).

The filament supplies (i), (ii), (iii), and (iv) are derived from a transformer fed from a constant-voltage transformer. This renders the performance of this unit substantially independent of mains voltage. Drifts caused by warming up are reduced by the use of generously rated wire-wound resistances at all strategic points; the circuit is stable within ten minutes of switching on.

V. THE CHANNEL UNITS

Figure 6 shows the circuit of a channel unit. The cathodes of the diodes (*V*101) in all the channels are connected to the output of the pretreatment unit (*V*15, 16 Fig. 4) and the anode load resistances to successive points on a resistance chain. This bias chain consists of 30 200-ohm wire-wound resistances and 30 100-ohm preset potentiometers with suitable padding resistances at each end connected in series between the +105-v and −105-v bias lines. (See Fig. 3.) The preset controls, readily accessible from the front of the instrument, allow small adjustments to be made to the bias voltage of each channel.

Consider the operation of the *r*th channel, i.e., the one biased to a voltage V_r by the *r*th potentiometer of the bias chain counting from the positive end. If the original input pulse is insufficiently large to cause the cathode of *V*101 to drop from its quiescent level of +105 v to below V_r, *V*101 will not conduct. A paraphase signal fed through a small adjustable condenser neutralizes the effect of the diode self-capacity (for wave forms see Fig. 7).

If the cathode of *V*101 falls below V_r, *V*101 conducts and a negative pulse appears on the grid of *V*102. *V*102 runs, during the quiescent period, at the limit of grid current; this assists in the rapid restoration of the original potentials after the pulse is over, since the coupling condenser is recharged by the flow of grid current rather than through the 10-megohm leak.

It should be mentioned here that before a channel conducts it imposes capacitative loads of 2 and 5 $\mu\mu$f on the signal and paraphase inputs respect-

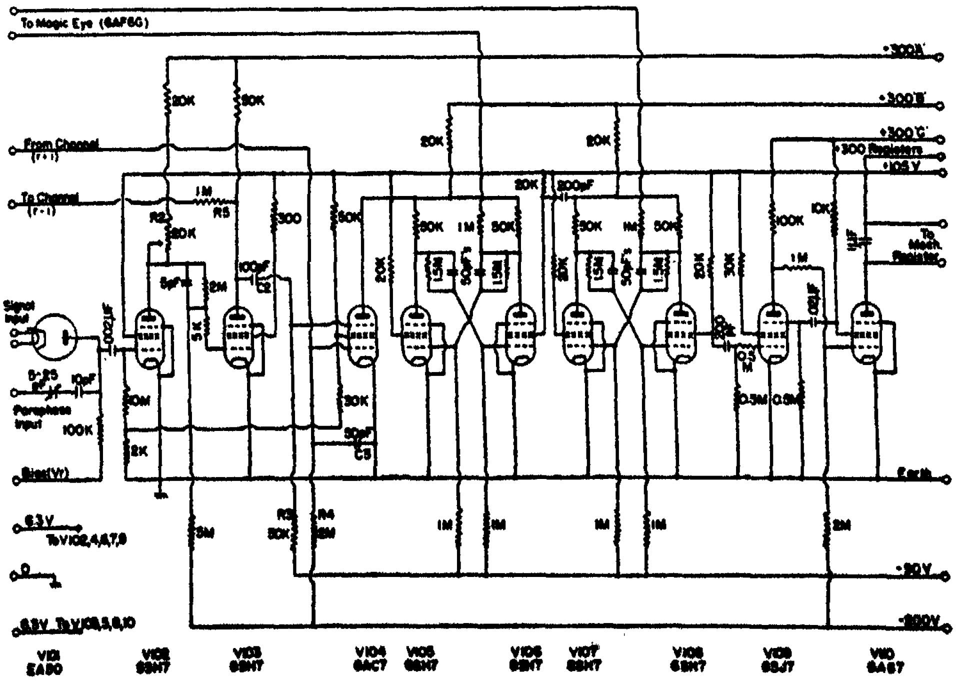

FIG. 6. Channel—circuit.

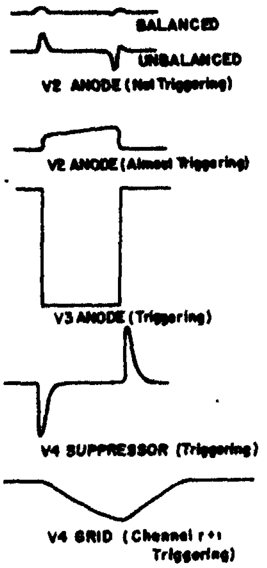

FIG. 7. Channel—wave forms. For $V2$, $V3$, $V4$, read $V102$, $V103$, $V104$.

ively. When the diode conducts the former load becomes 10 μA per volt above threshold, and the latter 17.5 $\mu\mu$f. These conditions determine the design of the output cathode followers $V15$, 16, and $V13$ in the pretreatment unit. The load current of course returns through the bias chain. The center point of this is earthed and each bias point connected to earth through a 1-μf condenser. This arrangement ensures that the threshold voltages are not displaced by more than 20 millivolts (mean) for a total counting rate of 2000/min.

The anode potential of $V102$ is set at +80 v by R_2. Its gain is about 160; consequently a pulse $\frac{1}{4}$ volt in amplitude applied to its grid will cause its anode to rise to +120 v. At this point $V103$ starts to conduct, a further change of 4 v in the anode potential of $V102$ causing $V103$ anode to fall from +300 v to about +30 v. Thus pulses of less than $\frac{1}{4}$ volt on $V102$ grid (resulting for example from imperfect neutralization) will have no effect, while a pulse exceeding this threshold by 25 millivolts will give a full-size negative square wave, of 80-μsec. duration, at the anode of $V103$.

In the canceling stage, $V104$, the suppressor is normally held at −90 v. The control grid is near earth potential drawing 150 μA of grid current. At the end of the negative square wave on $V103$ anode a positive "pip," obtained by differentiating with a 5 μsec. time constant ($C3$ and $R3$), allows a short pulse of anode current to pass which operates the first scale-of-2 circuit ($V105$, 106). If, however, the cathode potential of $V101$ falls below V_{r+1} the next $(r+1)$th channel will operate in a similar fashion. The anode of $V103$ in channel $(r+1)$ will drop to +30 v and the grid of $V104$ in channel r will start to fall, as current flows out of the 50-$\mu\mu$f condenser $C3$ through the resistances $R4$ and $R5$. By the end of the 80-μsec. wave it will have fallen to about −80 v, recovering over the next 30 μsec. Thus all current in $V104$ is cut off for a time comfortably greater than the duration of the positive "pip" on the suppressor and the scaling circuit is not operated.

The scaling circuits are of conventional type using two scale-of-2 pairs in tandem. The state of each pair is shown on a "magic eye" (a double tuning indicator type 6AF6G) fed from the anode of the second valve in each pair through a one-

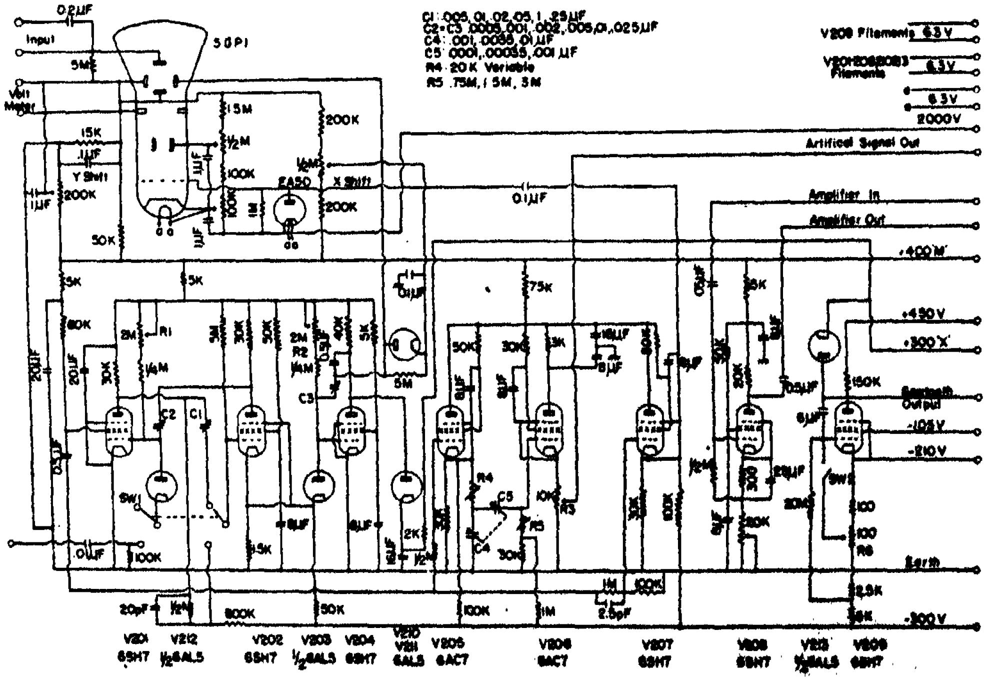

FIG. 8. Monitor—circuit.

megohm resistance which effectively isolates the valve from the self-capacity of the wiring to the magic eye.

The second scaling circuit drives a trigger circuit (*V*109 and *V*110) which provides a 50-ma current pulse lasting about 20 msec. to drive the mechanical register. A telephone call meter (GPO England, Type 100C) was chosen for this on account of its small size and cheapness. Unfortunately these machines are not very reliable at high counting rates and frequent checks of maximum operating speed are made (using the monitor unit). Registers failing at less than 15 operations/second are replaced; tightening the return spring frequently provides a satisfactory cure. The maximum counting rate which a channel can handle is determined entirely by the register. A counting rate of 720/min. (180 register clicks/min.) will be subject to a 1 percent loss; if a 10 percent loss is tolerable the rate may be increased to about 1600 counts/min. The register is highly inductive (about 30 *H*, its d.c. resistance being 2300 ohms). A 1-μf condenser is therefore connected across it to limit the instantaneous voltage surge which would otherwise break down the insulation.

Several h.t. supplies are used. A stabilized +105-v line is used as a screen supply. The +300-v "*A*" line provides a fully stabilized supply for *V*101 and *V*102 whose exact operating conditions are important. 300-v "*B*" and "*C*" are semistabilized supplies for the less critical circuits. Unstabilized lines are used for the register (*V*110 anode supply) and the magic eye. Such subdivision prevents feedback and simplifies circuit design, and is in any case not uneconomical since the total current drain on each supply is large enough to justify its separate existence.

TABLE I.

Line voltage	Current (ma)	Stability	To feed
+550	4	NS	Pretreatment V12
+450	3	NS	Monitor V209
+300 "*A*"	220	S	Channels
+300 "*B*1"	120	SS	Channels 1–15

+230	115	—	Magic eyes*

* These supplies are separately switched.

VI. THE MONITOR UNIT

The main purpose of this unit is to provide artificial signals for fault finding and calibration. They are generated by a self-running multivibrator which also drives a time base circuit for the oscilloscope. This multivibrator can be switched so that it operates only on external triggering pulses, thus providing single-sweep operation of the oscilloscope for monitoring the input to the pulse analyzer during normal operation. The circuit diagram is shown in Fig. 8.

When *SW*1 is raised *V*201 and *V*202 run freely. A set of switched condensers, *C*1, determines the repetition frequency and another set, *C*2, the duration of the positive square pulse on *V*202 cathode. This pulse cuts off the diode *V*203 and the anode potential of *V*204 falls almost linearly with time, from +300 v set by the "catching" diode *V*211, towards earth at a rate determined by *R*2 and *C*3. *C*3 is ganged to *C*2 so that the amplitude of the time base sweep (*V*204 anode) remains constant for different duration times. In addition, the variable parts of *R*1 and *R*2 provide a continuous and separate control of the duration and speed respectively of the time base.

A positive pulse is taken from the screen of *V*201 to brighten the oscilloscope for the duration of the time base and is fed to the cathode ray tube through *V*207.

The artificial signal is obtained from this positive pulse using the shaping network *R*4*C*4*R*5*C*5 driven by a cathode follower *V*205. *R*4*C*4 determines the rising and *R*5*C*5 the falling times of the signal. Its amplitude is adjustable by *R*3.

*V*208 is a simple amplifier with a gain continuously variable up to about 120. Its main use is the checking of h.t. lines for smoothness.

*V*209 provides a slow sawtooth wave rising from a little below earth potential to +100 v in about five minutes. This can be fed into the pretreatment unit input, which is meanwhile triggered by the artificial signal pulses, to check the equality of channel widths. Since the wave rises linearly with time and the pulse repetition frequency is constant, the count recorded in any channel will be proportional to its width. With *SW*2 closed the potential of *V*209 anode is set a few volts below earth using *R*6. As soon as *SW*2 is opened the 6-μf condenser starts to discharge through the 20-megohm resistance and the anode potential rises linearly, operating the first channel as soon as it exceeds earth potential. Thus a change in the setting of *R*6 merely alters the time between *SW*2 being opened and the check run starting. The 6-μf condenser has been chosen for high insulation resistance, any appreciable leak affecting the linearity of the sawtooth wave. *V*213 prevents excessive voltage appearing across the condenser when *SW*2 is left open indefinitely.

When the pulse analyzer is being used normally the monitor unit may be switched off. Alternatively *V*201 and *V*202 can be driven by an external negative lock (obtained from the pre-treatment unit) *SW*1 being depressed so that *V*202 is normally biased off. The duration controls and the time base stage, *V*204, operate as described above, giving a single-sweep time base of adjustable speed and duration locked to the input to the pre-treatment unit.

The oscilloscope itself is mounted on top of the console. Connections to it are made using multicore screened cable except for the vertical deflector plate input, which is a separate "flying" lead in the interests of low capacity. An external voltmeter may be connected to the vertical shift system if measurements of pulse amplitudes are required.

VII. POWER SUPPLIES

The power consumed by the pulse analyzer is approximately 2.5 kw at 115 v 60 c.p.s. The bulk of this power is taken straight from the mains, but two circuits are fed from a small mains-stabilizing transformer rated at 2 amps. These circuits are the rectifier system from which the +550-v supply is derived, and the heater transformer "*B*" which feeds valves in the pretreatment unit (see Section IV).

Closing the main switch energizes a large heater transformer "*A*" which feeds the other valves in the instrument from its 12.6 v 50 amp. center-tapped secondary. It also energizes the mains stabilizing transformer and, consequently, transformer "*B*." A relay prevents the +550-v supply from being energized immediately: this relay remains open until the h.t. switch is closed.

The h.t. power may be switched on after a 40-second thermal delay switch has closed. Circuits of all the rectifying and stabilizing circuits are not given but the requirements are listed below (see Table I). Three types of stabilization are used: "*S*," fully stabilized using a series valve controlled by a d.c. amplifying stage balanced against a neon discharge tube; "*SS*," semistabilized where the current is taken from the cathode of a power pentode with grid and screen held constant; and "*NS*," neon stabilized, i.e., across a glow-discharge tube (in the case of the neon stabilized lines below the +300-v level, the supply resistance is taken to an already stabilized line). The −90-v bias line for the channels is obtained from the −105-v line through a 2000-ohm dropping resistance and is decoupled to earth with a 16-μf condenser.

VIII. SUMMARY OF PERFORMANCE

The instrument will handle pulses of any shape provided that the rise-time is greater than 1 μsec. and the total pulse duration less than about 15 msec. These limits can, however, be extended in both directions by comparatively simple modifications to the pretreatment unit.

The maximum counting rate per channel is 700 counts/minute for 1 percent loss. The total counting rate acceptable is, of course, merely limited by the input pulse length when long pulses are being used, since the probability of two pulses overlapping must always be kept low if reliable analysis is required. For example with $a+b=500$ μsec. a total speed of 1200 counts/minute will give a 1 percent overlap probability. For short pulses the ultimate limit is set by the 80 μsec. channel-operating wave, giving 1 percent loss at 7500 counts/minute. In general these limitations are not serious, since the amplitude analysis yields information so much more rapidly than do successive measurements of points on a bias curve, that a reduction of the counting rate can usually be tolerated.

The channel positions are stable to within 0.04 volt (or 1.2 percent of 1 channel width) against mains voltage changes from 105 v to 120 v. They are subject to long term drift (over a period of weeks) of about 0.05 volt. The general reliability of the instrument is very good.

IX. ACKNOWLEDGMENTS

The work described in this paper was part of the research programme of the Atomic Energy Division of the National Research Council of Canada. The authors had the benefit of discussion with their colleagues throughout the work, and in particular they wish to acknowledge the contribution of Mr. A. G. Ward in the initial stages of planning the design of the instrument.

THE REVIEW OF SCIENTIFIC INSTRUMENTS VOLUME 20, NUMBER 3 MARCH, 1949

A Magnetic Ion Source

CARL BAILEY,* D. L. DRUKEY, AND F. OPPENHEIMER
Department of Physics, University of Minnesota, Minneapolis, Minnesota

(Received November 8, 1948)

An ion source for particle accelerators is described. The ion source utilizes an axial magnetic field for collimation of ion and electron beams and provides an electric field-free region for ion formation. The ion source has afforded yields of 500 microamperes of resolved protons when used in conjunction with a 200-kv high voltage set. A feature of the ion source is the possibility of obtaining favorable atomic to molecular ion ratios.

A MAGNETIC ion source yielding fairly large ion currents has recently been installed on the 200-kv ion accelerator[1] at the University of Minnesota. Sources utilizing a similar principle have been described by at least two authors.[2,3] The Minnesota source was patterned after one built at the University of California by one of us.

The essential features, although not the constructional details, of the present source are indicated in Fig. 1. The hydrogen supply, not shown, is from a supply tank with an electrically heated palladium leak. The field coil, about 400 turns of $\frac{3}{8}$-inch o.d. copper tubing cooled by kerosene flowing internally, supplies an axial magnetic field with its maximum intensity at the center of the arc chamber. The field is adjustable to an upper limit of about 1800 gauss. The filament consists of one and a half turns of 0.060-inch tungsten wire. The space between filament and arc chamber is about $\frac{1}{4}$ inch. The arc chamber is a non magnetic stainless steel cartridge with 0.050-inch molybdenum end plates and is so constructed that it can be removed as a unit from the brass shell of the source. The holes in the molybdenum plates at the filament and probe ends are, respectively, $\frac{3}{16}$ inch and $\frac{1}{16}$ inch in diameter. The $\frac{1}{16}$ inch is bevelled to an angle of 60° on the side facing the probe in order to improve the focussing properties of the gap somewhat. The entrance hole in the non-magnetic stainless steel probe is $\frac{1}{4}$ inch in diameter, and the gap between the probe and the molybdenum plate is $\frac{1}{8}$ inch. The focus electrode is also constructed of non-magnetic stainless steel. Liners of the same material hold the assembly in place. The insulators for the probe and filament leads are special spark plug type seals.

The accelerating tube consists of porcelain insulators very kindly supplied by R. G. Herb of the University of Wisconsin and steel spinnings similar in design to those used in the Wisconsin accelerator. The first few sections of the tube are indicated in Fig. 2. There are eight sections comprising a tube 20 inches long.

Power for the operation of the source is supplied by three generators located in the high voltage shell and driven by insulating belts from motors at ground potential. The first of these, a 3-kw, 32-volt d.c. generator, supplies up to 100 amperes to the field coil and is controlled by a series resistance and/or field rheostat. Normal power consumption is about 750 watts. A 250-volt d.c. generator supplies voltage to accelerate the electrons from the filament and maintains the arc. Control consists of a 70-ohm series resistor to limit the arc current. A 110-volt a.c. generator supplies power to operate the filament, heat the palladium leak, and for the probe high voltage supply. The filament is heated from the secondary of a 10-volt, 1-kw transformer with primary controlled by a Variac and uses about

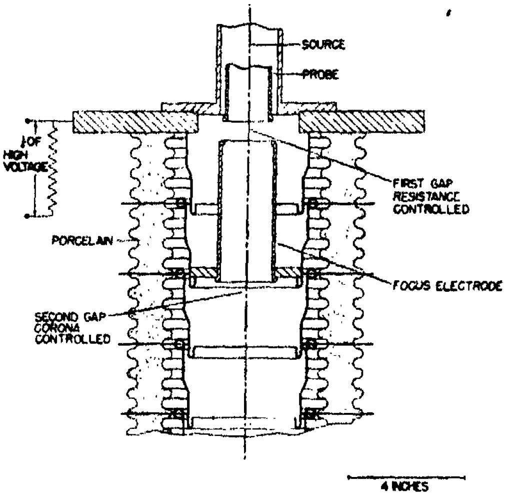

FIG. 2.

60A at 2.5 v. The palladium leak is likewise supplied by a transformer and Variac. The probe high voltage supply is a half-wave rectifier capable of delivering up to 10 kv at 20 ma. The high current rating is necessitated by the large current to the probe under certain defocusing conditions. Control is provided by a Variac in the primary of the high voltage transformer. Voltage to the focus electrode is supplied by a resistance divider across part of the main high voltage supply. For the above reason, this divider has been designed to carry 2 ma of current. Voltage on the spinnings is supplied from a series of corona gaps, the first of which is adjustable. Source body, filament, and magnet coil are cooled by kerosene pumped up from ground potential through insulating tubing. Rough measurements on the hydrogen flow to the source indicate that the gas is used at the rate of 10±5 standard cc per hour at maximum proton yield. At this flow, the pressure at the source is about 0.02 mm Hg, and at the ground end of the accelerating tube it is about 1×10^{-5} mm Hg. Differential pumping is not employed.

By proper manipulation of probe, focus electrode, and second gap voltages, the beam can be focused into a spot ⅛ inch to ¼ inch in diameter on a target seven feet from the source. A magnetic analyzer and a ½-inch diameter diaphragm serve to resolve the beam according to mass. A ⅜-inch diameter diaphragm located between the first diaphragm and the target, and at considerable negative potential, effectively prevents secondary electron emission from the insulated target cup.

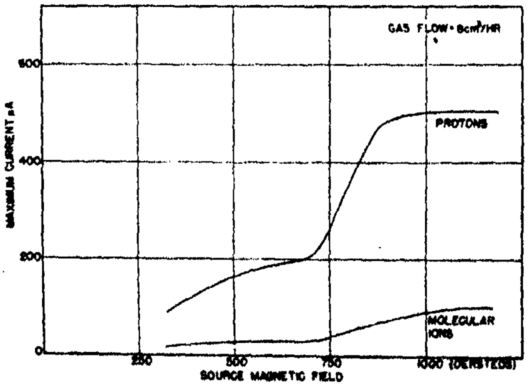

FIG. 3.

Performance curves for 160-kv accelerating voltage are given in Figs. 3 and 4. They show that a source magnetic field of 1000 gauss affords a good yield and that an excess of protons over molecular ions is obtained under usual conditions. This situation is reversed, however, if the gas flow is increased fourfold and the source magnetic field is reduced to about 400 gauss, in which case proton currents of about 100 μA and molecular currents of 200 μA are obtained. It is thus possible to obtain relatively heavy molecular beams also. With the filament, arc chamber, and probe aligned, it is found that optimum yields are obtained when the source magnetic field is coaxial with the source.

Use of a 0.080-inch diameter hole in the second molybdenum plate of the arc chamber resulted in a 20 percent increase in ion yield over that from the $\frac{1}{16}$-inch hole. The gas flow, however, increased by a factor of two with resultant increase in tube pressure. It is felt that the increase in yield might have been better with differential pumping, since tube pressure seems to have a strong influence on yield at these low energies.

Filament life with this design has proved good with operating lives of several hundred hours not uncommon. The arc starts readily, and when the tube is properly outgassed, nearly the maximum proton current is attained after a few minutes of operation.

The functions of the source magnetic field in improving the yield of the source are threefold. The electron beam is collimated by the magnetic field so that most of the arc is in regions from which the ions might be used. For a given gas flow, the yield is higher because the magnetic field keeps the ions from diffusing to the walls of the arc chamber and being lost. The ratio of ion density to arc pressure is thus higher in the presence of the magnetic field. At this field the average ionic radius of curvature is of the order of the diameter of the exit hole. The formation of atomic ions appears to be in large part a two-step process which is thus greatly facilitated by the increased ratio of ions and electrons to un-ionized molecules. The high ratio of protons to molecular ions obtained with this source and the dependance of that ratio on source pressure seem to bear out this point of view. The present limitation on the available ion current seem to be largely due to the inability of the present probe geometry to focus the ions leaving the plasma when the ion density of the plasma is increased by larger arc currents. At larger arc currents, the ion beam bombards the probe or other electrodes and is lost from the beam. Probe and focus electrode currents of several milliamperes have been observed under such defocused conditions so that it seems likely that this amount of current is really available for the beam. A calculation of the space charge limitation resulting from plane geometry with dimensions similar to that of the source indicates a current density such that from a $\frac{1}{16}$-inch aperture only about half as much current as actually reaches the analyzer might be expected. It thus seems necessary to open the exit hole or change the probe design so that larger voltages or smaller gaps can be used without defocusing the beam too badly if large currents are to be obtained.

The source in its present form does not represent a final design. It would be desirable to have the magnet coil removable over the head flanges, and differential pumping would be desirable and even necessary for a longer accelerator. It seems quite likely, on the basis of the present experience, that a permanent magnet might be substituted for the field coil with much saving in the cooling requirements for the source as a result of the much decreased power consumption.

THE REVIEW OF SCIENTIFIC INSTRUMENTS VOLUME 20, NUMBER 3 MARCH, 1949

A Theory of the Solenoid Beta-Ray Spectrometer

E. PERSICO
Université Laval, Québec, P. Q., Canada

(Received November 22, 1948)

A theory of the magnetic lens beta-ray spectrometer utilizing the uniform field of a long solenoid is developed. First the case of a point source is considered, and it is found that the resolving power, for a given solid angle, is maximum when the emission angle α (average angle between the rays leaving the source and the axis) is 45° 37′. Then the theory is extended to the case of a disk source, and it is found that for a given intensity (product of the source area by the solid angle) there is an optimum source diameter and an optimum emission angle, ranging in practical cases between 36° and 40°. The problem of optimum conditions when the quantity of copper in the solenoid and the electric power available are limited by economical considerations is also studied, and it is found that the optimum α-value is in this case about 21°.

INTRODUCTION

AMONG the different types of spectrometers used for analyzing beta-ray spectra, the solenoid spectrometer proposed by Kapitza in 1923[1] has been successfully employed by other physicists,[2] especially in cases where the radioactive material could not be concentrated on a very small area. This instrument is a particular kind of magnetic lens spectrometer, in which the focusing field is the uniform field produced by a long solenoid: this permits a rigourous calculation of the trajectories, and a study of the geometrical properties, which would be very difficult in the other types of magnetic lens spectrometers utilizing non-uniform fields.

A theory of the solenoid spectrometer has been given by Witcher,[2] but it is confined to the case of a point source and does not investigate the conditions giving the maximum resolving power for a given intensity. In this paper we start the theory for a point source in a manner more suitable to its exten-

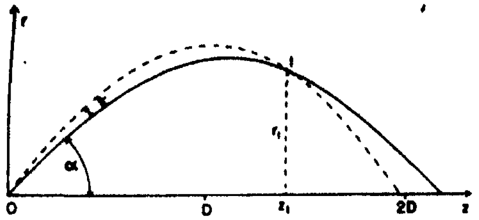

FIG. 1. Formation of the "ring image." The emission angle, α, has been chosen equal to 45° 37′, optimum value for a point source.

sion to the case of a source of finite area. Then we develop simple approximate formulas for the latter case, and apply them to find the optimum source diameter and the optimum emission angle (average inclination, with respect to the field, of rays leaving the source).

RING IMAGE OF A POINT SOURCE

Let us consider a point source, emitting isotropically electrons of momentum p, in a uniform field H. We shall assume cylindrical coordinates z, r, ψ (with the z axis parallel to the field, and the origin in the source) and put for conciseness:

$$D=2p/(eH), \tag{1}$$

(e being the electron charge in e.m.u.). This length determines roughly the linear dimensions of the apparatus.

The trajectory of any electron leaving the source at an *emission angle* α with the z axis will be, as is well known, a cylindrical helix of pitch $\pi D \cos\alpha$ and diameter $D \sin\alpha$, having the z axis as a generatrix. The equation for r will be (also in relativistic mechanics)

$$r=D \sin\alpha \sin\zeta, \tag{2}$$

where

$$\zeta(z)=z/(D \cos\alpha). \tag{3}$$

The sinusoid representing r as a function of z (Fig. 1) will be called, conventionally, a "trajectory," although it represents only the motion in a meridian plane revolving around the z axis so as to contain always the instantaneous position of the electron. We shall consider only the first half-wave-length of the sinusoid, that is, suppose as usual, that the electrons make less than one revolution. Let us now consider another electron leaving the source at an angle $\alpha+d\alpha$: its trajectory will intersect the preceding one at a point I such that

$$(\partial r/\partial\alpha)_I=0. \tag{4}$$

From (2) one gets for such a point

$$[\zeta^{-1} \tan\zeta]_I=-\tan^2\alpha. \tag{4′}$$

It will be useful in the following to introduce the function $\beta(\alpha)$ defined by

$$\tan\beta/(\pi-\beta)=\tan^2\alpha, \quad 0\leqslant\beta\leqslant\pi/2, \tag{5}$$

(whose diagram is given in Fig. 2). Then we have

$$\zeta_I=\pi-\beta, \tag{6}$$

$$z_I=(\pi-\beta)D \cos\alpha, \tag{6′}$$

and from (1)

$$r_I=D \sin\alpha \sin\beta. \tag{7}$$

If the rays where limited by a diaphragm with an infinitely narrow annular slit, so as to admit only rays with α ranging in an infinitesimal interval, they would produce, in the plane $z=z_I$, a circumference of radius r_I, which may be called a "ring image" of the source (giving a generalized meaning to the word "image").

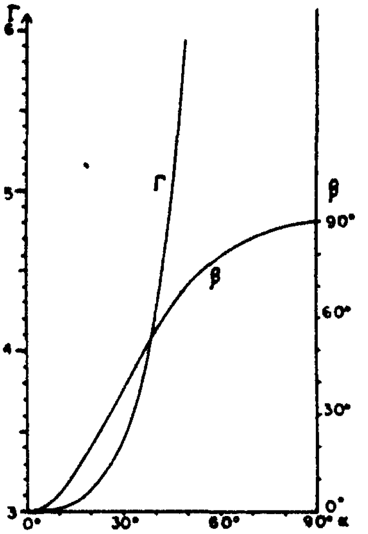

FIG. 2. The auxiliary functions $\beta(\alpha)$ and $\Gamma(\alpha)$.

If the diaphragm slit has a finite width, the ring image will be no longer an infinitely thin line, but will acquire a certain width, as a result of the difference in the spherical aberration of rays with different values of α. To take this effect into account we consider the trajectories leaving the source at angles $\alpha\pm\epsilon$ and develop (2) in Taylor series, neglecting powers of ϵ higher than the second and using (4):

$$r=r_I+(\partial^2 r/\partial\alpha^2)_I\epsilon^2/2. \tag{8}$$

As is seen, to this order of approximation the two trajectories corresponding to $\alpha+\epsilon$ and $\alpha-\epsilon$ fall together on the image plane, and so the width of the ring produced by all rays between $\alpha-\epsilon$ and $\alpha+\epsilon$ is

$$\Delta r=(\partial^2 r/\partial\alpha^2)_I\epsilon^2/2. \tag{9}$$

Differentiating (2), taking into account (4′) and introducing for simplicity the function of α defined by

$$\Gamma(\alpha)=3+\cos^2\alpha \tan^2\beta, \tag{10}$$

(whose diagram is shown in Fig. 2) one gets:

$$\Delta r = (D/2)(\sin\beta/\sin\alpha)\Gamma\epsilon^2. \tag{11}$$

RESOLVING POWER

We define the resolving power P by

$$P = p/\Delta p, \tag{12}$$

where Δp is the increase to be given to the momentum p of the electrons in order that the radius of the ring image be changed by an amount equal to its width (it will be noted that in this virtual change of p, α does not remain constant, its value being determined, for each value of p, by the radius and position of the diaphragm slit). This definition of the resolving power is somewhat more stringent than that usually adopted in optics, because it takes into account the *total* width of the spectral line instead of its half-value width.

Now, from (1) and (4) we get

$$dr_I = (\partial r/\partial D)_I(D/p)dp,$$

so that, identifying dr_I with the ring width Δr and dp with the corresponding Δp, we have

$$P = (\partial r/\partial D)_I D/\Delta r.$$

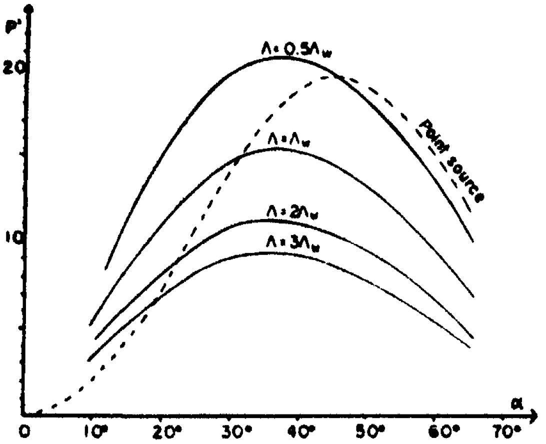

FIG. 3. The broken line represents (in an arbitrary scale), the resolving power *versus* emission angle for a point source (the scale of ordinates depends on the width of the diaphragm slit). The full lines represent the resolving power *versus* emission angle for a disk source of the optimum diameter, for different slit widths, corresponding to different values of Λ; ($\Lambda_W = 3.26\cdot 10^{-6}$).

Differentiating (2) with respect to D (contained also in ζ) and remembering that Eqs. (6) and (6′) apply to point I, we get

$$(\partial r/\partial D)_I = (\sin\beta)/\sin\alpha,$$

and therefore

$$P = (D \sin\beta)/(\Delta r \sin\alpha). \tag{13}$$

Putting in this formula the expression of Δr given by (11), we obtain the resolving power for a point source and a diaphragm admitting rays of emission angles between $\alpha-\epsilon$ and $\alpha+\epsilon$:

$$P = 2/(\epsilon^2\Gamma). \tag{14}$$

OPTIMUM VALUE OF α FOR A POINT SOURCE

In the case of a point source of given activity, the *intensity* of the electron current actually received on the detector will be proportional to the solid angle Ω filled at the source by all rays passing through the diaphragm, which is

$$\Omega = 4\pi\epsilon \sin\alpha. \tag{15}$$

Now suppose we try different values of α and for every one adjust the slit width so as to have always the same intensity: how will the resolving power vary? To find this, we eliminate ϵ between (14) and (15) and obtain for the resolving power

$$P = (32\pi^2 \sin^2\alpha)/(\Omega^2\Gamma). \tag{16}$$

This function is shown in Fig. 3 (broken line) for an arbitrary value of Ω (i.e., in an arbitrary ordinate scale). As is seen, it has a maximum which can be found by differentiation of (16) and elimination of $\tan\alpha$ with (5). After some reductions, one obtains the following equation for $x = \tan\beta$:

$$x/(\pi - \text{arc}\tan x) = (x^4 - 2x^2 - 3)/(x^2 + 3).$$

Numerical solution gives $x = 2.104$, whence $\beta = 64°\,35'$ and $\alpha = 45°\,37'$ (for any value of Ω). With this value of α, (16) gives the following relation between the optimum resolving power and the solid angle for a point source:

$$P_0 = 31.2/\Omega^2. \tag{17}$$

The coordinates of the ring image are obtained from (6′) and (7) and are $z_I = 1.408D$, $r_I = 0.645D$. Figure 1 shows the shape of this trajectory (full line) and the position of the image. The intensity and the resolving power are independent of D, that is of the linear dimensions of the apparatus.

EFFECTS OF THE WIDTH OF THE SOURCE

In most cases it is impossible to concentrate the radioactive substance on an area so small as to be considered a point source. So we shall now suppose

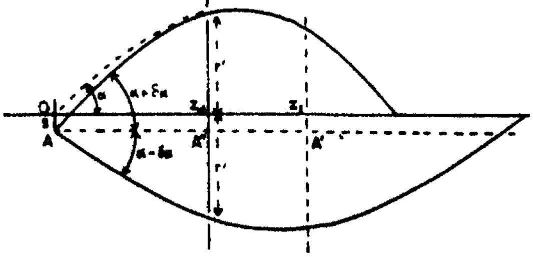

FIG. 4. Origin of "distortion."

that the source is no longer a point but a disk of radius $s=D\sigma$, perpendicular to the field, radiating isotropically, and that a practical limit is imposed not on the total quantity of radioactive substance but on its surface density. Then the intensity of the beam received by the detector will be proportional to the area of the source and to the (average) solid angle utilized, i.e., to the quantity $L=D^2\Lambda$, where

$$\Lambda=\epsilon\sigma^2\sin\alpha. \tag{18}$$

To see how the resolving power is affected by the finite diameter of the source, let us first of all study the ring image of a point A on the edge of the source, supposing the diaphragm slit infinitely narrow, that is $\epsilon=0$. To a first approximation (that is, ignoring the spherical aberration) one could consider A exactly like the point source of the preceeding theory and infer that it will give rise to a ring image centered on A', orthogonal projection of A on the image plane (Fig. 4). The image of the whole source, obtained by superposition of the ring images of all its points, would be a ring of width $2s$. But an additional blurring will be produced by an indirect effect of the spherical aberration, existing even if the slit is infinitely narrow (in which case there would be of course no *direct* effect of the spherical aberration). To see this, consider (Fig. 4) in the diaphragm plane $z=z_d$, an annular narrow slit of radius r', admitting the rays leaving the source center 0 at angle α. For a peripheral point A of the source (projected in A'') the slit is eccentrically placed: the distance of its points from A'' range from $r'-s$ to $r'+s$ and therefore the emission angle of the rays admitted will range from $\alpha-\delta\alpha$ to $\alpha+\delta\alpha$, where $\delta\alpha$ is given (neglecting second order terms) by

$$(\partial r/\partial\alpha)_{z=z_d}\delta\alpha=s. \tag{19}$$

Owing to spherical aberration, the rays emitted in different meridian planes will then meet the image plane at different distances from A', and the ring image of A will no longer be circular but will be flattened into an oval: we shall call this effect "distortion."[*] The superposition of the distorted ring images of all points of the source will give rise to a circular ring of width approximately given by (11), where ϵ is replaced by $\delta\alpha$.

If the slit has a finite width, so as to admit rays, from the source center, of emission angles $\alpha\pm\epsilon$, it will admit, from the source edge, rays of emission angles $\alpha\pm(\epsilon+\delta\alpha)$: therefore the effect of distortion may be approximately taken into account by replacing ϵ by $\epsilon+\delta\alpha$ in (11). One sees that $\delta\alpha$, and therefore the importance of distortion, depends on the position of the diaphragm: the nearer it is to the source, the greater is $\delta\alpha$. As far as distortion is concerned, it would seem advisable to put it as near the image plane as possible, but other practical reasons suggest locating it near the middle instead. We shall suppose it is put in the symmetry plane of the central trajectory (that is the plane where r is maximum). Then, from (19) and (2), one gets

$$\delta\alpha=\sigma/\cos\alpha. \tag{20}$$

Now let us consider the image of the whole source, obtained by the superposition of the distorted ring images of all its points. It will be a ring of width

$$\begin{aligned}\Delta r&=2s+(\partial^2r/\partial\alpha^2)_I(\epsilon+\delta\alpha)^2/2\\&=2s+(D/2)(\sin\beta/\sin\alpha)\Gamma(\alpha)(\epsilon+\delta\alpha)^2.\end{aligned}$$

Putting this expression in (13) we obtain for the inverse resolving power in the case of a disk source

$$1/P=2\sigma(\sin\alpha/\sin\beta)+\Gamma(\alpha)(\epsilon+\delta\alpha)^2/2. \tag{21}$$

If we neglect distortion this formula becomes

$$1/P=2\sigma(\sin\alpha/\sin\beta)+\Gamma(\alpha)\epsilon^2/2. \tag{22}$$

In the ensuing discussion we shall always begin with this formula and then estimate the corrections introduced by distortion.

OPTIMUM SOURCE DIAMETER

Suppose we vary the source diameter and also the slit width so as to get always the same intensity: how will the resolving power vary? To determine this, let us eliminate ϵ from (18) and (22):

$$1/P=2\sigma(\sin\alpha)/\sin\beta+\Lambda^2\Gamma/(2\sigma^4\sin^2\alpha). \tag{23}$$

Considering $1/P$ as a function of σ (for constant α and Λ) one finds easily, by differentiation, that it has a minimum (and therefore the resolving power a maximum) for σ given by

$$\sigma_0=\Lambda^{2/5}\Gamma^{1/5}\sin^{1/5}\beta\sin^{-3/5}\alpha, \tag{24}$$

or, if we prefer to express it in terms of ϵ, by means of (18),

$$\sigma_0=(\Gamma\epsilon^2\sin\beta)/\sin\alpha. \tag{24'}$$

This gives the optimum value of the source radius for a given α and a given intensity. Putting it in (23), we get for the resolving power

$$P=(2/5)\Lambda^{-2/5}(\Gamma\sin^2\alpha\sin^{-4}\beta)^{-1/5}. \tag{25}$$

Note that the factor 5/2 in $1/P$ comes from the addition of 2, from the first term in (23), and $\frac{1}{2}$, from the second (the expressions multiplying these factors becoming equal for $\sigma=\sigma_0$): so we can say that *the optimum source diameter is that contributing to the image width four times the width due to aberration.*

OPTIMUM EMISSION ANGLE FOR A GIVEN FIELD

Suppose we vary the emission angle α, adopting for each value of it the corresponding optimum source diameter and the slit width giving always the same intensity, that is the same Λ. Then (25) shows that the resolving power will vary proportionally to the function

---

[*] Of course this effect must not be confused with the aberration of the same name in the theory of ordinary (point) images.

$$\Gamma^{-1/5}\sin^{-2/5}\alpha\,\sin^{4/5}\beta. \tag{26}$$

This function has a maximum: it can be found by logarithmic differentiation of (26) which gives, after some transformations, the equation

$$(1+2\cos^2\alpha)\tan^4\beta+(2-\tan^2\alpha)\tan^2\beta-9\cos^{-2}\alpha=0, \tag{27}$$

which, together with (5), determines the values of α and β corresponding to the optimum. These are: $\alpha=40°\,25'$, $\beta=57°\,10'$. Inserting these values in (6′) and (7) we find the coordinates of the ring image of the source center: $z_I=1.63D$, $r_I=0.544D$. The corresponding resolving power (optimum for a given Λ and a given D) is

$$P_0=0.308\Lambda^{-2/5}. \tag{28}$$

The source radius is given by (24): $\sigma_0=1.69\Lambda^{2/5}=0.52/P_0$. The latter relation can be also written

$$2s_0/D=1.04\Delta p/p, \tag{29}$$

whence the following practical rule: *when the optimum emission angle is adopted, the source diameter, expressed in terms of D, must be equal to the desired* $\Delta p/p$.

Figure 5 shows the image position and the shape of the trajectory corresponding to the emission angle 40° 25′ (full line). The large diameter of the ring image makes obviously impractical the use of a conventional front-window counter for detection, suggesting instead the use of a counter with lateral windows covering almost the whole circumference, as is shown in the figure,** or some other device.

ECONOMICAL OPTIMUM

The optimum conditions we have discussed till now are those for a given value of D (and therefore of the field intensity H). If, in a disk-source spectrometer, we increase D, that is, increase all the linear dimensions of the apparatus in the same ratio, the resolving power will remain constant while the intensity will increase as the square of this ratio (owing to the increase in the source area). However it must not be forgotten that the background of spurious counts of the G-M counter increases with its surface: so the ratio between the intensity and the background will be almost independent of D, and the advantage of a bigger apparatus will be chiefly that of getting the same number of counts in a shorter time (which is important especially with short-lived isotopes).

A practical limit to the dimensions of the apparatus is given of course by economical considerations. If these, more than the signal-background ratio, are taken into account, the problem of the optimum must be put in a slightly different manner.

Calling l the solenoid length, R its average radius, t the thickness of the winding, the quantity of copper (for a given insulator-copper section ratio) is approximately proportional to the quantity $Q=tRl$, and the electric power needed to produce the field intensity H turns out to be approximately proportional to H^2Rl/t, that is to the quantity $w=Rl/(tD^2)$. The space in which field uniformity is required is that between source and image slit, that is, a cylinder of radius $r_{\max}=D\sin(\alpha+\epsilon)$ and length $z_I=(\pi-\beta)D\cos\alpha$. To insure uniformity in this space the solenoid must be given a supplementary length, proportional to its radius, which can be taken as three times the latter, if small supplementary windings are used to correct the field.[3] Then we can take, approximately (neglecting ϵ)

$$R=D\sin\alpha,\quad l=D(\pi-\beta)\cos\alpha+3\,D\sin\alpha,$$

and therefore

$$Q=tD^2y(\alpha),\quad w=y(\alpha)/t,$$

where

$$y(\alpha)=[(\pi-\beta)\cos\alpha+3\sin\alpha]\sin\alpha.$$

Now the problem is to find such values of t, D, σ, ϵ, α, that the whole set of four functions $-Q$, $-w$, L, P of these five variables is "simultaneously optimum," by which we mean that for any small variation of the variables one at least of the four functions decreases. This problem is equivalent to that of finding the maximum of P subject to the condition that Q, w, L (instead of D, Λ) have constant values, and can be solved in the routine way.

One finds that the optimum source radius is still σ_0 given by (24) or (24′), producing an image width four times that due to the aberration. With this value of σ the resolving power, as a function of α, is

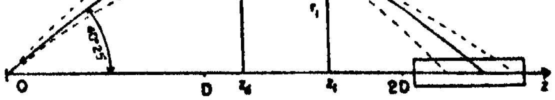

FIG. 5. Shape of trajectory and image position for the optimum emission angle with a disk source of the optimum diameter.

** In this figure we have put the two edges of the image slit in the same plane. As Stanley Frankel, Phys. Rev. 73, 804 (1948) has suggested, it is advantageous to put the inner one a little nearer the source and the outer one a little farther. This improves the "shape" of the resolution curve, but does not affect its total width. Besides, Frankel's reasoning holds only if the first limiting diaphragm is very near the source.

[3] G. Hall, unpublished.

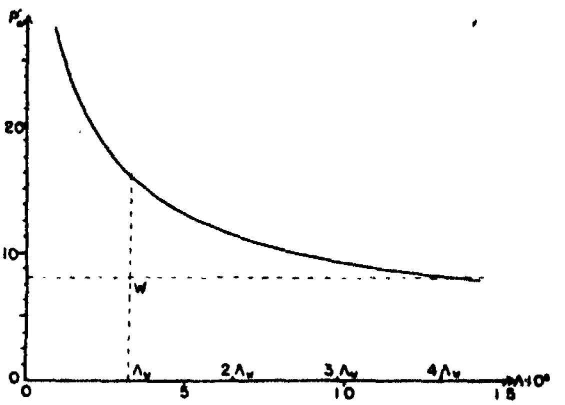

FIG. 6. Resolving power *versus* intensity in the optimum conditions for a given magnetic field.

given (neglecting distortion) by

$$P=(2/5)(Qw/L)^{2/5}(\Gamma\sin^2\alpha\sin^{-4}\beta)^{-1/5}y^{-4/5}.$$

This function has a maximum, which by numerical calculation results about at $\alpha=25°$: this is therefore the most economical angle when distortion is negligible.

With this value of α, formulas (6′) and (7) give, for the coordinates of the ring image: $z_I=2.39D$, $r_I=0.206D$. The optimum source radius and the corresponding resolving power are

$$\sigma_0=1.85\Lambda^{2/5},\quad P_0=0.225\Lambda^{-2/5}, \tag{31}$$

so that, instead of (29), we have

$$2s_0/D=0.83\Delta p/p.$$

EFFECTS OF "DISTORTION"

In the preceding calculations we have disregarded the effect we have called "distortion": so the formulas we have obtained for the disk source are valid only as a limiting case for very small slit width. We shall now take this effect into account and find the corrections for finite slit width. To this end we must start with (21) instead of (22): using (18) and (20), this formula gives (if we call P' the resolving power corrected for distortion)

$$1/P'=2\sigma(\sin\alpha/\sin\beta)+(1+\sigma^3\Lambda^{-1}\tan\alpha)^2\Lambda^2\Gamma/(2\sigma^4\sin^2\alpha). \tag{32}$$

Differentiating with respect to σ and equating to zero we get the optimum value of σ, corrected for "distortion."

$$\sigma_0'=\sigma_0(1+\varphi/2-\varphi^2/2)^{1/5}, \tag{33}$$

where σ_0 is defined by (24), and φ by

$$\varphi=\sigma_0'^3\Lambda^{-1}\tan\alpha. \tag{34}$$

This correction to the source radius is of no practical importance: with ordinary conditions it may amount to a few units percent. Of considerable importance however is the effect of distortion on the resolving power. If, neglecting the difference between σ_0 and σ_0', we replace σ in (32) by σ_0 given by (24), we get

$$P'=P[1+(2/5)\varphi_0+(1/5)\varphi_0^2]^{-1}, \tag{35}$$

where $\varphi_0=\sigma_0^3\Lambda^{-1}\tan\alpha$. The resolving power is therefore reduced by an amount depending on Λ. Figure 3 shows its dependence on α (supposing D fixed) for different values of Λ (expressed as multiples of $\Lambda_W=3.26\cdot10^{-6}$, which is the value of Λ in Whitcher's apparatus). One sees that the optimum is shifted to about 36° for the whole represented range of Λ, and the maximum resolving power ranges from 20.9 for $\Lambda=0.5\Lambda_W$ to 9.43 for $\Lambda=3\Lambda_W$.

These results are better represented by Fig. 6, showing the corrected resolving power *versus* Λ (and therefore *versus* the intensity), assuming a fixed D and for each Λ the optimum α and σ. Point W represents Λ and P for Witcher's spectrometer ($\alpha=18°$): one can see that there is the theoretical possibility of doubling the resolving power while keeping the same intensity, or of quadrupling the intensity for the same resolving power.

If the corrections for "distortion" are applied to the determination of the most economical conditions, one finds similar results. For instance, for $\Lambda=\Lambda_W$ the most economical angle is shifted to about 21°, the corresponding resolving power is $P_0'=12.7$.

The author is glad to express his sincere appreciation for the valuable help given him by Professor G. Hall, who proposed this problem, made part of the calculations and contributed many useful discussions. Thanks are also due to Professor L. Kerwin for revising the manuscript.

THE REVIEW OF SCIENTIFIC INSTRUMENTS VOLUME 20, NUMBER 3 MARCH, 1949

A Simplified Chronotron-Type Timing Circuit

J. Warren Keuffel*
California Institute of Technology, Pasadena, California

(Received November 8, 1948)

A timing circuit is described similar in principle to the Neddermeyer "chronotron," but with the following simplifications and modifications: parallel-wire polythene-tape line to eliminate co-ax "plumbing," germanium crystal detectors, and a delay-line presentation circuit. This circuit uses a single common amplifier for all pulses, which increases stability, makes adjustment easy, and effects a tenfold saving in the number of tubes. It simultaneously records time intervals in two ranges, e.g., 0–0.1 and 0–5 μsec. The precision is 1×10^{-9} sec., but may be increased at the expense of the range. Problems connected with coupling the instrument to parallel-plate counters are discussed.

I. INTRODUCTION

THE timing circuit to be described below was developed in conjunction with the parallel-plate counters discussed in the preceding paper. An instrument having a precision of the order of 10^{-9} sec. is required if the full potentialities of the new counters for the measurement of ultra-short time intervals are to be realized.

Now the pulse from a parallel-plate counter is easily adequate for direct deflection of the plates of a cathode-ray tube, but the problems of providing a precision time base and of recording the measurements photographically are formidable ones. A very elegant timing circuit, the chronotron, has been described by Neddermeyer and co-workers;[1] this instrument uses as a "time base" the precisely known motion of electromagnetic pulses on transmission lines and permits easy photographic recording. In the form developed by these authors, however, it is quite cumbersome, with over 100 tubes, and rather difficult to adjust and maintain. Both these difficulties have been overcome in the present design, and it is believed that the performance has been improved in some respects.

The basic principle of the chronotron is as follows. Two pulses whose time difference we wish to determine are applied, one to each end of a transmission line. They travel towards each other, and their point of intersection is ascertained by a suitable array of detectors distributed along the line. If the pulses are applied simultaneously to the ends of the line, they will evidently meet in the middle, while if one pulse is delayed with respect to the other, the meeting point will be shifted towards the side of the later pulse. The time interval between the two pulses is given by $2x/c$, where x is the distance from the center of the line to the point of intersection and c is the velocity of propagation of the pulses on the line.

In order that the detector array may indicate the point of intersection, a detector must respond differently to two pulses which traverse it simultaneously and two pulses which pass at different times. If the detector responds like a peak voltmeter, for example, then the pulses produce twice the output from the detector located at their meeting point than they produce from detectors some distance away from this point.

A plot of the detector outputs against the detector positions along the line is called a *superposition locus*, and the position of the peak of this curve gives, of course, the meeting point of the pulses.

If the number of detectors is limited, the detector spacing determines both the range of the instrument and its precision; close spacing gives a high precision but a limited range of measurable intervals. The pulse width must, of course, be chosen somewhat greater than the detector spacing for any particular setup.

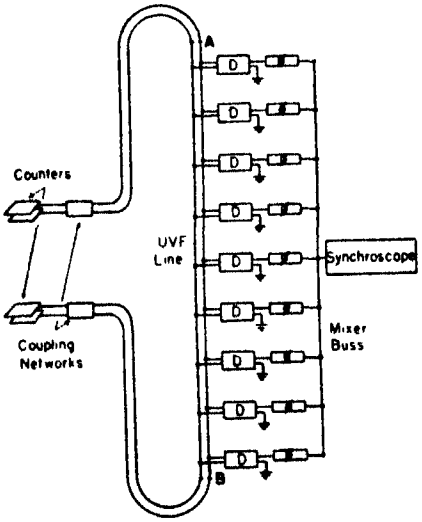

FIG. 1. Chronotron timing circuit. The array of detectors D determines the point of intersection of the pulses from the counters along the UVF line. Video pulses from the detectors are "sorted out" by the delay lines ϕ, so that they appear in order on the synchroscope screen.

---

* Now at Princeton University, Princeton, New Jersey. This paper is based on part of the work done for the doctoral thesis at the California Institute.

[1] S. H. Neddermeyer, E. J. Althaus, W. Allison, and E. R. Schatz, Rev. Sci. Inst. 18, 488 (1947).

A block diagram of the present instrument is shown in Fig. 1. The detectors produce video pulses proportional in amplitude to the detector outputs, *but which are very much broader than the original pulses on the line and are not used as direct carriers of time information to the synchroscope.*** These pulses are sorted out by a series of delay lines, each slightly longer than the next, and present upon the trace of a synchroscope the *superposition locus* corresponding to the event being recorded.

To facilitate the discussion of the instrument, it is convenient to introduce the term "ultra video-frequency" (*UVF*) to describe wide-band circuits for the range of approximately 50 to 1000 mc/sec. and pulses of the order of 5×10^{-9} sec. in duration. Some such terminology is necessary to distinguish between the pulses produced by the detectors, which are in the usual video range, and the actual *UVF* pulses on the timing line.

Before proceeding to a detailed discussion, it might be well to mention a possible generalization of the instrument to the study of arbitrary fast wave forms. If a gate pulse which is short compared to the wave form of interest, but higher than the peak of that wave form, is sent down the timing line in one direction and the wave form of interest sent in the opposite direction, the superposition locus will trace out the wave form of interest. (The detectors may be biased to respond only to voltages greater than the gate pulse.)

Finally, it should be pointed out that the presentation system described in Part V offers possibilities for recording any multiple set of data which may be translated into video pulses.

II. THE *UVF* LINE

The use of an open parallel-wire line is very tempting indeed from the standpoint of ease of construction and manipulation, especially now that there is on the market a flexible parallel-wire line embedded in polythene tape.*** The radiation from the line has not proved serious; the chief difficulty has been found to be with the unbalanced currents.

A characteristic impedance of 300 ohms is a reasonable compromise between the following two desiderata: (a) the capacitors coupling the counter to the line should be small, to minimize the energy which flows in the spark; hence the characteristic impedance of the line should be *large* to preserve a suitable coupling *RC* time constant; (b) the detector impedance being more or less fixed by crystal characteristics and stray capacitances, the characteristic impedance of the line should be *small* for low loading of the line by the detectors.

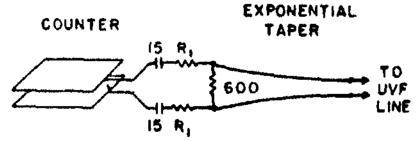

FIG. 2. Coupling network. The step-function wave form from the parallel-plate counter is differentiated to form an ultra-short pulse on the *UVF* line of the chronotron.

A 300-ohm parallel-wire line was therefore adopted. The section along which the detectors are mounted is an air dielectric line, made of No. 14 copper wire spaced 3/8″ center to center. Connections are made with the flexible polythene tape, as are also fixed delay sections which may be introduced to shift the detector section about with respect to the midpoint. In this connection it should be noted that, although the velocity of light on the polythene tape line is slower by about ten percent than in air, the velocity is independent of frequency, and hence the line is non-dispersive, provided only that the dielectric constant of the polythene is independent of frequency over the *UVF* band.

Even if this condition is not strictly true, the velocity is very insensitive to changes in the dielectric constant since so little of the space about the line is filled with dielectric, and because the square root of the dielectric constant enters the equation.

Finally, it may be remarked that no difficulty has been encountered with reflections on the line from supports and from soldered joints between sections of line. Coupling between adjacent sections of line has likewise not been troublesome; a spacing of a few inches has been easily adequate.

III. COUNTER-TO-LINE COUPLING

The present instrument is designed to work with the parallel-plate counters described in the preceding paper. The counters are coupled to the *UVF* line through small capacitors (10 to 15 $\mu\mu f$) for two reasons: (a) the effective capacitance in shunt with a counter must be kept low to minimize the charge, and hence the total energy, which flows through the counter per discharge; (b) the step-function wave form of the counter proper must be converted to a short pulse. Since the line looks like a pure resistance if it is either matched or long compared to the pulse length,**** we have here the usual differentiating circuit which will give us just the wave form desired, if the time constant is properly chosen.

The coupling network is shown in Fig. 2. The exponential taper section† converts the 300-ohm

---

** We shall point out later how they may *also* be so used for the measurement of time intervals in the 0.3- to 5-μsec. range.

*** Amphenol "Twin Lead" designed for television and f-m lead-ins.

**** There may, of course, be reflected pulses in the case of the unterminated line, but the pulse which starts down the line is still the same as in the terminated case.

† See, for example, F. E. Terman, *Radio Engineer's Handbook* (McGraw-Hill Book Company, Inc., New York, 1943), p. 196.

line to a 600-ohm impedance; it was made by splitting the last 30 cm of the polythene tape line and supporting the wires on appropriate Lucite spacers.

The coupling network also matches the counter impedance to the line, so that pulses travelling back along the line towards the counter are absorbed. The elimination of unwanted reflected pulses in the timing circuit is, of course, essential. The coupling network shown here was tested for reflections by connecting the counter and coupling network directly to the end of the timing line. A pulse from another counter was then sent down the line towards the network to be tested, and the superposition locus of the incident pulse plus its reflections, if any, was observed. It was found that the reflected pulse was less than 1/10 the amplitude of the incident pulse and of the opposite polarity. It was also found that the resistors R_1 could be left out without seriously impairing the line-to-counter match. They may be given any value up to a few hundred ohms if a longer *RC* constant is desired.

So far, the performance of ordinary midget resistors in the *UVF* band has been consistent with the assumption that they look like approximately their nominal resistance in parallel with 0.5 $\mu\mu$f.

IV. DETECTORS

Figure 3 shows the circuit diagram of a detector, together with the video pulse-forming network. A small fraction of the voltage pulse appearing on the *UVF* line at the location shown is impressed across the crystal and C_2 by means of the voltage divider R_3R_4. If the pulse is positive, the capacitor C_2 then charges up to the peak voltage across R_4—provided that the time constant involved is less than the duration of the *UVF* pulse. In the case of a negative pulse, the backwards resistance of the crystal is so great (150,000 ohms for the 1N34) that negligible current flows.

The charge on C_2 now flows off, relatively slowly, through *L* and R_5; since these elements, together with C_2, form a resonant circuit which is approximately critically damped, the wave form appearing at the grid of the 6AK5 cathode follower is a sort of half-sinusoid with an exponential tail. The output of the detector is thus a video pulse of width about 0.3 μsec. whose amplitude is proportional to the peak voltage which appeared on C_2. These pulses are then fed into the presentation circuit, which will be discussed in the next section.

To avoid confusion, note that the sole function of these video pulses is to carry to the synchroscope one particular set of data—the peak voltages at the several detectors. They do not directly carry time information to the trace of the cathode-ray tube.

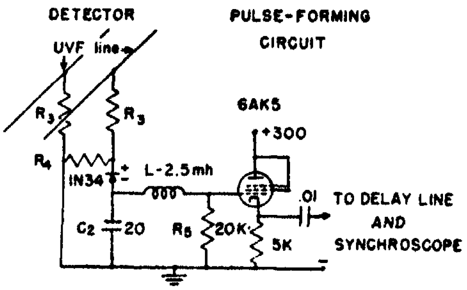

FIG. 3. Detector and pulse-forming circuit. The output is a pulse whose amplitude is proportional to the charge placed on C_2 by the detector.

The detector cannot be coupled directly to the 300-ohm *UVF* line, since the impedance of the crystal is too low and the line loading too great. At the same time, the charging time constant of C_2 must be kept low. A voltage divider of some sort is therefore required. The resistive coupling which was adopted has the advantage that the dispersion of the pulse produced by the presence of the detectors is to the first approximation zero.

The loading effects of detectors on the line have been calculated, and we may summarize the results as follows. With the resistive detector shown in Fig. 3, the attenuation is 0.30 db per detector over the central portion of the *UVF* band and the frequency at which the attenuation caused by stray shunt capacitance in the midget resistors is equal to the attenuation produced by the pure resistance alone is about 1500 mc/sec. Since it is voltage and not power which is our primary concern, it is thus possible to use about 20 detectors for a maximum voltage ratio from one end of the detector line to the other of two-to-one.

It is not essential that a detector operate strictly as a peak voltmeter, but only that it should discriminate between two pulses arriving at different times and two pulses arriving simultaneously. If the crystal is operated along a portion of its characteristic which follows approximately a square law, such discrimination is provided. However, the crystal characteristics are not exactly identical, and may change with use; these disadvantages are minimized if the charging time constant is made so small that the detector behaves as a peak voltmeter. In practice, a value of 300 ohms for R_4 has been found to give a satisfactory compromise between the demands of a short charging time and a large output voltage, even though this resistance, plus the estimated 100-ohm forward resistance of the crystal, gives a time constant of 8×10^{-9} sec. It is to be noted that C_2 may not be reduced, in order to reduce this time-constant, below 10 $\mu\mu$f or so, because the charge stored on it would then leak off through the backward resistance of the crystal rather than through the pulse-forming network.

V. PRESENTATION CIRCUIT

By "presentation circuit" we shall mean the circuit which takes the information contained in the series of charges stored on the detector condensers and transforms them into laboratory data—for example, pulses on a synchroscope screen. There are, no doubt, many ways to do this; the present system is quite simple and, in addition, has the major advantage that all the pulses pass through the same amplifier. The shape of the superposition locus therefore depends only on passive, relatively stable circuit elements and cathode followers.

As already mentioned in the preceding section, the charge stored on a particular detector condenser (C_2 in Fig. 3) flows off through L and R_5, forming a rounded pulse roughly 0.3 μsec. wide at the grid of the 6AK5 cathode follower. The pulses from the pulse-forming circuits are next passed through delay lines (ϕ in Figs. 1 and 4) whose function is to sort them out so that they appear in order upon the trace of the synchroscope. These delay lines are of the continuously loaded coaxial-line type,†† with a characteristic impedance of 1000 ohms and a delay of 0.6 μsec./foot.

Since the attenuation of this delay line is about 2.5 db per μsec., the shortest pulse which may be passed without serious dispersion should be used if many pulses are to be sorted out by this method. The 0.3-μsec. pulses used suffer but very little dispersion in traversing a 5-μsec. delay line. The attenuation introduced by the longer lines is compensated by a potentiometer in the output of each line. This system is now functioning satisfactorily with ten detectors, using 0.3-μsec. pulses spaced 0.5 μsec. center to center.

The unidirectional mixer circuit (Fig. 4) is of considerable importance. It functions as follows: consider a pulse coming from one of the delay lines, and further, suppose that the amplitude of this pulse is larger than any of the voltages at the other potentiometer outputs at this instant. Only the crystal at the output of the line we are considering will conduct, provided that the response of the cathode-follower grid circuit is fast enough. The pulse emerging from this line therefore sees an impedance which is approximately the 1000-ohm resistance of the output trimmer potentiometer; this match is adequate to prevent troubles from reflected pulses. Furthermore, the voltage at the cathode-follower grid is the voltage of the pulse of interest only; the voltages at the other outputs produce no flow of current in the grid resistor since the other crystals are nonconducting. The delay line whose output voltage is, at any given instant, the highest thus dominates the others.

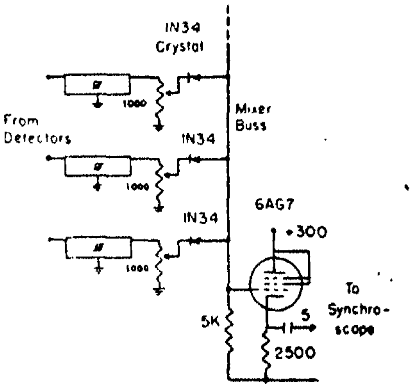

FIG. 4. Presentation circuit. The time delays of the video delay lines ϕ differ by 0.5 μsec. increments, so that signals applied almost simultaneously from the detectors appear in sequence on the synchroscope trace.

TABLE I. Chronotron tests. Polarities of pulses are reckoned with respect to detectors on line. In (a), (b), and (c), two simultaneous pulses are produced by dividing the signal from a single counter at a junction.

Test	Connection to *UVF* line at *A*	Connection to *UVF* line at *B*	Superposition locus
(a)	Pos. pulse	Pos. pulse	Max. at center
(b)	Pos. pulse	Neg. pulse	Null at center
(c)	Neg. pulse	Pos. pulse	Null at center
(d)	Pos. pulse	Terminated in Z_0	No max. or min.
(e)	Neg. pulse	Terminated in Z_0	Locus everywhere zero
(*f*)	Pos. pulse	Open end	Max. at *B*
(g)	Neg. pulse	Open end	Locus zero
(h)	Pos. pulse	Shorted end	Dip at *B*
(i)	Neg. pulse	Shorted end	Dip at *B*
(j)	Pos. pulse	15 additional ft. of line, shorted at the end	Flat (as (d))

This has a twofold effect: first, the "tails" of neighboring pulses do not contribute underneath the dominating pulse, making possible the small pulse separation cited above; second, the video lines can all be connected to the cathode-follower grid without the large voltage losses which a linear matching network would entail.

The output of the final cathode follower is fed directly to the 70-ohm input of a synchroscope††† whose amplifier has a gain of several thousand and a rise time of 0.1 μsec. The 3BP1 cathode-ray tube of this synchroscope was replaced by a 3FP7 tube, with 5000 volts on the post-deflection accelerator electrode. The superposition loci were recorded photographically. With the f:4.5 lens which was available, it was necessary to reduce the 10-pulse picture to about 2×5 mm on the film to obtain sufficient intensity; the present photographic image, viewed through a small magnifier, was large enough to determine with ease which pulse of the superposition locus was highest. It was not dense enough, however, to make reproduction possible here.

---

†† Now manufactured by James Millen Manufacturing Company, Malden, Massachusetts.

††† U. S. Navy type "LZ" oscilloscope.

VI. PERFORMANCE

The instrument was set up for tests as follows. One end (*A* in Fig. 1) of the *UVF* line was connected to a parallel-plate counter, while the other end (*B*) was terminated in a 300-ohm resistor. The synchroscope sweep was triggered by the counter pulses. The detector outputs were then roughly equalized by means of the potentiometers at the delay-line outputs. The final adjustment was made by alternately reversing the direction of travel of the pulse on the line, and leveling the video pulses on the synchroscope screen as well as possible considering the attenuation the *UVF* pulse suffers in traveling past the detectors. For these tests, the pulses were about 5 feet long, and the detector spacings 2 feet.

The qualitative tests described in Table I were then made. These tests confirm in every case the behavior of the superposition locus to be expected for pulses about 5×10^{-9} sec. in duration.

In accord with the predictions of electromagnetic theory, there is for the electric vector a reflection with polarity inversion at a shorted line, a reflection without inversion at an open ended line, and no reflection at a line terminated in its characteristic impedance. Maxima and minima appear in the superposition locus only where two pulses, or a pulse and its reflection, meet.

In addition, a quantitative test was made by using the arrangement in (a), Table I, but inserting several different lengths of Twin-Lead in either side. The displacement of the superposition locus as a function of the length of lead added to one side is shown in Fig. 5. (At the time the test was made there were five detectors spaced two feet apart.) The velocity of propagation of the Twin-Lead as measured by the slope of this graph is 0.90c, while from measurements of the resonant frequency of a length of Twin-Lead it is 0.87c.

These checks, together with the general consistency of the results of the preceding paper on the counter reaction times, provide a very satisfactory verification of the chronotron performance. As regards stability, it has not been found necessary to change the trimmer settings over a period of a couple of weeks. In any case, it is a very simple matter to take an occasional calibration picture as a routine check while taking data.

The over-all precision of the instrument is evidently a function of the detector spacing; precise measurements call for close spacing, with the width of the *UVF* pulses being measured made correspondingly short. For some applications it will be necessary to sacrifice some precision to obtain a wide range of measurable intervals. The possible number of detectors will be limited by the detector loading, and it may be necessary to go to special platinized glass resistors to get away from the shunt capacitance of the midget resistors now used. The precision of the present instrument, with detectors spaced two feet apart, is about 1×10^{-9} sec.; its range (with 10 detectors) is 40×10^{-9} sec. Better photographic and oscilloscopic equipment should make it possible to improve the precision for the same range, or to get a range of, say, 0.1 μsec. with a precision of 1×10^{-9} sec. Work is continuing along these lines in connection with meson decay experiments.

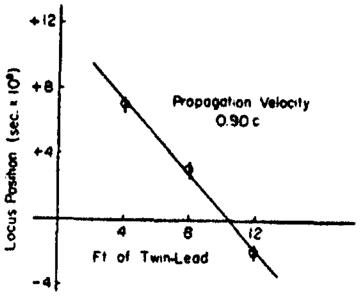

FIG. 5. Test of chronotron. Fixed delay sections of polythene tape line were inserted in one side of the timing line and the shift in the locus position observed. There was a fixed 10-foot delay line in the other side of the loop.

A pulse from a single counter was divided at a 3-way junction to supply a precisely simultaneous pair of pulses.

VII. TIME MEASUREMENTS IN THE MICROSECOND RANGE

It is interesting to inquire as to the appearance of the synchroscope picture if two pulses appear on the line separated by a time interval of the order of several μsec., rather than an interval short compared with the video pulses formed by the detectors. Evidently the pattern to be expected will consist of two flat superposition loci, the one displaced several μsec. with respect to the other, and this shift can thus be used to measure such an interval, without any changes in the instrument or its adjustment. No experimental verification of this effect has yet been carried out, but there appears to be no reason why the chronotron cannot be simultaneously used as a dual-range instrument in this manner. This rather fortuitous circumstance is expected to aid greatly in the study of meson decay, which is now being undertaken and where this instrument and parallel-plate counters are used.

Parallel-Plate Counters

J. WARREN KEUFFEL*
California Institute of Technology, Pasadena, California

(Received November 8, 1948)

The counter characteristics of a discharge tube using plane-parallel electrodes have been investigated, particularly with regard to the short time lags inherent in the streamer type of spark which occur with such a geometry at near-atmospheric pressure. Construction details for parallel-plate counters with good counter characteristics are given. Spurious counts were minimized by an argon-xylene filling mixture and the use of a univibrator quench circuit. The uncertainty in the reaction time of the counters is $\pm 5\times 10^{-9}$ sec.

I. INTRODUCTION

THERE has been considerable interest lately in the measurement of very short time intervals between ionizing events. This problem arises, for example, in studying the various mesotron decay phenomena and the gamma-decay of metastable states of nuclei. Until now, time measurements have been limited by the variable lags of the conventional Geiger-Müller tube, which introduces an uncertainty of about 0.1 µsec.[1, 2]

It has been known for some time, thanks to the work of White,[3] Wilson,[4] and Newman,[5] that the time lag of breakdown of overvolted plane-parallel spark gaps is exceedingly short, and indeed Wilson found at 100 percent overvoltage lags of the order of a few times 10^{-9} sec., with no apparent lower limit as the overvoltage was increased. The short lags of the streamer-type spark are due primarily to the important role played by photo-ionization,[6] but even apart from the spark lag studies one would expect from elementary considerations a shorter lag with the plane-parallel geometry—where the field strength is everywhere sufficient to propagate a Townsend electron avalanche—than with the cylindrical shape, where the initiating electrons must first drift into the strong field near the wire.

Here, then, was a prospective fast mechanism. Could a parallel-plate spark gap be made to trigger if and only if an external agent produced an electron within the active volume? In the answer to this question, it was realized, lay the key to the problem. A preliminary investigation of the origins of ions within the active volume was undertaken, and it turns out that one has to deal with after-effects of previous discharges similar, if not identical, to the spurious counts observed in conventional cylindrical counters. These after-effects are very poorly understood, but it has been possible, nevertheless, to minimize them to the point where the spurious counting rate is but a small fraction of the true counting rate, for a considerable range of overvoltages, and thus produce a workable parallel-plate counter. Although the feasibility of using the fast streamer spark mechanism as a counter has been demonstrated, many questions have yet to be answered. It seems worth while, however, to report the work which has been accomplished so far.

Parenthetically, it should be noted that the parallel-plate counters are "fast" only in the sense of a very short reaction time. They are not capable of high counting rates because of the large quench time (0.01 to 0.05 sec.) which has so far been necessary, although there is some hope of improvement along these lines.

A timing circuit which permits the measurement of time intervals commensurate with the fast reaction time of the parallel-plate counters is described in a companion paper which follows this one.

II. DESCRIPTION OF PARALLEL-PLATE COUNTERS

A. Counter Characteristics

In this section we discuss the characteristics of parallel-plate counters other than the reaction time, which is reserved for Part V.

An external electronic quench circuit (see Part IV) is necessary with a parallel-plate counter for two reasons. First, unlike the cylindrical G-M tube, the space-charge geometry is not such that the discharge is self-quenching. Second, the intensity of after-effect or spurious activity is such that a "cooling off" period has been found necessary. Evidently this "cooling off" time or quench time, T_Q, is a parameter which must be specified when discussing a counter operated with such a circuit; in what follows, it has the value 0.05 sec. unless otherwise stated.

The first experimental counter consisted of molybdenum disks spaced 3.0 mm and 3.1 cm^2 in area. The counters to be discussed in this paper are rectangular sheets of copper or copper-plated steel spaced 2.5 mm and 35 cm^2 in area; the early counter and the present counters differ significantly only in the higher background rate of the larger counters (approximately a factor of 11 as would be expected from the areas). The filling used in the present counters is 6 mm of xylene plus argon to give a total pressure of ½ atmos.

[6] L. B. Loeb, *Fundamental Processes of Electrical Discharge in Gases* (John Wiley and Sons, Inc., New York, 1939), p. 426.

A typical plateau for such a counter is shown in Fig. 1. With careful preparation, this plateau was consistently reproducible.

If we assume that only one electron is required to initiate a discharge, the calculated efficiency of the counter filled with the above argon-xylene mixture for a singly charged fast particle passing normal to the plates is about 98 percent. The validity of the above assumption depends on the distance of the single electron from the anode and on the overvoltage, according to the streamer theory of Loeb and Meek, and the efficiency is therefore expected to increase with overvoltage.

A rough experimental check on the efficiency may be made by comparing the coincidence rates obtained in the course of the uncertainty time measurements (see Fig. 7) with the rates calculated from the known cosmic-ray intensity in the basement of the laboratory. The rates agree within the rather large uncertainties of the method (say ±25 percent) but, since the coincidence rate is very sensitive to counter inefficiency, the efficiency must be of the order of 90 percent for overvoltages of 500 or more.

Although the coincidence rate increases with overvoltage, a part of this increase probably results from edge effects. No very definite conclusions may be inferred until further experiments have been made.

In a recent note, Madansky and Pidd[7] report efficiencies of 10 percent for parallel-plate counters. The overvoltages they used, however, were considerably lower than 500, and this explains the discrepancy.

The counters tested to date have exhibited a useful lifetime of one or two months of background-rate counting, at overvoltages of 500 to 1000 and a quench time of 0.05 sec. The usefulness of the counter ends invariably with the occurrence of "spot bursts," localized bursts of spurious counts from one or two points on the cathode. Most counters may then be washed, re-baked and re-filled to produce a counter good for another month or two.

The quench time has been held at 0.05 second largely because the longer quench time is thought to prolong the lifetime. Most counters may be run at quench times of a millisecond or less for short periods with no apparent harm, but at present little is known about the effect of quench time, overvoltage, external circuit capacitance, and counting rate on the useful lifetime.

Finally, two more characteristics of parallel-plate counters should be mentioned. First, the discharge is localized in a fine, plainly visible streamer channel presumably in the neighborhood of the initiating ion. This has obvious possibilities as a means of determining the path of a particle, and it also makes the study of the spurious count phenomena considerably easier. Second, the amplitude of the pulse from a parallel-plate counter is several hundred volts; unlike the cylindrical counter, which is a constant-charge device, the voltage swing is substantially independent of the external circuit capacitance. The latter should be kept small, however, to minimize the energy which flows in the spark and hence the intensity of after-affects. The voltage swing is large even just above the counting threshold, because the streamer persists until the voltage has fallen well below this value.

B. Construction

A counter construction which has been used for experimental work is illustrated in Fig. 2. The ground joint makes it possible to take the tube apart without glass blowing. This joint is sealed with beeswax and rosin. It is located about 4″ below the electrode structure so that the important parts of the tube may be outgassed and the electrodes baked at 500 degrees C, while the ground joint, which projects from the oven, is maintained at room temperature with the aid of a blower.

Two profiles have been used, the one a rounded 45-degree bevel, the other flat with edges rounded by emery paper. These are illustrated in Fig. 2. No significant difference in performance between the two has been noted, but the beveled-edge construction with copper-plated steel as the material is far better mechanically and can be made flat to within perhaps 2 mils if bent around a form in a brake. The precision with which the plates must be held parallel depends on the precision desired for time measurements. We shall discuss this in Part V.

The electrodes have in all cases been polished with successively finer grades of emery cloth, ending up with crocus cloth. Just before final assembly they

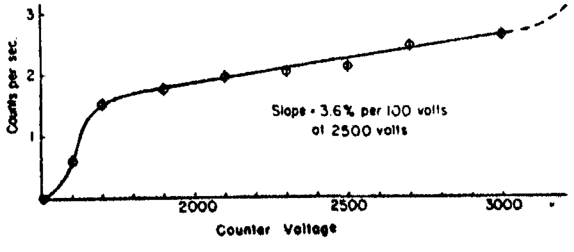

FIG. 1. Typical plateau for a counter filled with argon and xylene. Quench time: 0.05 sec.

[7] L. Madansky and R. W. Pidd, Phys. Rev. 73, 1215 (1948); also a discussion with these authors.

are thoroughly swabbed with xylene, and after the tube has been assembled, rinsed with xylene, alcohol, distilled water, and alcohol. The tube is next evacuated to a high vacuum and baked at 500 degrees C for two hours; in the case of the copper electrodes, hydrogen is admitted for 10 min. or so at this temperature to reduce off oxides. The tube is again evacuated to 10^{-5} mm or better, cooled, and filled. Successful results have been obtained only when the xylene has been admitted first, followed by the argon; indeed, the best counters have resulted when the argon rushing into the tube has actually condensed droplets of xylene on the envelope, so that the tube has contained saturated xylene vapor. (The threshold then becomes slightly temperature dependent, but with the parallel-plate counter operated far above threshold, the change is not important in a normal laboratory room.) The importance of admitting xylene first is possibly due to the formation of a layer of xylene on the cathode.

III. THE AFTER-EFFECT

As a first step in studying the parallel-plate counter, an external quench circuit (see Section IV) was constructed which permitted the device to be studied under conditions which would otherwise lead to a continuous discharge. The counter, initially charged only to a small clearing potential, is rapidly charged to the full potential and isolated. A discharge then occurs when an electron appears in the active volume. At a known time T_Q following the discharge, the counter is recharged, and so on. The quench time, T_Q, is adjustable from milliseconds to minutes.

The presence of spurious counts is indicated if the mean interval (as measured, say, with an integrating circuit) between the charging of the plates and the subsequent discharge is much shorter than is to be expected on the basis of the natural background radiation. In an extreme case, the counter counts just as rapidly as the quench circuit will permit.

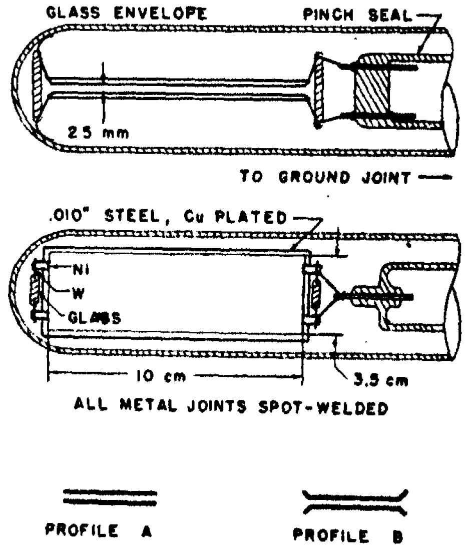

FIG. 2. Schematic drawing of the experimental parallel-plate counters.

Using this circuit, the following conclusions were reached: (a) all counters so far studied need a quench time of at least 0.01 to 0.05 sec. but (b) if a counter is "bad," the spurious activity has a persistence so long (of the order of minutes) that to circumvent it by increasing the quench time is impractical. The use of a quench time of the order of 0.01 second is thus a necessary, but not a sufficient, condition.

The length of the plateau is not very sensitive to the quench time, although the situation was complicated by the fact that the leads to the electrodes began to count at voltages in the vicinity of the upper end of the plateaus of "good" counters. (The end of the plateau is almost by definition the voltage at which the aftereffect begins to mask the true counting rate.)

Another requirement for the suppression of the aftereffect seems to be the use of a small percentage of organic vapor in the tube. Counters filled with pure argon or pure air exhibited no plateau at all even at the longest quench times, although a somewhat critical mixture of 3.4 mm air and ½ atmos. argon did produce a workable counter; the plateau slope was about 10 percent per 100 volts, about three times the slope for a typical argon-xylene counter.

Now it is well known that the addition of one of the so-called "self-quenching" vapors to the conventional G-M counter enables it to be used with a low value of external resistance in a "fast" circuit. The vapor is believed to have two effects. First, it suppresses the production of photoelectrons at the cathode by absorbing ultraviolet photons. Second, it greatly reduces the production of secondary electrons by positive ion bombardment. With a parallel-plate counter operated at a quench time of 0.05 second, however, neither of these effects enter the picture: we wish to point out that in this case, at least, the primary function of the vapor is the suppression of the after-effect.

In addition to the use of a quench circuit and the admixture of organic vapor, a third factor of importance in suppressing the aftereffect is the preparation of the electrodes; successful results have been obtained only when the baking and hydrogen treatment outlined in Section II has been followed.

The plateau slope for an argon-xylene counter, constructed according to the foregoing section, is invariably about 4 percent per 100 volts. To investigate the origin of the plateau slope, plateaus were taken at two widely different quench times. It was found that the slope changed from 4.4 percent at a 0.05-sec. quench time to 2.9 percent at 3.4-sec. quench time. The plateaus were, of course, measured by plotting the reciprocal of the mean interval between the charging of the plates and the subsequent discharge, since the longer quench time was very much longer than the mean interval between natural background counts.

Some, at least, of the plateau slope is therefore to be attributed to the aftereffect. The remainder is due to an increase in the efficiency with overvoltage, a fringing of the field at the edges of the plates, or some other unknown cause.

While a carefully prepared argon-xylene counter is substantially free of aftereffect, it eventually deteriorates. The usefulness of the counter ends invariably with the occurrence of "spot-bursts;" spurious counts are observed to originate from one or more very definite spots on the cathode, the counts occurring in bursts which are easily distinguishable from the normal background counts which are scattered in a random fashion over the surfaces of the plates. At first these bursts choke themselves off, presumably when, by chance, genuine counts occurring elsewhere in the counter give the spot a chance to "cool off." Once such a spot starts, it gets worse and bursts occur more and more frequently. Although lengthening the quench time helps somewhat, as does reducing the overvoltage, in all cases the spot eventually develops until even at the longest quench times the counter counts at the spot almost as fast as the quench circuit recharges the electrodes. The spot may be remedied only by rebaking and refilling, and in the worst cases the counter must be taken apart and the spot swabbed with xylene.

Because of their localization, the spot bursts must be connected with the state of the electrodes. It is not merely a matter of the formation of a sharp point, as the spots do not alter the threshold nor do the sparks favor the spots at low voltages. Indeed, until the spot is very bad the counter operates stably at lower voltages.

In Section II we have mentioned the importance of admitting the xylene first, followed by the argon. The other order of filling, despite ample time for diffusion, exhibited invariably a very bad aftereffect and, in addition, the threshold voltage and visual appearance of the sparks were markedly different, being very similar to the characteristics of pure argon counters.

This effect and the spot bursts are consistent with the suggestion of Professor H. V. Neher that surface films on the cathode and anode play an important role in determining the characteristics of a counter. According to this picture, the aftereffect is suppressed by a film of xylene on the electrodes. A spot burst occurs when the film is locally altered or destroyed in some manner.

An alternative picture would be to suppose that the ultraviolet absorption of the vapor is chiefly responsible for the suppression of the aftereffect, while the spot bursts are caused by an accumulation of material deposited on the electrodes by the action of the sparks. While this picture is inconsistent with the behavior of counters filled with argon and xylene in that order, we feel that more information is needed before a definite conclusion may be reached.

As to the actual mechanism of the spurious counts, one can only say that the evidence points towards the Paetow effect.[8, 9] Submicroscopic bits of insulating materials such as dust or oxides are charged up by photons or positive ion bombardment from the sparks. High fields are formed because of the extremely small size of the particles, and delayed electrons or photons are produced either by breakdown of the insulating matter, field emission, or some other process.

IV. QUENCH CIRCUIT AND AUXILIARY ELECTRONICS

A. Quench Circuit

The quench circuit used with the parallel-plate counters is shown in Fig. 3.

The very fast negative-going pulse from the positive counter plate triggers the univibrator T_1T_2, which in turn causes T_3 to conduct for the duration T_Q of the univibrator swing. When the univibrator flops back, the counter is rapidly recharged and the circuit is ready for another count. The counter is very loosely coupled to the univibrator in order that very little of the charge stored in the stray capacitances of the circuit may flow through the counter during the breakdown, which occurs very much faster than the univibrator swing.

None of the circuit parameters is very critical, nor is the adjustment of the bias on T_1 particularly ticklish since a pulse of several hundred volts is supplied by the counter.

Some factors which influenced the design of the circuit are low current drain on the counter high voltage supply, wide range of quench times, good response to random pulses, and a recharging time short compared with the mean interval between counts (to avoid longer lags due to discharges occurring before the counter reaches the full potential). The use of a receiving-type tube at T_3 has given no trouble, despite the fact that the rated plate voltage is exceeded by a very large factor; the plate dissipation is, of course, kept very low. It is important that T_3 be a sharp cut-off pentode.

B. Auxiliary Electronics

Figure 4 shows how two counters may be connected simultaneously to a common quench circuit

---

[8] H. Paetow, Zeits. f. Physik 111, 770 (1939).

[9] Reference 6, p. 498.

as well as to an auxiliary coincidence circuit without appreciably disturbing the initial *UVF* pulse** which each counter sends down the timing line. The time constants are such that a counter is "left alone," so to speak, until the *UVF* pulse is over; the large series coupling resistors also minimize the charge which flows through a counter and hence the energy in the spark, as a result of external circuit capacitance.

Both counters are connected to the same quench circuit for three reasons: it eliminates the need for another quench circuit, it minimizes relative lags due to different voltages on the counters, and it increases the coincidence rate in the case where the quench time is of the same order of magnitude or larger than the mean interval between background counts.

The voltages V_{C1}, V_{C2} clear the tube of residual ions during the quench periods and compensate for individual variations in counter thresholds; they must not, however, be more negative than -600 volts for complete quenching.

The 1N34 crystal diodes form a simple coincidence circuit of the type discussed by Howland *et al.*[10] The large voltage swing of the parallel-plate counter makes it possible to use a resistance-capacitance divider instead of the conventional amplifier required to drive the circuit with cylindrical counters. The coincidence output is coupled to succeeding circuits through a cathode follower since stray capacitances *must* be kept small at this point. The resolving time of the circuit is around 1 to 2 μsec.

Originally, the resistance-capacitance divider had a 2-μμf capacitor across the 10,000-ohm midget resistor, but the stray shunt capacitance alone is adequate to drive the coincidence circuit.

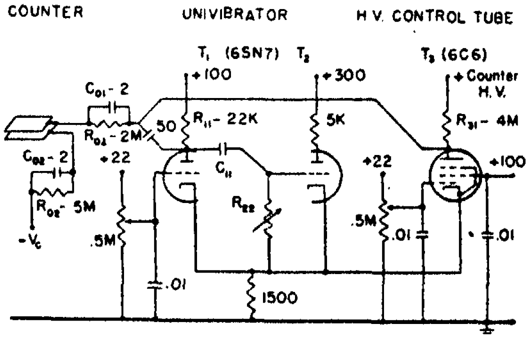

FIG. 3. Quench circuit. Capacitances are in μμf except for the three 0.01-μf bypass condensers; resistances are in ohms, with $K=10^3$, $M=10^6$. For a quench time of 0.05 sec., R_{22} is $20M$, C_{11} is 0.002 μf. V_c is a "clearing field" of about 500 volts.

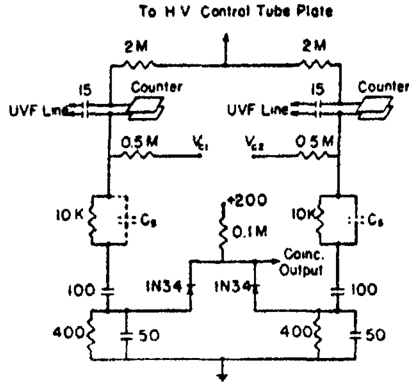

FIG. 4. Two counters coupled to a single quench circuit and to a simple coincidence circuit. Large resistances isolate the counters from these circuits during the initial fast transients, which are sent down the *UVF* timing line. C_s is the stray capacitance of the 10*K* resistors (about 0.5 μμf).

V. THE REACTION TIME

A. Experimental Arrangement

In order to ascertain the precision with which a time interval between two ionizing events may be measured, one needs to know the uncertainty in the reaction time of the parallel-plate counters. The reaction time itself—the time between the appearance of an ionizing event in the counter and the maximum of the short electromagnetic pulse sent down the timing line—is fortunately of less interest, since it would be much more difficult, if not impossible, to measure.

The reaction time uncertainty was measured as follows: two argon-xylene counters of the type described in Part II were placed directly one above the other with their plates horizontal. The auxiliary coincidence circuit described in Part IV selected those events where a particle from the cosmic radiation passed through both counters; because of the proximity of the two counters and the speed of a particle capable of penetrating the counter envelopes and plates, it could be assumed that the counters were tripped simultaneously. As a result, however, of the uncertainty in the time lag between the initiating event in a counter and the electromagnetic pulse which it sends to the timing line, the pulses will enter the timing line not simultaneously but separated by a small time interval ΔT.

A distribution curve of the relative lags ΔT then gives a measure of the uncertainty in the reaction time.

The resolving time of the auxiliary coincidence circuit in the above measurement was about 1 to 2 μsec. This is large enough so that we may safely assume no true coincidences will be missed, yet small enough so that the rate of accidental coincidences is only a few per day.

The timing circuit (similar in principle to the Neddermeyer "chronotron"), used for the very short

---

** In this paper and in the companion paper describing the timing circuit, the term "ultra-video-frequency" (*UVF*) will be used to describe pulses of the order of 5×10^{-9} sec. in duration.

[10] B. Howland, C. A. Schroeder, and J. D. Shipman, Jr., Rev. Sci. Inst. 18, 551 (1947).

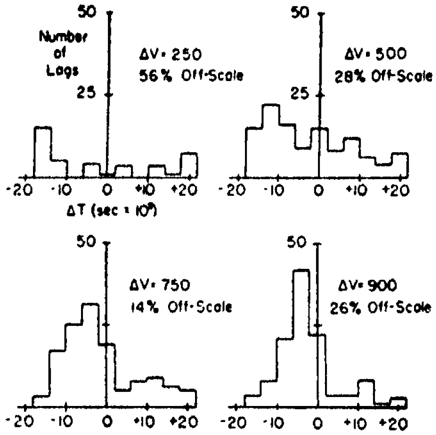

FIG. 5. Distribution of relative lags between two counters tripped simultaneously by a cosmic-ray particle. A relative lag is "off scale" if it lies outside the chronotron range, -20×10^{-9} to $+16\times10^{-9}$ sec. Distributions are given for four different overvoltages, ΔV.

time measurements, is described in a companion paper. The instrumental error is approximately 1×10^{-9} sec., using ten detectors spaced two feet apart; the range is from -16×10^{-9} to $+20\times10^{-9}$ sec. Cases where the coincidence circuit records a coincidence but the chronotron shows no peak in the superposition locus are recorded as "off scale" lags, that is, lags which lie outside of the above range. The superposition loci are recorded by photographing the synchroscope screen.

From the appearance of the superposition locus it is always possible to tell whether two pulses have passed (whether or not they intersect in the measurable range) and thus check the operation of the coincidence circuit. The width of the superposition locus peaks gives a measure of the rise time of the slowest of the two pulses which met, but this rise time tells us very little, of course, about the reaction time itself; it may be some time between the formation of the initiating ion pair and the first observable voltage surge.

B. Results

In Fig. 5 we present distribution curves of the relative lags between two parallel-plate counters. The ordinates of these histograms represent the number of lags occurring in a range 4×10^{-9} sec. wide in approximately 18 minutes of counting; the total number of coincidences is not the same for each graph, however, as will be noted from the variation in coincidence rate shown in Fig. 7.

If we define the uncertainty $\langle\Delta T\rangle$ to be such that one-half the lags (including those off scale) fall within $\pm\langle\Delta T\rangle$ of the center of the distribution curve and plot this uncertainty against overvoltage, the curve in Fig. 6 is obtained. We see that the uncertainty varies from 17×10^{-9} sec. at an overvoltage of 250 to about 5×10^{-9} at 900 volts.

Pulse rise times as measured from the width of the superposition loci at half-maximum range from 8×10^{-9} sec. at the lower overvoltage to 3×10^{-9} sec. at an overvoltage of 900. As mentioned before, these figures represent little more than a lower limit on the absolute reaction time.

C. Discussion of Results

In Fig. 5 we notice that the centers of the lag distributions fall to one side of the zero point. This means that the average lag of one counter is slightly greater than that of the other. Recent results with counters of better mechanical tolerances show that this effect may be greatly reduced; any remaining effect may be corrected by a calibration of the counters.

Also from Fig. 5 we note that the percentage of "off scale" lags decreases as the overvoltage is raised up to approximately 750 volts, after which the percentage increases by a significant amount. This trend is borne out by measurements made using visual observation of the synchroscope at overvoltages up to 1250. However, at the higher overvoltages the superposition loci exhibit sharper peaks with subsidiary maxima and the counters tend to deteriorate rapidly. For these reasons, the behavior of the counters and timing system at overvoltages greater than 1000 require further study before quantitative data may be presented.

Because the percentage of long lags increases at the highest overvoltages, while at the same time the peaks of distribution curves narrow markedly, it seems likely that we are dealing here with at least two effects, which we will, for convenience, refer to as short lags and long lags.

The long lags are probably connected with sparks occurring in the weaker fringing fields at the edge of the plates. To estimate the magnitude of this effect, we note that the effective area of a counter 1.5 in. ×4 in., spaced 0.1 in., increases by about 18 percent if we suppose the field to fringe out a distance equal to the spacing. Bearing in mind that a lag results if *either* counter is triggered in the edge region, this figure must be doubled. The magnitude of the effect is of the right order. In support of this interpretation

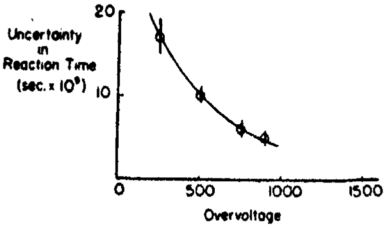

FIG. 6. Uncertainty in the reaction time, $\langle\Delta T\rangle$, as a function of overvoltage. Half the relative lags of two counters tripped simultaneously fall between $\pm\langle\Delta T\rangle$ of the center of the distribution. Data from Fig. 5.

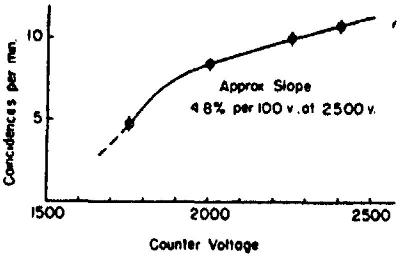

FIG. 7. Coincidence rate *vs*. voltage for two counters, one 6 cm directly above the other, with their plates horizontal.

are the following: (a) the *increase* in percentage of long lags at high overvoltages; (b) the increase as shown in Fig. 7 of the coincidence rate with voltage; (c) an increase in the number of sparks visually observed to go at the edges at the higher overvoltages.

Since the superposition locus has no peak if only one pulse passes down the line, such an occurrence would be recorded as an "off scale" reading. Such cases are fortunately easily recognizable by the fact that, if only one pulse passes down the line, attenuation along the line gives the pattern a tilt one way or the other which is balanced out in the two-pulse case, and it was thus possible to reject this explanation of the long lags with certainty.

Since the reaction time is a function of the field strength at the point where the streamer occurs, non-uniformity of the plate spacing will introduce an uncertainty in the reaction time. The variations from point to point in the spacing of the present counters may be as large as 5 percent. To estimate the importance of uniform spacing, the field strength on one counter was varied by varying the voltage, while the other counter voltage was held constant, and the shift in the position of the maximum in the lag distribution curve was observed. A shift of about 1×10^{-9} sec. was produced by a one percent change in total voltage in the vicinity of 900 volts overvoltage. We conclude from this that the shorter lags are at least in part caused by non-uniformity of the plate separation.

Until further, more detailed investigations have been carried out, it is not possible to state how much of the uncertainty observed in this experiment is due to edge effects and non-parallelism and how much to the ultimate statistical fluctuations in the streamer build-up.

Improvements in the geometry of the counters should virtually eliminate lags due to the former cause, while the lags due to the latter may be minimized in two ways: one may, by further work on the spurious count problem, produce a counter which may be operated at still higher overvoltages, and one may use greater spacings or higher pressure, thus smoothing out the scatter resulting from statistical variations in the number of ion-pairs formed by the initiating event.

ACKNOWLEDGMENTS

The author is deeply grateful to Professor H. V. Neher for advice and guidance. Acknowledgment is also due Professor C. D. Anderson for encouragement during the early stages of the work, Professor L. B. Loeb for a very stimulating discussion, and Betty H. Keuffel for her help in preparing the figures.

(Received May 28, 1948)

A single lens convergent light apparatus is described with which diffusion in liquids may be studied by an interference method. Details of the optical elements and their mounting and alignment are given as well as the design of a temperature control regulating near 0°C to within 0.01°C. A modified Polson sharpening technique has been used successfully in forming diffusion boundaries in a Tiselius cell. A modification of the Rayleigh interferometer has been employed as an aid in the measurement of the refractive index increment parameter, j_m, which is required for the evaluation of the diffusion coefficient. During diffusion a reference slit image obtained by the employment of special cell and plate masks permits more accurate measurements of the undeviated slit image position than have been obtained from the interference diffusion fringe picture. Results indicate that the apparatus is capable of 0.1 percent precision.

INTRODUCTION

WHEN monochromatic light from a horizontal slit is brought to a focus by a lens system, and a column of liquid containing a diffusing boundary is placed in the optical path, an interference phenomenon is produced in the focal plane below the undeviated slit image. The description and qualitative explanation of this phenomenon were published by G. L. Gouy in 1880.[1] In recent companion papers, the theoretical basis for converting the interference fringe spacing into an interpretation of the diffusion phenomenon,[2] and the verification and practical utilization of this theory for evaluating diffusion experiments[3] have been reported. In addition, Longsworth[3] has described innovations in equipment and technique which were employed in experimental studies of diffusion with this method.

It is the purpose of this paper to present features of equipment design and methodology developed and employed in this Laboratory during the past year for diffusion studies with the interference method.

APPARATUS DESIGN AND CONSTRUCTION[4]

The study of Longsworth[3] has shown that a high quality single lens convergent light apparatus such as the horizontal slit source and schlieren lens of his electrophoresis schlieren scanning apparatus[5, 6] together with a photographic plate replacing the schlieren diaphragm in the plane of the slit image, constitutes a precise optical system for the photographic observation of the diffusion interference fringes. For the present studies the equipment has been arranged as shown schematically in Fig. 1. The framework supporting the bath and optical parts of the system consists of two parallel 5×8 inch I beams bolted on top of three concrete pillars of about 2000 pounds each. To insulate the system from vibration, mats of Keldur[7] of proper area to bring the dead load up to that specified by the manufacturer are placed between these pillars and the floor. The bath stirrer and refrigeration coil are mounted separately on a stand bolted to the floor. As a result of the use of a condensing lens for the illumination of the slit source, heating of the slit mechanism is reduced, and filters can be mounted

on the lamp side of the slit rather than in the optical system proper. The apparatus makes use of a single 170-cm focal length, 6.3-cm clear aperture, air-spaced compound lens[8] corrected for mercury green and yellow lines, and designed to project at full aperture a sharp image of the slit source on the optic axis, at unit magnification. While the use of this long focal length lens results in lower light intensity at the photographic plate than when using the optical equipment of the conventional electrophoresis apparatus,[6] the greater optical lever arm so obtained gives proportionally greater fringe displacements below the undeviated slit image. This allows observation of the diffusion for a longer time than is feasible with a lens of shorter focal length.

The windows[8] for the water bath thermostat are borosilicate crown glass, 10 cm in diameter and 1.5 cm thick, with surfaces flat to one-half wave and parallel to within 30 seconds of arc. Since the water bath is operated near 0°C to minimize refractive index and reduce density fluctuations with changes in temperature, enclosed dry gas spaces[6] adjacent to each bath window are employed to prevent condensation of moisture on the optical elements. Dry nitrogen is passed through those spaces as needed by means of the tubes shown in Figs. 2 and 3. In addition, certain new mounting features render the optical system independent of the water bath position, provide for maximum rigidity of the optical elements, and at the same time afford flexibility of adjustment. Details of the mounting are shown diagrammatically in Fig. 2 and photographically in Fig. 3. The water bath itself is insulated with Foamglas,[9] and all joints and spaces around this insulation are filled with asphalt roofing cement. Along the optical channel, the insulation is further sealed from the atmosphere and the water in the bath by means of hard rubber flanges and pipe[10] fastened to both walls of the bath. Window 6, Fig. 2, or the lens in its cell, is mounted in a bronze collar 5 and fastened to the main bronze tube 3 with alternate pressure and tension screws, so as to make tilting adjustments possible in all directions. Connections between the optical assembly and the water bath are made only through two large synthetic rubber diaphragms of $\frac{1}{16}$-inch Fairprene,[11] which serve to seal the assembly while providing for independence of the bath position. To permit tilting of the entire assembly and adjustment of the inner window, the bronze tube 3 is held firmly in a cast iron bracket, Fig. 3, mounted to channel iron across the supporting I beams with pressure and tension bolts. Further adjustment is possible by rotation of the channel about a vertical axis. Focusing and alignment of this assembly and the slit source were accomplished by alternate use of a leveled surveyor's transit and a Gauss eyepiece telescope. In final adjustment the flat side of the compound lens is parallel with all window faces within about 30 seconds of arc and the normals to these surfaces are horizontal within the same limit of error. No appreciable distortion of the windows resulting from making them water-tight has been detected

from Gauss eyepiece reflections, which appear the same whether the bath is empty or filled with water. Without lateral or vertical movement, or rotation, the leveled transit could be focused alternately on the slit source and on the slit image projected when the lens was screwed into place, thus precisely defining the optic axis. In order that the photographic plate could be aligned perpendicular to the optic axis within about 20 minutes of arc, the telescoping camera tube (outside diameter, 4 in.), to which the plateholder adapter and shutter were fixed, was mounted in a cast iron bracket similar to that shown in Fig. 3. The camera tube was focused carefully by eye to bring the emulsion side of the photographic plate to the focal plane of the lens.

Prior to assembly the window thicknesses were measured with micrometer calipers. Their refractive indices were obtained by focusing the microscope of a Gaertner slide comparator on a fine line scratched on a metal plate, and refocusing to obtain the apparent change in position of the line after interposing the windows of known thickness. For measuring the distances between the various optical elements, special inside calipers were constructed of long brass rods with collars at intervals, threaded into rods of larger diameter, with lock nuts for setting. These could be measured after each setting with a 24-inch vernier caliper. The optical distance **b**, from the center of the diffusion cell to the photographic plate, thus mechanically measured, was calculated to be 306.45±0.02 cm in vacuum, assuming the bath and cell to be filled with water at 0.5°C.

In order to obtain diffusion measurements accurate to 0.1 percent, it is necessary to regulate the temperature of the diffusion column to 0.025°C. The method successfully employed to maintain the water bath temperature constant is illustrated diagrammatically in Fig. 4.[12] The mercury thermoregulator (*T*) which is placed close to the cooling coil (*CC*) controls through a relay (*R*) the solenoid (*SV*) in the suction line. On closing, the solenoid instantaneously stops all refrigeration of the bath. The surge tank (*ST*) is then exhausted by the compressor unit (*C*) until the unit pressure control switch shuts off the compressor motor. When the thermoregulator reopens the solenoid, a rapid surge of refrigerant into the tank provides adequate cooling in 10 to 15 seconds, with better than 0.01°C control of the entire bath, and no icing of the coil even below 0.4°C.

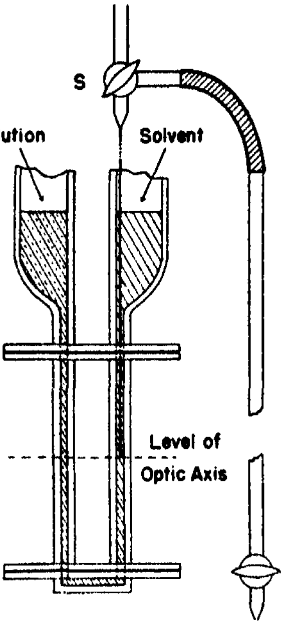

FIG. 5. Capillary siphon for boundary sharpening.

TECHNIQUE OF MEASUREMENTS

The diffusion measurements have been performed with a long center section Tiselius cell[13-15] whose top section is extended with tubes reaching above the bath water. However, the disturbance[8] of the boundary during shifting from behind the opaque horizontal plates where it is formed has been rectified by a slight modification of the boundary sharpening technique due to Polson.[16-18] In

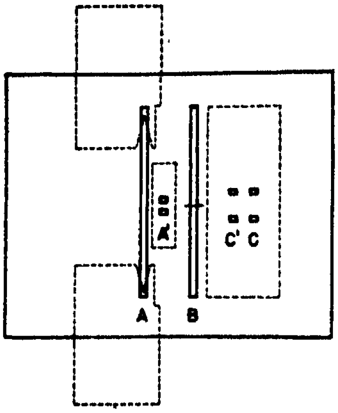

FIG. 6. Diffusion cell mask.

filling the cell, Fig. 5, the bottom section, both channels of the center section, and the left arm of the top section are filled with solution. The right arm of the top section is filled to the same level with solvent, or less concentrated solution. For equilibration to bath temperature, the top section is aligned with the bottom section, and the center channels remain isolated by displacement to one side. Immediately after sliding the center section to the position shown in Fig. 5, a capillary of about 0.5 mm outside diameter, connected to a siphon through a stopcock, is lowered by rack and pinion[18] until the tip is within 0.5 mm of the optic axis, Fig. 5. To locate the optic axis conveniently for positioning the capillary tip, a fine wire is incorporated into the cell mask, as shown in slot *B*, Fig. 6.

Incorporation of the double slits in sections *C* and *C'* into the sliding section of the cell mask, Fig. 6, makes it possible to use the optical system as a Rayleigh interferometer[19] to aid in the evaluation of the refractive index increment of the dissolved solute. If the slits in section *C* are separated by a vertical distance of about 1 cm, the sharpened boundary may be centered between them so that the original solution is in front of the lower slit and and solvent is in front of the upper one, and Rayleigh fringes of a convenient breadth (0.167 mm) may be photographed at the camera plate. The theory for the diffusion interference phenomenon[2] shows that the number $\mathbf{j}_m$[2] of waves retardation by the solution as compared with the solvent is given to the next larger integer by the inequality $\mathbf{j}_m \leqslant \mathbf{N}$, where $\mathbf{N}$ is the number of bright fringes wholly or partly resolved from the undeviated slit image in the diffusion interference pattern. This choice of the integral part of $\mathbf{j}_m$, i.e., $\mathbf{N}-1$, is confirmed below and elsewhere[2,20] by diffusion data for a single homogeneous solute. For this case the same value of the diffusion coefficient is obtained from each fringe of a given photograph as predicted by theory[2] when calculations are based on the correct value of $\mathbf{j}_m$. Use of the wrong integer for $\mathbf{j}_m$ results in values which drift markedly with increasing fringe number. The additional fraction comprising $\mathbf{j}_m$ may be obtained by observing the fractional downward displacement of the Rayleigh interference fringes within the central diffraction zone when solvent replaces the solution in front of the upper slit.[21] In use, section *C*, Fig. 6, is aligned with the cell while light from *C'* passes through the adjacent water bath to provide a reference. With the Tiselius cell in its open position, and the sliding mask moved to align section *C* with the cell, it is possible to cover either *C* or *C'* by rotating a long vane, supported by a heavy vertical wire fastened to the cell holder frame.

To prevent superposition of successive fringe system photographs from sections *C* and *C'*, the mask shown in Fig. 7 is used in front of the photographic plate. Part "a," Fig. 7, was made to fit snugly into the slot in front of the photographic plate. This part was constructed of three sheets of metal firmly fastened together with small screws after the middle sheet was cut as indicated by the dotted line. The thin metal slide, "b," Fig. 7, could be lowered inside "a" through the opening at position 2, and moved so that any one of the levels *A*, *B*, or *C* was located in opening 1. Opening 1 was cut at the level of the undeviated slit image. There is sufficient friction between parts "a" and "b" to hold the slide wherever it is set.

With the cell filled and the capillary adjusted as shown in Fig. 5, section *C* of the cell mask, Fig. 6, is aligned with the right channel of the cell, slot *B* of the slide "b," Fig. 7, is adjusted at the opening 1 in the plate mask "a," and the vane turned to close off light coming through section *C'* and the water bath. The plateholder dark slide is then opened and exposure is made with the manual shutter, Fig. 1. Immediately thereafter, the vane is turned to close off light coming through the cell and section *C*, slot *A* of the slide "b," Fig. 7, is aligned with the opening in the plate mask "a" without disturbing the photographic plate, and a reference photograph is taken. Slot *C* of Fig. 7 is included in the slide to make possible a reference picture both before and after the cell photograph to check periodically the over-all stability of the optical system. Typical photographs are shown in Fig. 8a. The stopcock is then opened, and siphoning commences. As this proceeds, the boundary is swept down to the capillary tip. Schlieren observation with the telescope placed behind the slit image plane, as well as direct observation of the diffusion interference fringes, indicates considerable boundary disturbance during this period. When the boundary reaches the level of the capillary tip, sharpening takes place very rapidly. To insure that gradients of concentration are swept away from the cell walls above the boundary, siphoning is continued at a rate of from 0.3 to 1.5 ml per minute for a time sufficient to replace the liquid in that region at least three times. Throughout this period successive Rayleigh fringe photographs through the cell and the water bath are made as described above. Typical photographs, showing the displacement of the fringe system on replacement of solution by solvent in the cell in front of the upper slit, appear in Fig. 8b. The evaluation of the successive photographs serves to determine whether all refractive index gradients have been swept out from above the thin opaque layer between the slits. The diffusion experiment is started by closing the three-way stopcock *S*, Fig. 5, between the capillary and siphon. The capillary is immediately withdrawn with the rack and pinion. Then the center section of the cell is closed off to prevent any possibility of condensation of atmospheric moisture into the diffusion column. With the cell in this position, the mask, Fig. 6, is moved so that the slot *A* is aligned with the right arm of the cell containing the diffusion column. The vane attached to the frame then serves to screen off either section *A* or section *A′*. During the diffusion experiment, photographs are made through the cell with slot *A*, whose upper and lower ends are made V-shaped to reduce diffraction, and are arranged so they may be opened symmetrically about the boundary as it spreads.[3] The V-shaped ends are produced by thin sheet brass plates, shown with dotted lines, which are actuated to move in vertical ways by a single vertical rod having right- and left-hand threads.

[21] The application of the Rayleigh interferometer has been made in an entirely equivalent fashion by Coulson, Cox, Ogston, and Philpot, Proc. Roy. Soc. A192, 382 (1948) in their independent development of the Gouy interference method, and their paper presents the complete theory for this application.

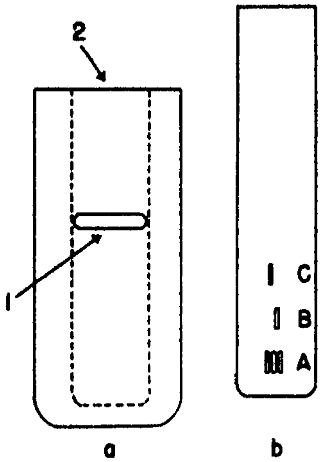

FIG. 7. Photographic plate mask for refractometer photographs. a. Slide holder. b. Slide.

The detachable plate *A′* contains two slits symmetrically located about the level of the optic axis. The purpose of the double slit in section *A′* is to provide reference photographs for each diffusion photograph so that the position of the undeviated slit image may be located. The double slit separation in *A′* is less than in *C′* so that wider openings of the source slit, required for early diffusion photographs, may be used without blurring the fringes in this reference pattern. Photographs of the diffusion interference fringes are followed immediately in each case by the reference double slit interference photograph through section *A′* and the water bath adjacent to the cell. To prevent the alternate diffusion and double slit exposures from superposing on the photographic plate, which must be absolutely stationary between these exposures, interchangeable masks, shown in Fig. 9a for diffusion and 9b for reference photographs are inserted in front of the plateholder. Satisfactory control of exposures is accomplished by the manually operated shutter.

A typical photograph showing both diffusion and double slit reference fringe systems is shown in Fig. 10. The central portion of the pattern shows successive steps taken through increasing thicknesses of gelatin filter according to the technique described by Longsworth.[8] The central maximum of the double slit pattern denoted by "Ref." determines the undeviated slit image position independently. Since this pattern is symmetrical about the center of the slit image, the position of the latter can be located accurately from the two sur-

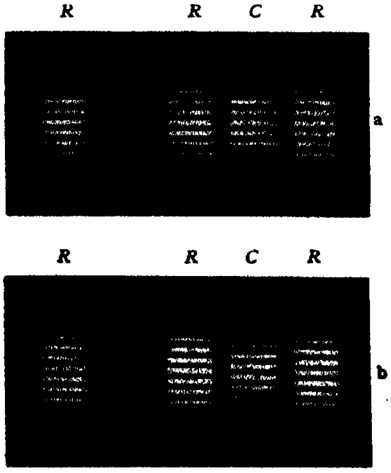

FIG. 8. Sample refractometer photographs, with reference pictures "*R*" and cell pictures "*C*." a. Capillary inserted, but before siphoning, i.e., solution is in front of both slits of *C*, Fig. 6. b. During sharpening, i.e., solvent is in front of upper slit of *C*, Fig. 6, while solution is in front of the lower slit.

rounding minima. Because the double slit pattern is obtained at all times from the same small portions of the lens near its center, this reference is not subject to the same spherical aberration errors as the slit image itself photographed through portions of the lens which approach the periphery as the diffusion proceeds. The precision depends on the stability of the optical track, but the time intervening between the reference and diffusion photographs is so short that the present equipment has in the majority of cases been found to give slit image positions self-consistent to within two or three microns.

On comparison of Rayleigh fringe photographs taken through the cell when filled with homogeneous liquid with those through the adjacent thermostat using reference *A′*, Fig. 6, a constant displacement, δ, was noted that is doubtless due to small prismatic effects in the cell and/or bath windows. This was added to the measured displacement of each fringe below the reference slit image position to give the correct downward displacement, $\mathbf{Y}_j$, of each fringe from the true undeviated slit image.

The optical quality of this combination of bath windows and cell walls was tested by successively placing other double slits with gradually increasing spacings ranging from about 3.3 to 23.3 mm behind the cell and measuring successive "δ" distances as described above. Water filled the cell during these tests, and each pair of slits was always symmetrically spaced about the level of the optic axis. The value of δ decreased slightly as the slit separations were increased, but had not changed by more than 5 microns when slit separations of 20 mm were reached. Thus the central portion of the cell and windows, from which all diffusion data are derived when the slit image position is obtained from a reference double slit beside the diffusion cell, were found to be of good quality.

TEST OF THE APPARATUS

As a demonstration of the precision attainable with the equipment and procedure described above the results of a typical experiment on the diffusion of sucrose in water are summarized in Tables I and II. In the first table the refractometric data, together with the results for a typical diffusion fringe photograph are presented. In the second column of Table I are given the observed displacements, $\mathbf{Y}_j$, from the undeviated slit image position of the fringes whose numbers, j, are indicated in the first column. The third column contains the theoretical[8] values of these displacements in normalized units while the last column gives the ratio, $\mathbf{C}_t$, of the observed and theoretical values. If the theory is valid, and if sucrose diffuses as an ideal solute, the values of $\mathbf{C}_t$ in Table I should be constant for each fringe and this is seen to be accurately true.

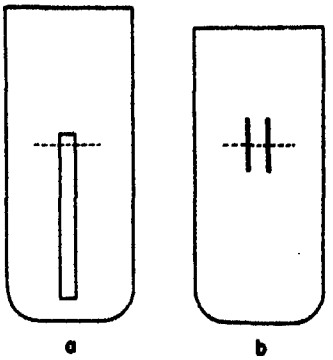

FIG. 9. Photographic plate masks for diffusion. a. Mask for diffusion pictures. b. Mask for reference pictures.

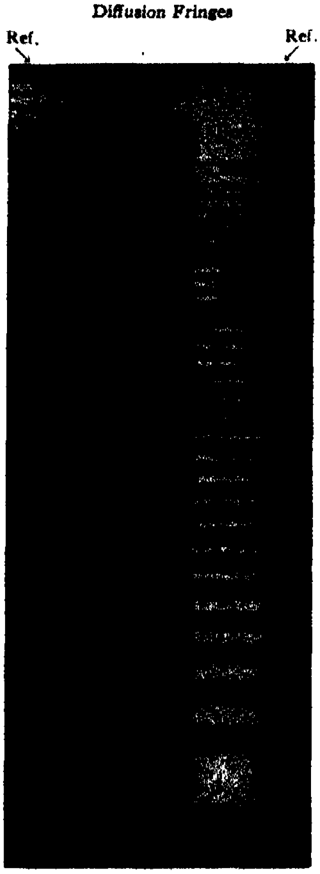

FIG. 10. Sample diffusion interference fringe system, with reference picture "Ref."

The diffusion coefficient, $\mathbf{D}'$, is given by the relation

$$\mathbf{D}' = (\mathbf{j}_m\lambda\mathbf{b})^2/(4\pi\mathbf{C}_t^2\mathbf{t})$$

in which the wave-length, λ, is 5462.2A, the optical distance, **b**, is 306.45 cm, and **t** is the time after cessation of the boundary sharpening procedure. If each of the diffusion fringe photographs is analyzed as is illustrated by Table I the results for the complete experiment may then be summarized

TABLE I. Data for one photograph of a sucrose diffusion at 1.00°C. "Solvent"—2.001_7 g per 100 ml solution. Solution—2.502_5 g per 100 ml solution. Photograph taken 30060 seconds after start of diffusion. Number of diffusion fringes in pattern $= N = 34$. Displacement of Rayleigh fringes on replacing solution by solvent in front of upper slit $= (0.41 \pm 0.01) \times$ (fringe spacing) $\therefore j_m = (N-1) + 0.41 = 33.41$. Displacement of Rayleigh fringes through cell from reference $= \delta = 0.0008$ cm.

1 j (minima)	2 Y_j (cm.)	3 $e^{-z_j^2}$ ($j_m = 33.41$)	4 $Y_j/e^{-z_j^2} = C_t$
0	0.5388	0.90402	0.5960
1	0.4966	0.83347	0.5958
2	0.4624	0.77655	0.5954
4	0.4065	0.68210	0.5960
6	0.3588	0.60240	0.5956
8	0.3168	0.53197	0.5955
10	0.2789	0.46823	0.5956
12	0.2442	0.40978	0.5959
14	0.2120	0.35566	0.5961
16	0.1819	0.30525	0.5959
18	0.1534	0.25814	0.5943
20	0.1273	0.21401	0.5948
24	0.0797	0.13392	0.5951
28	0.0382	0.06438	0.593

as shown in Table II. Here the values of **D′** in the second column show a slight downward drift with time which is due to the fact that the boundary at zero time is not infinitely sharp as required by the theory. Correction for this initial mixing is made[3] by plotting **D′** *versus* 1/**t** to obtain a zero time correction, **Δt**, that amounts to 30 seconds in the present experiment. Column 3 of Table II then gives the final value of the diffusion coefficient, **D**, after application of this zero time correction. The results indicate that the method is capable of a precision of 0.1 percent.

Laboratory and Shop Notes

Note on the Preparation of Beta-Ray Sources

LAWRENCE M. LANGER
Indiana University, Bloomington, Indiana

January 7, 1949

IN order to measure the true momentum distribution of beta-particles in a nuclear spectrometer, it is important to avoid introducing distortion because of the preparation of the source. Several problems arise in connection with the preparation of a suitable source. Although the solution to these problems is not unique, it is believed that the following suggestions may be of interest.

In order to minimize distortion of the spectrum because of scattering, it is necessary to mount the radioactive sample on an extremely thin backing of low atomic number material which is isolated at some distance from the walls of the spectrometer. Since the materials usually used for making the thin backings (Zapon, Collodion, Formvar, etc.) are usually very good insulators and since the electrical capacity of the source is small, it is found that with strong radioactive deposits the source may charge to several kilovolts, with respect to the vacuum chamber, in a rather short time. Such a charging of the source may introduce an electrostatic acceleration of the emitted particles which will affect the spectrum distribution at very low energies. It will also result in shifting the energies of beta-spectra end points and of internal conversion lines.

The charging of sources may be avoided in many ways. One can, of course, deposit, by evaporation in vacuum, a thin metallic film on the backing material which is mounted on a grounded aluminum ring. This, however, may not always be convenient and the following two techniques are simple effective ways of keeping the source at ground potential. It is found that a solution of Zapon in amyl acetate can be loaded with colloidal graphite ("Aquadag"). Films made from such a solution are much poorer insulators. Such foils, however, do not have the strength of normal Zapon and so must be sandwiched between unloaded films. Another method which may be used satisfactorily with spectrometers employing sources of large area is to stretch a fine hair across the aluminum source supporting frame. The hair is then made conducting by painting with a suspension of colloidal graphite in alcohol. The thin layers of backing are then laid down over the hair in the usual way. For a source which is several millimeters wide, the scattering from the 0.001″ hair is quite negligible.

It is sometimes necessary to prepare the source from solutions which chemically attack the usual backing materials. For this purpose, it is found that backing films can be prepared from clear LC 600[1] which when dry are resistant to acids, alkalis, or alcohol. LC 600 films may be prepared by the usual technique of spreading on a surface of clear water.[2] One drop of one part LC 600 to four parts LC 600 thinner yields a double film of about 0.006 mg/cm^2. Such films do not spread over as large an area as Zapon films, since the solvent dries much more rapidly. They are as a result not as uniform as Zapon films and therefore, when prepared by this technique, are not too suitable for Geiger counter windows.

It is found that deposits of certain chemical compositions tend to break thin backings, presumably by mechanical action, during the last stages of drying. For the preparation of such sources, it may be necessary to use two or more layers of backing in order to obtain sufficient strength. When such a stack of films is prepared wet, there is little tendency to trap air bubbles between layers. The stack should then be thoroughly dried before laying down the sample.

Samples laid down from solutions have, in general, a tendency to clump or "ball-up" while drying. As a result, such deposits may have local thicknesses much greater than that of the average. It is found that such effects are almost completely eliminated by first treating the backing material with a thin layer of insulin.[3] A drop of Lilly insulin diluted with 20 parts of water is led over the backing surface with a dropper so as to wet the area desired for the source. The excess insulin is then drained off with the dropper. When a drop of radioactive solution is now placed on the wetted area, it immediately spreads uniformly to fill the entire area. The source is then dried by evacuation, care being taken to avoid freezing.

This work was supported by a grant from the Frederick Gardner Cottrell fund of the Research Corporation and by the joint program of the ONR and AEC.

On the Design of a Radiofrequency Cockroft-Walton Accelerator

PAUL LORRAIN
Laboratory of Nuclear Studies, Cornell University, Ithaca, New York

December 13, 1948

IT seems that Cockroft-Walton accelerators (Fig. 1),[1,2] which have been used so extensively in the range of energies between a few hundred thousand and a few million electron volts, have always been operated at frequencies of the order of a few hundred cycles per second or less. However, relatively small Cockroft-Walton (henceforth written CW) generators, supplying up to 200 kilovolts and operating at frequencies of the order of 10 kilocycles per second, are now commercially available.[3,4] The numerous advantages gained by using a high frequency have long been recognized. It was thought worth while to investigate the upper frequency limit and the difficulties to be expected at high frequencies, so as to exploit these advantages to their full extent.

Let us call f the operating frequency, C the capacity of one of the condensers, v the peak-to-ground alternating voltage at the source S, and n the number of stages (one-half of the total number of condensers). Then,[2] for ideal rectifiers and for a load

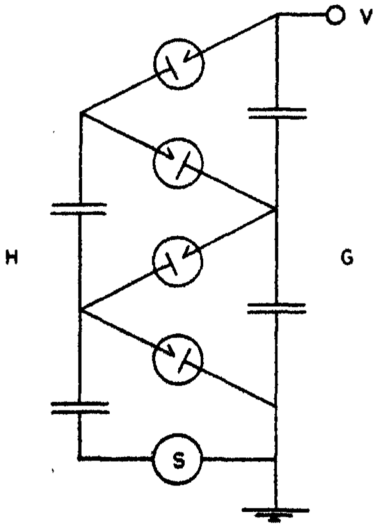

FIG. 1.

current i, the average output voltage V is given by

$$V=2nv-(i/12fC)(8n^3+9n^2+n),$$

and the ripple voltage δV at the output is

$$\delta V=\pm(i/4fC)n(n+1).$$

Practical units are used.

Obviously, the product fC should be large. Now the most economical way to do this is to use as large an f as possible, and then to choose C accordingly. The reason for this is that the cost of a condenser increases much more rapidly with capacity than does the cost of a source of alternating voltage with frequency. Other advantages of lower capacity condensers, aside from their lower cost, are their smaller weight and smaller volume. Also, for a sufficiently high frequency, the number of stages "n" could be made fairly large for a given generator internal impedance or a given ripple voltage. This means that lower voltage ratings for both the condensers and the rectifiers would be permissible. The total number of condensers and rectifiers would be increased proportionately, but their total cost would nevertheless be considerably reduced. Finally, the ripple could have a very low value to facilitate accurate energy measurements.

All this is particularly interesting in view of the fact that high voltage, low capacity "television" condensers are now available at very low prices. For example, a 30-kilovolt 0.0012-microfarad condenser which sells for about three dollars is roughly one inch long and two inches in diameter.[3]

The upper frequency limit is fixed by the electron transit time in the rectifiers. Beyond this frequency, the voltage drop in the rectifiers would increase, with a resultant increase in the internal impedance of the generator. In a two-stage model, this voltage drop was found to be approximately the same at sixty cycles per second and at radiofrequencies ranging up to 21 megacycles per second. The internal impedance was constant for any given current as long as the product fC was sufficiently large to make the second term on the right-hand side of the first equation negligible. The no-load output voltages were in the neighborhood of 1200 volts and currents up to a few milliamperes were drawn. The upper frequency limit thus appears to be above 21 megacycles per second. A rough calculation shows that it cannot be much higher. At the high r-f voltages required for an accelerator, the upper frequency limit would be somewhat lower than at the voltages used, but by less than one order of magnitude.

With small condensers and at high frequencies, stray capacities would be important. The stray capacity between column H (Fig. 1) and ground, and between the two columns, would have two effects. First, the r-f voltages on the condensers of column H would be reduced. This would lower the output voltage even at no load. Second, large r-f currents would flow in the condensers, particularly in the lower ones. These effects could be largely cancelled by using an r-f choke of the proper inductance, with a blocking condenser, in parallel with each rectifier (Fig. 2). However, these effects should preferably not be too large. Then f should not be much higher than a few megacycles and C not much smaller than 0.001 microfarad.

The rectifier filaments are thus provided with a very convenient source of power, for the chokes can be used as transformers to heat the filaments without reducing their Q value significantly (Fig. 2). Usually this power is supplied by storage batteries, or by generators run through a belt from a motor at ground potential, both methods being quite objectionable for various reasons. A two-stage model connected as in Fig. 2, with type 8016 rectifiers and 0.01-microfarad mica condensers operated satisfactorily. Some care has to be used, however, to operate the filament of this tube at the proper brightness, as suggested by the manufacturer. No attempt was made to tune the chokes so as to cancel the effects of the stray capacities, as these are important only for high r-f voltages and small condensers. The filament power can be applied independently of the high tension by opening the plate circuit of the diode nearest to ground.

The ion source could be fed from a transformer in the same manner as the filaments.

The upper limits for the voltage and for the voltage gradient attainable with this generator are comparable to those attained with the electrostatic generator. The output currents could be relatively high and there would be no moving parts.

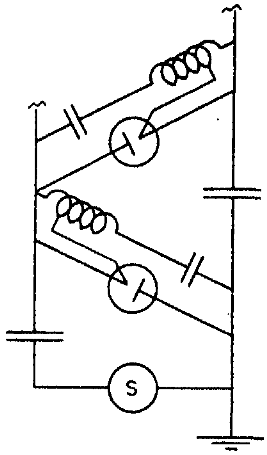

FIG. 2.

The following is a tentative design for a 500-kv generator: $f=5$ megacycles per second; $C=0.0012$ microfarad, 30 kv; $v=15{,}000$ volts; $n=17$; ripple voltage about ±50 volts for a load current of 1 milliampere; rectifier type 1B3 for currents up to 1 milliampere, or type 8013A for higher currents; total cost of condensers and rectifiers, three hundred dollars with the 1B3 and four hundred and seventy dollars with the 8013A (list prices). This is less than for a low frequency design by a factor of about 10. The whole accelerator should be submerged in oil or pressurized (this would require special rectifier tubes designed to withstand the pressure) to reduce the length of the accelerating tube and to facilitate shielding the r-f and other stray radiations.

Rejuvenation of Geiger-Mueller Tubes*

L. SHEPARD
Department of Physics and Laboratory for Nuclear Science and Engineering, Massachusetts Institute of Technology, Cambridge, Massachusetts

January 3, 1949

IT is well known[1] that Geiger-Mueller tubes filled with a self-quenching mixture of argon and ethanol deteriorate with use, and that refilling the tubes with new gas, though it may improve the operation somewhat, does not restore the original counting characteristics. We wish to report that a simple treatment has been found which, in conjunction with replacing the gas, restores the tube to its original state. This treatment consists of heating the center wire to a dull red by an electric current for about ten minutes while the tube is evacuated, preparatory to filling with new gas.

The tubes for which this treatment has been used are made from a one-inch diameter brass cylinder with a 0.005-inch tungsten central electrode, which is supported at each end by a Kovar glass seal. The assembly is such that an electrical connection can be made at each end of the central wire. In one group of 52 tubes ranging in length from ten inches to thirty inches, the plateaus extended from 900 volts to 1150 volts for each tube. After some months of use during which time about 10^8 counts occurred in each tube, the thresholds had risen to 1000 volts and the plateaus terminated at about 1050 volts. Merely changing the gas brought the thresholds back to 900 volts but the plateaus still extended only to 1050 volts. When the tubes were again evacuated and refilled after the center wire had been heated, the plateaus were the same as when the tubes were first made. Of the 52 tubes so treated, the original characteristics were not restored in only three tubes.

The heating current of about 0.5 ampere is supplied from a Variac, which is adjusted until the wire, as observed through one of the end seals, is visibly red.

A Thyratron Square Wave Generator

Leonard Reiffel*
Department of Electrical Engineering, Illinois Institute of Technology, Chicago, Illinois

November 10, 1948

The purpose of this note is to describe a simple versatile circuit for generating square wave pulses of large amplitude via a gas filled triode. Under special operating conditions, a thyratron may be used as a trigger tube for the production of approximately square voltage pulses, in discontinuous or continuous wave trains, with widely variable amplitude and symmetry characteristics. If a thyratron with plate supply voltage E_{bb} and a load resistance R_1 is fired at a time t_1, the voltage across the tube will fall rapidly from E_{bb} to E_0, the arc drop; thus a voltage step of amplitude $(E_{bb}-E_0)$ will appear across the tube. If at a time t_2, the thyratron could be made to deionize, the voltage across the tube would rise from E_0 to E_{bb}. This sequence of events would thus produce an approximately square pulse of amplitude $(E_{bb}-E_0)$ and duration (t_2-t_1). It is evident that if the thyratron were ionized (and deionized) N times per second, a square wave of frequency N would appear across the tube.

The mechanism for firing the thyratron offers no difficulty since the mere application of a grid over-voltage will serve to ionize the tube. However, deionization ordinarily can only be commenced by opening the plate circuit or by driving the plate current to zero by applying an inverse voltage across the tube. It is evident that neither of these possibilities is well suited to the production of square waves in the manner outlined.

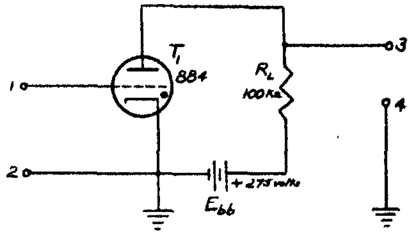

FIG. 1. Thyratron square wave generator.

Under normal operating conditions attempts to interrupt the plate circuit arc by driving the *grid* negative are unsuccessful. This is true because once the plate arc has been formed, the grid structure is immersed in a plasma which effectively shields the plate circuit from voltage variations of the grid. Any variations in grid voltage serve merely to change the thickness of an ion sheath which forms around the grid. The ion sheath thickness can be made as great as desired by raising the grid potential and/or decreasing the plate arc current.[1] If the current in the plate circuit of the thyratron (in which the arc is formed) is limited to a very low value by use of a large plate resistor and the grid is driven sufficiently negative, it is perfectly possible to get a positive ion sheath to extend across the entire discharge region in the tube. This ion sheath effectively cuts the arc in two and causes the plate current to go to zero (i.e., extinguishes the arc).[2]

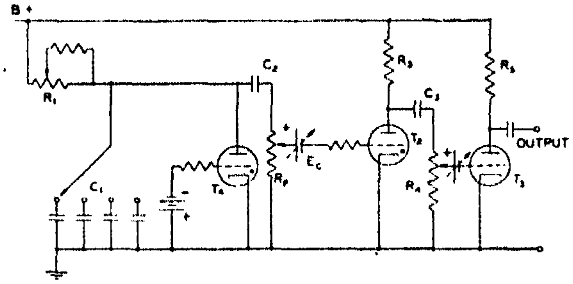

FIG. 2. Thyratron square wave generator.

The circuit of Fig. 1 with thyratron T_1 operating under the special conditions above, becomes, in essence, a square wave generator. Positive and negative pulses must be supplied at terminals 1–2 so as to alternately fire and extinguish T_1 and thus produce *approximately* square pulses across terminals 3–4.

If the squareness of the pulses to be generated at terminals 3–4 is not too critical, the grid (terminals 1–2) may be driven from an ordinary sine wave generator such as is found in most electronics laboratories. The circuit of Fig. 1, with the components listed, produces square waves suitable for many applications across terminals 3–4 at the sine wave oscillator frequency from 10 to about 5000 cycles per second and amplitude 250 volts. It is to be noted that the output impedance of such a circuit will be very high since the high resistance R_1 prevents appreciable current flow through a load impedance coupled to the generator at terminals 3–4. High impedance output is, of course, undesirable if any amount of power is required by the load across terminals 3–4, and a more versatile circuit is shown in Fig. 2.

It has been found that a relaxation oscillator is ideally suited to provide the alternating grid voltage necessary for driving

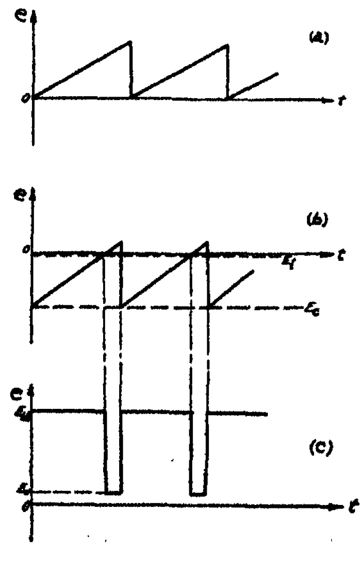

FIG. 3. Thyratron square wave generator.

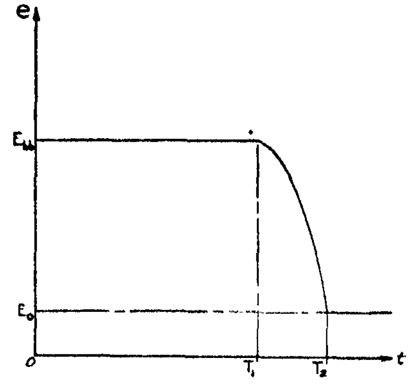

FIG. 4. Thyratron square wave generator.

the grid of the main thyratron T_3. The thyratron T_4 is arranged in such a variable frequency relaxation oscillator. The period of oscillation P of the relaxation oscillator is controlled by varying the magnitude of R_1 and/or C_1. Thus C_1 is used as a frequency range selector and R_1 is used as a frequency vernier. Since this type of relaxation oscillator produces sawtooth wave forms, the mere addition of a variable grid bias on the main thyratron T_3 permits control of the symmetry of the final square wave output, as indicated in Fig. 3.

Figure 3a shows the sawtooth output of the relaxation oscillator; Fig. 3b shows the total grid voltage applied to the main thyratron T_3 (sawtooth plus bias) and Fig. 3c shows the resulting square wave which appears across thyratron T_3. It is evident from the figure that the further the sawtooth is dropped below the level E_i of Fig. 3b, the more asymmetric the resulting square wave will be. Obviously, the upper limit to this procedure is the point at which the peak of the sawtooth falls at the level E_i, since any further increase in bias will prevent the tube T_3 from firing entirely. Also, since E_c must be large enough to extinguish the arc, there is a lower limit on the variation of E_c.

An obvious alternative method of symmetry control consists in varying the amplitude of the sawtooth wave form while maintaining a constant grid bias on T_3. The amplitude of the sawtooth may be conveniently controlled by the potentiometer at the output of the relaxation oscillator.

To accomplish the very desirable reduction of output impedance and increase of power output mentioned earlier, the square wave output of thyratron T_3 is coupled to a low mu, high power output triode.

It should be mentioned that the coupling networks between the relaxation oscillator and thyratron T_3 and between thyratron T_3 and the amplifier consist of 1.0-microfarad condensers (C_2 and C_3 of Fig. 2) and 1.0-megohm resistors (R_3 and R_4 of Fig. 2). This combination yields a time constant of 1.0 second which permits the passage of 20-cycle per second square waves with little or no distortion.

In addition to the distortion in square waves introduced by stray circuit parameters, the thyratron square wave generator produces variations from the ideal output via "ionization time distortion" and "deionization time distortion." The curve of plate voltage *versus* time for a thyratron upon the application of a grid over-voltage represents the best possible "rise curve" of the output square wave, and has been found experimentally by A. E. Harrison[3] and others to be of the form shown in Fig. 4.

The time lag portion of the ionization time, about 1 microsecond long, produces no square wave distortion, but merely a slight asymmetry in the final output. However, the breakdown time portion of the ionization time represents the *minimum rise time* of the output square wave, about 0.2 microsecond for type 884 thyratrons. Although the figure of 0.2 microsecond applies only to the circuit of Fig. 1 with no load, the rise time of the circuit of Fig. 4 with its additional capacitive loading is adequate for most applications.

The deionization time of the thyratron represents the minimum decay time of the output square wave. Ordinarily the deionization time in a type 884 thyratron ranges from 10 to 1000 microseconds. However, there are two factors contributing to a substantial reduction in the recovery or deionization time of the gas. Both the very low arc current being used, and the fact that the grid is driven considerably negative as deionization commences, lead to a much shorter recovery time (about 5 microseconds).

It is possible, by employing hydrogen-filled tubes,[4] that the rise and decay times of square waves produced by thyratron square wave generators can be considerably reduced. The deionization time limits the frequency at which good square waves can be produced to approximately 12,000 cycles per second for argon-filled tubes. Here again, hydrogen-filled thyratrons hold a promise of extending this upper frequency limit to perhaps 40 kilocycles per second.

It is evident from the theory of the basic square wave generator circuit of Fig. 1 that the only limit on the amplitude of the square waves produced is the maximum plate voltage that the thyratron can withstand. Thus, with the proper tube,[5] square waves of 1000-volts in amplitude are easily produced by the basic circuit.

[2] The negative grid voltage required to extinguish the arc varied from tube to tube, however, a 25-volt pulse was usually found to be sufficient for type 884 and 885 tubes. A similar method has been used to quench tubes in some counting circuits described in the literature and in a transient visualizer described by Reich.

[5] The tube geometry is of great importance because of the mechanism utilized for extinguishing the arc. No investigation has been made with high voltage commercial tubes.

A New Principle in Controlled Vacuum Leaks

C. H. BACHMAN
Syracuse University, Syracuse, New York

December 20, 1948

MEANS for admitting small quantities of gas to a vacuum system (controlled leaks) have depended upon constrictions for their operation. Typical examples are finely drawn glass capillaries, flattened copper tubing, the porosity of unglazed porcelain, and needle valves of various designs.[1] These all have two basic weaknesses. They are not easily adaptable to be varied over wide values of leak rate, and they are subject to fluctuations in leak rate as particles of dust are drawn into the constrictions.

In an attempt to develop a means of moving strip film into and out of a vacuum chamber between two rubber rollers, it was found that removal was easily accomplished but insertion of the film was always accompanied by some air, apparently carried in on the surfaces of the rollers. This has led to the application of a completely different principle for the operation of controlled leaks which obviates both of the basic weaknesses indicated above in connection with constriction or capillary type leaks.

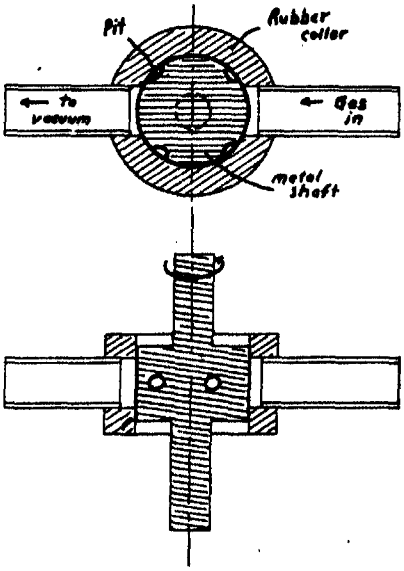
Instead of introducing gas at a slow steady rate through a constriction, it is introduced in short bursts or pulses through a comparatively large opening. The amount of gas in each pulse as well as the pulse frequency is controlled. With such an arrangement dust particles can have no effect and the leak rate can be adjusted through great ranges.

Two types of pulsed leaks are being investigated currently. These two types are indicated in Figs. 1 and 2. Each has certain advantages and disadvantages which make its use preferable for certain applications.

In Fig. 1 is shown an arrangement consisting of a metal shaft having pits drilled or bored into its surface as indicated. The pick-up tube leading to the vacuum system is inserted into the rubber collar which is shaped to fit the rotating shaft. The collar is held against the shaft with sufficient pressure to give a good vacuum seal between pits. Lubrication with vacuum oil or grease is essential. As the shaft is rotated each pit delivers its volume of gas to the evacuated pick-up tube and moves on to be recharged.

The capacity of this leak is governed primarily by the volume of the pits and the pit or pulse frequency. The bore of the pick-up tube is definitely out of the class of capillaries, being ¼ in. or larger. The pulse frequency is limited by the geometry of the pick-up tube and pit diameters, and by the relative linear speed of the two members. At linear speeds much greater than about 1 foot per second, lubrication and heating problems develop.

Using a variable speed drive the leak rate may easily be adjusted over a 100 to 1 range. The vacuum attained, of course, will depend upon the pump speed and the pit volumes for any given pulse frequency. For extremely slow leak rate a smooth shaft may be used in place of a pitted shaft. Arrangements are easily made to interchange shafts to provide different leak rate ranges.



Sectional Views

FIG. 1. Principle of rotary pulsed leak.

This type of leak has the great advantage that its capacity or leak rate can be predicted from a knowledge of the pit dimensions and operating speed (pulse frequency). When used in this type of application care must be used that the pit volume not be reduced during operation by accumulated oil from the lubricated running surface.

Using the displacement of a Hg pellet in a capillary tube as a means of checking the flow rate, repeated measurements on a rotary pulsed leak showed the actual leak rate to check the calculated rate to within a few percent. These measurements were made at pressures below one mm Hg.

One disadvantage possessed by the rotary leak for some applications is the presence of vapor from the lubricating oil. The arrangement of Fig. 2 eliminates this difficulty. The line drawing depicts a rather simplified version of a cam-operated valve. As the cam rotates the rubber cap opens and closes the opening to the pick-up tube.

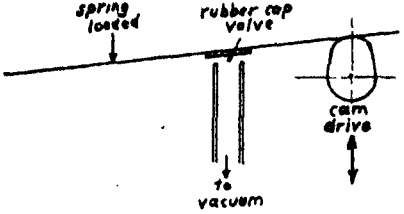


FIG. 2. Principle of valve type pulsed leak.

This leak, although operating on the pulsed leak principle, differs from the rotary leak in that for normal cam speeds the leak rate does not depend directly upon rotational speed. For a given pick-up tube size, the relative open and closed times determine the rate and this is set by the position of the cam. The cam should be adjustable along the line shown by the double-headed arrow. In one extreme the valve will ride open during the complete rotation. In the other extreme it will remain closed. Intermediate positions give "open to closed ratios" between these extremes. The pulsed valve leak, although eliminating the oil vapor, does not lend itself to precalculated design as does the rotary pulsed leak.

Such a pulsed leak, provided with a screw adjustment of cam position, easily controlled the pressure from atmospheric down to 10^{-4} mm Hg. The pumping system consisted of a Welch Duo-Seal No. 1400 mechanical pump, and at the lower pressures a D.P.I. two-stage glass oil diffusion pump was in operation. Pressures were read with Hg manometer, thermocouple gauge, and ionization gauge, each in its range.

Either the rotary or the valve type leak lends itself nicely to applications where a desired vacuum value is held by balancing the leak rate against the pumping speed. The results are even more striking, however, when the pulsing leak is turned on and off by a vacuum switch such as the SMCI[2] monitor, or the type recently described.[3] Although these switches may be used directly with solenoid valves, the use of the proper pulsed leak gives extremely accurate control and eliminates overshooting and relay chattering.

Many variations of the two basic types of pulsed leak described here are possible and a large number have been tried successfully, including the use of solenoid mechanisms instead of motor drives. Both types may be adapted to introduce gas of desired content. Investigations now under way are concerned with the operating characteristics of some of the better designs, and the accuracy with which the leak rate of the rotary pulsed leak can be precalculated.

Although the work to date has been in connection with vacuum systems, the pulsed leak principle should be useful in any application where it is desired to have control over the transfer of gas from a high pressure region to one at lower pressure.

An Absorption Cell and Loader for Use in Microanalysis by Infra-Red Spectroscopy*

Seymour H. Wollman**
Sloan Kettering Institute for Cancer Research, New York, New York

December 6, 1948

IT has become recognized that certain substances of great biological activity occur in small quantities in living organisms. Because of the small quantities present it is difficult to

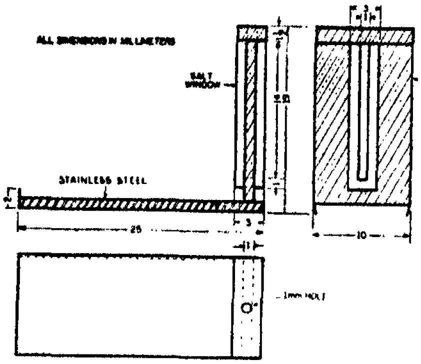

FIG. 1. Absorption cell.

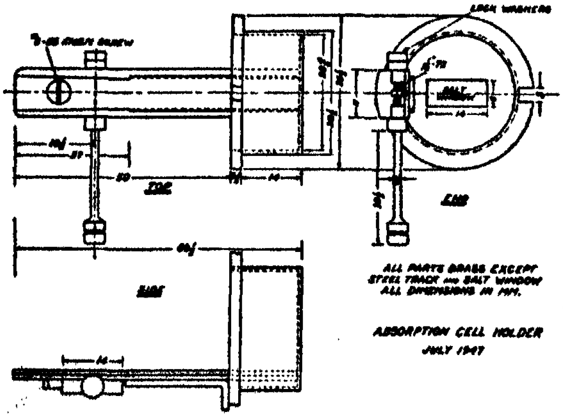
obtain a sufficient amount to give quantitative and qualitative analyses. Any tool which would allow analysis of small quantities of chemicals should be a very useful tool in biological research and medicine. In recent years infra-red spectroscopy has proved useful as an analytical tool. This paper presents a simple modification of a commercially available automatic recording infra-red spectrometer[1] which makes it possible to reduce the quantity of material required for analysis by a factor of ten to thirty or more.

In the spectrometer, radiation from a glow bar is focused on the entrance slit of the spectrograph by a mirror (aperture approximately f:4.5). The sample cell is held in the convergent beam of radiation 2 cm in front of the entrance slit. At this distance the beam has a width of 7 mm.

Since, according to Beer's law, the percent of radiation transmitted through a sample depends only on the number of the particular absorbing molecules per square cm, i.e. on the concentration of molecules times the cell thickness, it is possible to reduce the area of the absorbing cell and thereby its volume, and hence the number of molecules required without changing the absorption spectrum. It is possible to reduce the cell size without reducing the amount of radiation transmitted simply by placing the absorption cell very close to the entrance slit, in as narrow as possible a part of the convergent beam of radiation.

In the following paragraphs a narrow absorption cell and a new cell holder, which holds the absorption cell close to the entrance slit, will be described. A cell loader to take care of difficulties in the handling of small amounts of solution will also be described.

Absorption cell: A diagram showing construction of the absorption cell is given in Fig. 1. The absorption cell consists of a brass spacer mounted on a stainless steel platform which fits on and slides over a track to the window of the cell holder. The cell is mounted with 2 mm of the entrance slit, and since the convergence of the beam is about f:4.5, the minimum allowable width for the absorption cell is about 0.7 mm. A slot in the spacer determines the height and the width of the cell, while the spacer thickness determines the thickness of the absorption path. The absorption cell which is 1 mm thick has a height of 12 mm and a width of one mm (volume about 12 mm^3).*** The slot in the spacer is covered with one-mm thick salt plates cemented in position with an adhesive which is insoluble in CS_2 (National Starch Products, Inc. Adhesive No. 2654) and resistant to acetone (used as a cell cleaner). At first the salt crystals used as windows were cut the width of the spacer. These were found to be unsatisfactory for the small cells since it did not seem to be possible to make the volume available to solution between spacer face and salt plate small enough. This space was present because of the small lack of planarity of the salt windows. It was difficult to fill the space with an inert material without having the material flow into the path of the beam of radiation. A satisfactory solution lay in cutting the salt plates to overlap the space beyond the slot by no more than one mm, and in clamping them in position before painting the edges with adhesive. The top of the spacer is covered with a brass block with a one-mm diameter filling hole. This hole can be stoppered by covering it with lead foil and universal wax during absorption measurements. It is vital that the seal be airtight since CS_2 is volatile, and losses of solvent due to evaporation will be a considerable percent of the total solvent volume if care is not taken. If this happens, the absorption curve will be distorted.



LOCK WASHERS
SALT WINDOW
TOP
END
SIDE
ALL PARTS BRASS EXCEPT STEEL TRACK AND SALT WINDOW ALL DIMENSIONS IN MM.
ABSORPTION CELL HOLDER
JULY 1947

FIG. 2. Absorption cell holder.

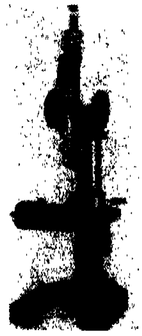


FIG. 3. Absorption cell loader.

Cell holder: Construction of the new cell holder is shown in Fig. 2. It is installed very simply. The spectrometer cover has a window in front of the entrance slit. This window is mounted in a slip ring and can be easily removed and replaced by the cell holder (provided that a baffle is removed from in front of the entrance slit). The cell holder has a small rectangular hole in its end into which a thin rectangular salt crystal window is cemented with Glyptal. The end of the cell holder just misses touching the adjustment screws in the jaws of the slit. An adjustable stainless steel track is installed in the cell holder so that the absorption cell can be accurately lined up in front of the slit. With such a narrow cell this lining up must be done each time the spectrometer cover is removed and replaced. The track is dovetailed in section so that the absorption cell cannot be brushed off accidentally. A notch in the face of the cell holder is provided so that the cell holder can be rotated on its axis until the cell is parallel to the slit; the holder must then be fastened in position by a screw which fits into a hold drilled into the spectrometer cover.

The small volume of a volatile solvent used in the 1-mm cell may be considered an objectional feature; of course it is possible partially to avoid this difficulty by making the cell thicker, increasing the volume of solvent, and reducing the concentration of absorber proportionately. However, with increasing cell thickness two difficulties arise: (a) the solvent itself begins to absorb with consequent difficulties in the detection and analysis of absorber spectrum; (b) the solute molecules are not used as efficiently.

Cell loader: To make it easy to handle small quantities of solutions a cell loader was developed (Fig. 3). It consists of a ¼-cc tuberculin syringe modified by fitting on a capillary pipette to the end. The syringe is fitted with a screw control for fluid delivery, and is mounted on an old microscope base, the stage of which is modified to mount controls to hold and manipulate the absorption cell into position, relative to the pipette. In dealing with small quantities of solution all the solution must be in the pipette and none in the syringe chamber in contact with the plunger. If the plunger is wet, by the solution there may be significant material losses.

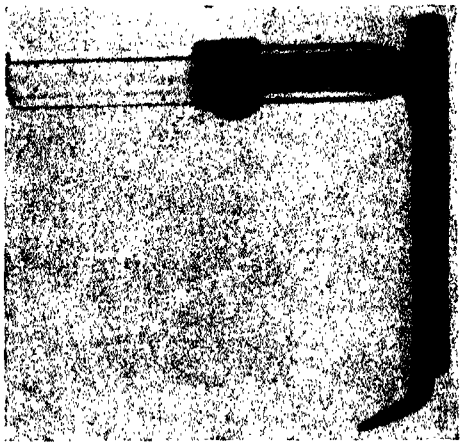

FIG. 4. Sample holder.

If the top of the pipette is centered in the cell, the delivered solution will not flow to the bottom of the cell, but instead will rise up between the absorption cell and the pipette, overflow, and be lost. In order to fill the cell the pipette tip must be placed in contact with the side of the absorption chamber near the top, and the solution must be poured down the side of the chamber. There does not seem to be any corresponding difficulty in recovering the sample. The pipette tip is introduced into the top of the chamber and solution is withdrawn as the pipette is moved to the bottom.

Since the quantities of material, both solute and solvent, are small, unknowns can be stored in small tubes made from small bore glass tubing. A simple tube holder has been made, as shown in Fig. 4, which allows mounting the tubes on the track of the loader stage for convenience in dissolving samples and loading them into the capillary pipette.

I want to thank Dr. K. Dobriner for pointing out the need for these gadgets, and Mr. A. Schreiner for valuable design suggestions.

*** For less soluble materials a larger cell with three, mm spacer thickness (volume about 40 mm³) has been designed. It has a slot with trapezoidal cross section because of the converging beam of radiation.

Octane Vapor Proportional Counter

T. P. Pepper
Division of Atomic Energy Research, National Research Council of Canada, Chalk River, Ontario

January 14, 1949

CHEMICALLY pure *n*-octane vapor at room temperature has been used in a proportional counter for the study of the relative yields of the concurrent nuclear reactions: D(*d*, *p*)T, and D(*d*, *n*)He³.

The 3-Mev protons, 1-Mev tritons, and 0.8-Mev He³ particles so produced penetrated a thin Formvar counter window and emerged into the counter in a cone of semi-angle 20°. The thinner the window the easier were the detection and resolution of the ionization pulses from the three groups of charged particles. An octane-filled counter behaved as expected by giving a pulse distribution similar to that of a methane-filled counter at roughly six times the pressure. A representative pulse distribution as recorded on a 30-channel pulse analyzer is given in Fig. 1. The He³ peak could be narrowed to resemble the T peak of Fig. 1 simply by reducing the counter stopping-power and allowing the He³ particles to dissipate most of their energy in the far wall of the counter.

This preliminary success suggests using the saturated vapor of organic compounds of large molecular stopping-power for filling proportional counters. Two useful properties peculiar to such counter fillings are the following:

1. They present molecular stopping power at least equal to the heaviest gases normally used (e.g. Xe), a large fraction of which ($\geqslant \frac{1}{2}$) is due to the hydrogen constituent. This aids experiments requiring low pressure fillings containing one or other of the hydrogen isotopes. Such, for example, is the detection of the reaction D(*T*, *n*)He⁴, an experiment recently performed using the 1-Mev tritons from the reaction D(*d*, *p*)T mentioned above.

2. The pressure, hence stopping-power, of the counter filling is a function of the temperature alone. A liquid reservoir attached to the counter can be thermostatically controlled, thus enabling the counter pressure to be held constant or altered as desired without resort to opening or closing any part of the system to permit the flow of gas. (To avoid condensation

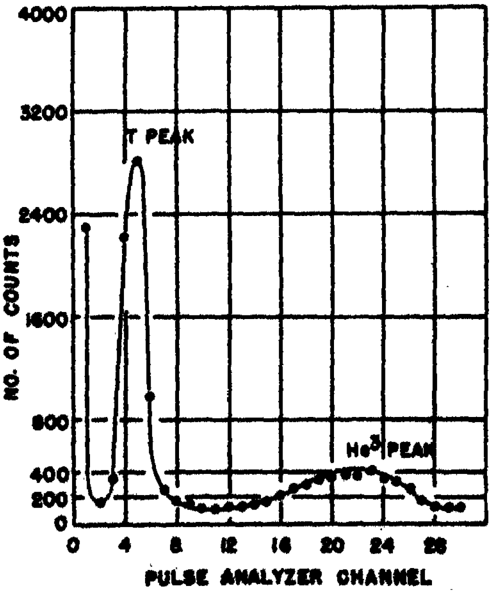

FIG. 1. *T and He³ peaks from the nuclear reactions* D(*d*, *p*)T and D(*d*, *n*)He³ presented on a 30-channel pulse analyser. Proportional counter filling: *n*-octane vapor at room temperature (~20°C). Counter window: Formvar 0.12 mg per cm².

TABLE I.

Organic compound	Molecular weight	Vapor pressure in mm Hg at 20°C
butylethylene	84	138.8
2,2-dimethylpentane	100	84
2,2,4-trimethylpentane	100	38.7
heptane	100	35.5
n-octane	114	10.45
2,5-dimethylhexane	114	38.5

within the counter the reservoir must be kept cooler than the counter.) Pressure determined by temperature alone permits some leakage of the counter filling, thus permitting the use of normally unacceptably thin, porous windows between the counter and evacuated source of charged particles. Flow of vapor through the window keeps purer the filling of the counter, thus lengthening its life.

The work of Farmer and Brown[1] on the life of methane-filled Geiger counters suggests that proportional counters filled with selected vapors would be long-lived. Other important properties, e.g., electron attachment and degree of dissociation of molecular ions, must be investigated for the individual vapor used. Table I presents selected organic compounds of large molecular stopping-power and vapor pressures of a few cm Hg at room temperature whose vapor may, therefore, be suitable for filling proportional counters.

National Bureau of Standards, Washington, D. C.

Silicone Rubber

The chemical steps involved in the production of G.E. silicone rubber may be briefly outlined as follows. Elementary silicon, prepared by the reduction of silica sand with carbon, is reacted directly with methyl chloride in the presence of a copper catalyst. Dimethyldichlorosilane is then obtained by fractional distillation of the resulting mixed methylchlorosilanes. This product is treated with water, which replaces the chlorine atoms with hydroxyl groups. These, in turn, react with each other to form the methyl silicone polymer. The addition of the methyl organic group imparts flexibility, plasticity, and even fluidity to what would otherwise be a purely inorganic silicon oxide. The properties of the silicone polymer are determined by the organic group and its size in relation to the silicon-oxygen framework. The polymerized silicone has great chain length and high molecular weight and possesses elastic properties. When it is milled with fillers and curing agents it can be cross-linked (vulcanized) to form a synthetic rubber-like substance.

The compounded and cured elastomer has the same characteristic of exceptional thermal stability as other silicone products. G.E. silicone rubber can be continuously exposed to temperatures of 300 to 325°F, and for short periods up to 520°F without decomposing or becoming brittle or tacky. It contains no plasticizing or other components which tend to evaporate under high temperature or vacuum. Room temperature flexibility is retained down to −70°F. It has been used successfully in contact with many lubricants and industrial chemicals and is highly resistant to oxidation, ozone, corona, ultraviolet radiation, and fungus growths. Over its entire temperature range it is a good insulator, its electrical properties remaining unchanged even after prolonged exposure to high temperature. Its resiliency is comparable to that of natural rubber at room temperature. The tendency to recover its original size and shape after deformation is a necessary characteristic in many gasket applications and is retained even after long exposure to high temperature. Heat does not make it tacky or adhesive. When used in gaskets, sealing rings, and the like, it can be removed easily from metal surfaces without tearing. High speed shaft seals do not tend to grab or tear. However, it has good adhesive properties when cured on glass, ceramics, or steel, and it may be reinforced with glass cloth or asbestos where high strength is essential.

In view of the non-adhesive characteristics of the cured silicone rubber, a high temperature adhesive G.E. No. 12509 has been developed for bonding the cured compound to metals, glass, or to itself. Possessing high thermal stability, the adhesive combines chemically with the silicone rubber to form a continuous phase with no distinguishable glue line. It may be used for laminating layers of sheet stock, for butt-joining flat stock and gaskets, and for incorporating metal inserts in silicone rubber molded parts.

G.E. silicone rubber may be extruded or compression molded (using a pressure of 100–200 p.s.i.). It is also available in flat stock in 14″×14″ sheets with thicknesses ranging from $\frac{1}{32}$″ to 1″, and as a coated glass cloth in widths up to 36″.

The above material was abstracted from a General Electric booklet entitled *Silicone Rubber*.—PLASTICS DEPARTMENT, GENERAL ELECTRIC COMPANY, *Pittsfield, Massachusetts.*

Plastic for Film or Fabric

Velon plastics are modified copolymers of the polyvinyl and vinylidene series. They are combined with plasticizers and stabilizers and other compatible synthetics to secure abrasion resistance, toughness, high tensile strength, tear resistance, and control of elasticity. *Velon* is produced in three major forms: as a film, as a heavier gauge sheeting, and as a filament. The film is non-flammable (does not support flame), is resistant to staining, and may be cleaned with a damp cloth and soapy water. It is produced in thicknesses from 0.004 inch up, and in addition to its extensive applications in yard goods is used for making waterproof covers, liners, bags, etc. The sheeting, embossed with a grain design or polished as a patent leather, may replace leather in many applications. It has advantages in being scuff-resistant, non-absorbent, and easily cleaned. Its abrasion resistance is several times that of leather, and it is capable of withstanding considerable stress, either continuously or intermittently applied. It is also fungus, mold, and mildew proof. In addition to uses in luggage and upholstery, it has special applications as protective fronts for coats and aprons in chemical and allied industries.

Velon filaments, woven in a conventional mesh, make a screening which is superior to metal cloth. It is weatherproof even under severe salt air conditions, can easily be cleaned, and has many times the impact strength and resilience of metal cloth. For textile applications it has been produced both as a monofilament and as a multifilament yarn. The monofilament is made from a resin composed principally of vinylidene chloride with a small portion of vinylchloride. The resin is melted and extruded through orifices in a die. The emerging hot monofilament is plunged into water and then stretched to four times its original length. This treatment orients the structure and increases the tensile strength of the filament by 10 times.—FIRESTONE PLASTICS COMPANY, *Akron, Ohio.*

High Strength Varnish

Harvel 1012 C is an internal-curing insulating varnish developed particularly for the impregnating of wound structures which require very high mechanical bonding strength. It is finding application for the treatment of windings operating at high peripheral speeds and for those subject to high mechanical stress. It is fast curing and the cured film is oil proof, has good chemical and moisture resistance, and excellent resistance to decomposition under high temperature operating conditions. Full information and test samples may be obtained from the manufacturer.—IRVINGTON VARNISH AND INSULATOR COMPANY, *Irvington 11, New Jersey.*

Metal Stripper

Enthone Metal Stripper has been developed for chemically dissolving nickel and other metal coatings from steel without attacking the base metal. It is alkaline in nature, requires no electric current, and can be contained in a steel tank. The parts to be stripped are immersed in a solution of the stripper salts, at a temperature between 160 and 180°F. Stripping speed varies from 0.0002″ to 0.001″ per hour depending on concentration and operating temperature. The base steel is not etched nor attacked in any way, but is left in the same condition as it was prior to plating. In most cases the work can be replated after an acid dip. In addition to nickel, the stripper is effective in removing copper, silver, cadmium, and zinc plate from steel. It is not suitable for removing nickel coatings from zinc-base die castings or copper alloys.—ENTHONE, INC., *442 Elm Street, New Haven, Connecticut.*

Graded-Glass Seals

Technological advances in the art of processing various glasses have made possible a mechanical procedure for making graded seals from fused quartz to soft glass. Substitution of a mechanized process for the previous highly skilled handcraft has made price reductions of the order of 40 percent possible. The present process is applicable to the fabrication of graded seals up to two inches in diameter.—HANOVIA CHEMICAL AND MANUFACTURING COMPANY, *Newark 5, New Jersey.*

New Instruments

Microwave Dielectrometer

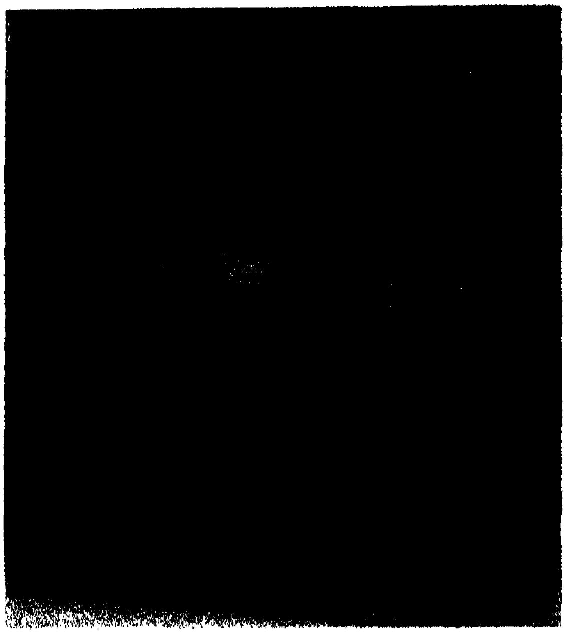
The Central Research Laboratories' microwave dielectrometer is now available for measuring the dielectric constant and loss of a wide variety of materials at nominal frequencies of 1000, 3000, and 9000 megacycles. The instrument consists of a slotted wave guide, precision traveling probe, modulated klystron oscillators, probe output amplifier, associated power supplies, and equipment. The sample to be measured is inserted ahead of a short-circuiting plug, and the effect of this arrangement on the standing-wave pattern in the guide provides data for calculating the dielectric constant and loss of the material.

At 1000 and 3000 megacycles, the wave guide is used as a coaxial line operating in the *TEM* mode, and at 9000 megacycles, either as a circular pipe operating in the TE_{11} mode or as a coaxial line operating in the TE_{10} mode. Solids are measured directly in the wave guide in the form of cylindrical samples 1 inch in diameter and about 1 to 2 inches long with a ⅜-inch hole coaxial with the outer surface except when the guide is operated as a circular pipe at 9000 megacycles. Auxiliary sample holders can be used for measuring liquid samples and also for measurements at controlled high and low temperatures. The range of measurement of dielectric constant extends from 1 to 100; of dissipation factor from 0.0001 to 1.0. With ordinary care in sample preparation, an accuracy of 1 to 2 percent can be achieved for most materials.

To insure dimensional stability, ruggedness, and precise alignment, the wave guide is machined out of a solid 2-inch diameter copper bar and mounted on a substantial heat-treated Meehanite support which also carries the necessary mechanical assemblies. The crystal-detector probe is mounted on a precision ball-bearing carriage permitting longitudinal motion along the center line of the wave-guide slot. A spring-loaded, backlash-free, drive mechanism allows setting and reading probe position to 1 micron (0.001 millimeter). The maximum error in measuring displacements of 100 millimeters is approximately 30 microns.

The detector-output indicator is a selective amplifier tuned to the repetition frequency of the square-wave klystron-modulating voltage together with a logarithmic step attenuator and a linear output meter. An auxiliary overload meter with a nearly logarithmic range of 60 db is provided as an aid in tuning.

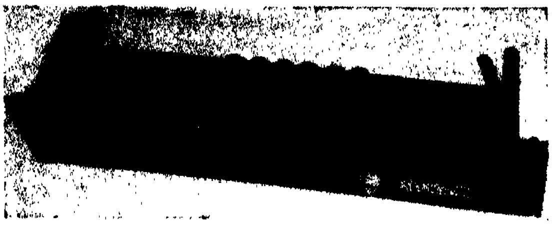
Routine maintenance is facilitated by built-in test features for measuring all critical circuit voltages and currents. Necessary adjustments are made by convenient screw-driver controls.



A line-voltage stabilizer and electronically-regulated power supplies provide optimum operating conditions in spite of line voltage fluctuations. Power consumption is 500 watts at 115 volts, 60 cycles.—CENTRAL RESEARCH LABORATORIES, INC., *Red Wing, Minnesota.*

Wide Band Chain Amplifier

The Model 200A chain amplifier is a traveling wave amplifier with a band width of 200 megacycles and a gain of 10 db per stage. With a useful range from 100 kilocycles to 220 megacycles at an impedance level of 200 ohms, the amplifier is especially adapted for use in television testing, nuclear instrumentation, oscillography, and general laboratory measurements. The transmission



characteristic is ±1.5 db from 100 kilocycles to 200 megacycles, and the standing wave ratio is less than 1 db over this band. Phase shift in the amplifier is substantially linear within the pass-band, owing to mutual-inductance coupling between adjacent sections. Each stage has a tube complement of six 6AK5 tubes. Either one-stage or two-stage amplifiers are available in standard rack or table mounting. For additional information write to: SPENCER-KENNEDY LABORATORIES, INC., *Dept. SI, 186 Massachusetts Avenue, Cambridge 39, Massachusetts.*

Radiation Standards

High accuracy radiation standards, developed for the calibration of Geiger counters and other instruments measuring radioactivity, are now being supplied by the United States Radium Corporation. In addition to the conventional type standard, consisting of hermetically sealed capsules containing a radium salt, the company is offering a new type of calibrated source based on the incorporation of radium or its related elements in foil.

The new type standard is available as a point source or linear source, calibrated for alpha-, beta-, and gamma-radiation. It offers new latitude in design as compared to capsules, making it possible to fit the configuration of the standard to the specific instrument or counter tube, and also making possible the accurate duplication of standards.

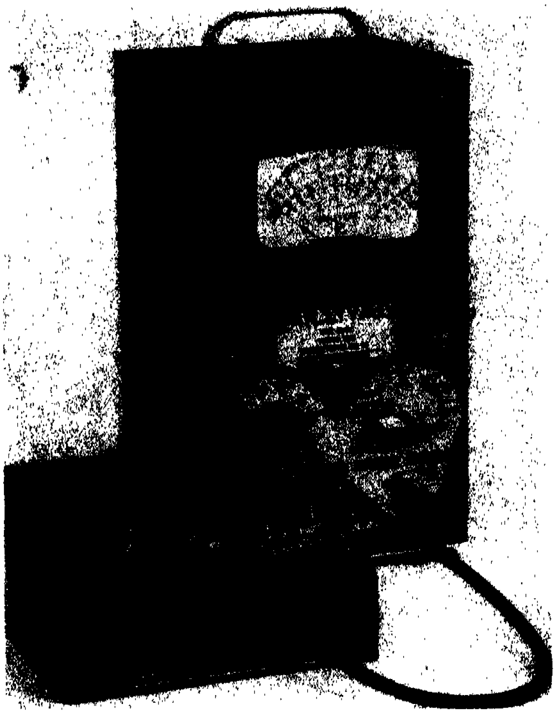
While radium is a suitable source of radiation and is used in most of the items discussed, arrangements can frequently be made to supply standards utilizing a source of either virtually pure beta- or gamma-radiation alone. The methods of preparation are applicable to standards of almost any radiation intensity but can be particularly well applied to those of low radiation intensity, standards normally the most difficult to prepare accurately. Stable and accurate alpha-ray sources present no more difficulty than the more readily prepared beta- and gamma-sources.

The wider use of radioactive materials, stimulated by the Atomic Energy Commission's program of releasing new isotopes for research, medical, and industrial use, has created a demand for accurate and reliable measuring equipment. Such equipment, in the form of Geiger counters, ionization chamber survey instruments, and dosage meters, is supplied by a number of manufacturers and is normally furnished with a reasonably accurate initial calibration. Through mechanical shock or vibration, weakening of the power supply, radioactive contamination of the equipment, aging of the counter tube, and many other causes, this initial calibration usually changes in time, and recalibration is necessary. For dependable results in survey work, and especially for the highly accurate measurements required in research, industry, and medicine, dependable, accurately calibrated radiation standards must be available at all times for recalibration or on-the-spot checking of radiation-measuring equipment.

All radiation standards of the United States Radium Corporation are produced to special order, being constructed to meet the specific requirements of the instrument with which they will be used. Correspondence as to their applicability and use to meet new situations is invited by the company.—UNITED STATES RADIUM CORPORATION, *535 Pearl Street, New York 7, New York.*

Micromicroammeter

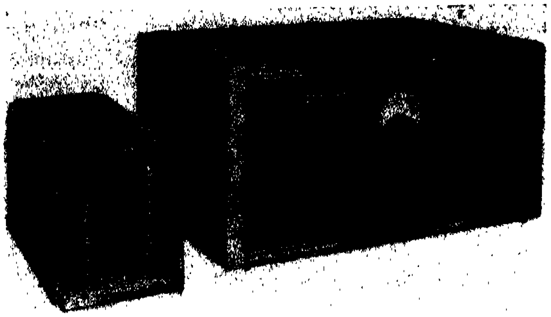
A new shunt box, type MV-171, converts the MV-17a Millivac vacuum tube millivoltmeter for d.c. into a highly sensitive wide range ammeter. With a total of 23 ranges, it covers all d.c. measurements between 10 micromicroamperes and 10 amperes. Due to a time constant of only 0.3 second, readings are practically instantaneous. Other outstanding features are heavy overloading (100,000 fold on low ranges) without damage to the instrument and exceptionally small voltage drops (1 mv on low ranges, 25 mv from 1 microampere up). With an external voltage source, resistance measurements up to 100 meg-megohms (10^{14} ohms) can be made. The shunt box and meter are operated from 115 v, 60 cycles, no batteries being required.—MILLIVAC INSTRUMENTS, *Post Office Box 3027, New Haven, Connecticut.*



Hand Alpha-Counter

The RCL hand alpha-counter is a completely self-contained assembly which consists of two alpha-sensitive, ten-wire, air proportional counters and a recording electronic circuit which is calibrated to read from 0–20,000 counts per minute. The air proportional counters themselves are designed such that electric field stresses on the insulators are as low as is consistent with good practice, thereby eliminating spurious pulses. Each counter is electrically heated to minimize humidity effects. An Aquadagged Nylon film two ten-thousandths of an inch thick protects the counter volumes from dust, yet permits transmission of alpha-particles. The Nylon film is protected by stainless mesh. The counters are so arranged that close proximity to the hand is assured. Operating in the proportional region, the counters are very stable.

The electronic circuit of the RCL hand alpha-counter consists of a linear amplifier, a multivibrator to equalize the incoming pulses, an *RC* tank circuit, a vacuum tube voltmeter calibrated to read directly in counts per minute, and a regulated high voltage power supply. An internal calibration de-



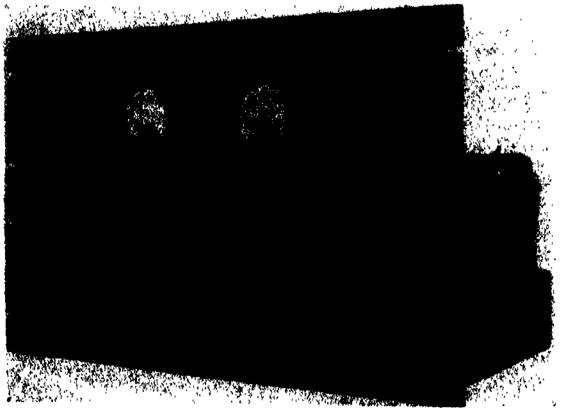
vice enables the user to check the panel meter at will. A convenient output jack permits connection of a recording milliammeter, or an auxiliary alarm circuit, if desired. The counting rate ranges are 0–200, 0–600, 0–2000, 0–20,000 counts per minute and the counter operates at approximately 2150 volts from a 115-volt, 60-cycle power supply.—Radiation Counter Laboratories, Inc., *1844 W. 21st Street, Chicago 8, Illinois.*

"Super-Regulated" Power Supply

The Model 252 regulated d.c. power supply, for applications where super-regulation at moderate power is required, has the following characteristics:

Input:	115 volts, 60 cycles, 400 watts.
Output:	Adjustable from 260 to 300 volts d.c., negative grounded.
Regulation:	With load changes from 400 to 600 milliamperes, the output voltage change at any setting is less than 0.05 percent, varying between individual units from 0.015 percent to 0.04 percent. Equal stability exists with respect to minor line voltage changes.
Noise Level:	Less than 0.001 percent.

This power supply has applications wherever extremely good regulation and stability are required. This includes computer circuits, television amplifier circuits, servomechanism directors, etc. The warm-up time required until the drift is less than 0.005 percent is approximately four hours. After steady state is reached, the instability is less than 0.001 percent per minute.



The power supply can be either relay rack panel mounted or supplied in a cabinet.—Beta Electronics Company, *1762 Third Avenue, New York 29, New York.*

Spiral Contractometer

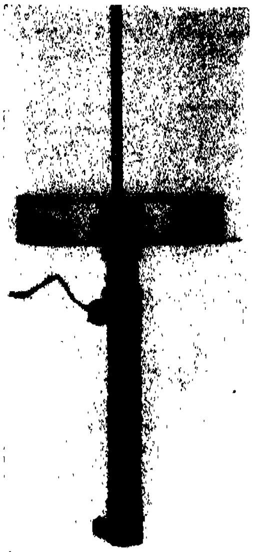
The spiral contractometer, a new direct-reading instrument developed by Abner Brenner and Seymour Senderoff of the National Bureau of Standards, offers a convenient and accurate method for measurement of stress in electrodeposits. Compression or tension in a specimen coating deposited on a standard helix is immediately read from a dial as the helix changes curvature in response to forces acting within the plated layer. The device is rugged and self-contained, requires no auxiliary apparatus, and is well adapted to both industrial process control and laboratory research.

Essentially the new instrument consists of a flat metal strip wound in the form of a helix and mechanically connected to the pointer of a dial on which the rotation of the free end of the spiral with respect to its fixed end is indicated. The helix is connected at its upper, fixed end to a negative lead and suspended vertically in a plating solution along with a suitable anode. As it is plated with a sample coating on the outside, the stress in the deposit causes it to wind more tightly or to unwind, depending on whether the stress is compressive or tensile. A rod running down the axis of the helix is attached to its lower or free end so that rotation of this end due to stress is transmitted to the rod. The rotation of the rod, in turn, is applied to a gear train which produces a tenfold magnification in the rotation of the dial pointer. The angular displacement of the rod is read directly from the dial in degrees and converted to units of stress on the basis of the calibration of the helix used.

In making a stress determination, the helix is first cleaned and, when necessary for good adherence of the deposit to be tested, a "strike" plate is applied. After the helix has been dried and weighed, the inner side is brushed with thinned "stop-off" lacquer to prevent plating on this surface. The helix is then dipped in hot alkali and acid baths, or other preplating dips, and rinsed before it is mounted in the contractometer and immersed in the plating solution.

The helix may be allowed to twist as plating progresses, and a record kept of the displacements with time, or twisting may be prevented until the end of the run by clamping the pointer. Both methods give the same results within the experimental error.

At the end of a run the helix is taken out of the solution, cleaned, and dried, and the lacquer is removed from the inside with acetone. The deposit may then be stripped off as soon as it has been weighed to determine its average thickness. Stress is calculated from the observed deflection of the pointer, the physical constants and dimensions of the helix, and the average thickness of the coating.



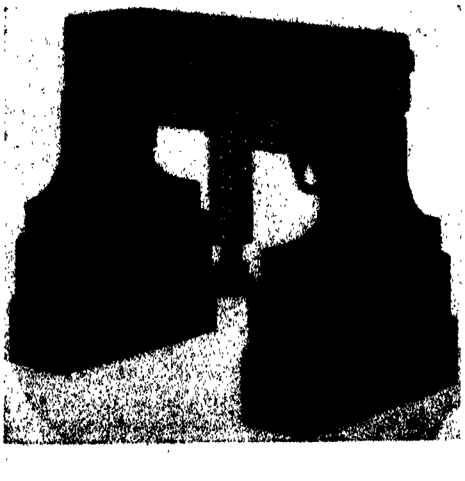
A single helix can be used almost indefinitely without appreciable change in its dimensions, elastic moduli, or deflection constants, provided reasonable precautions are taken in handling and storing.—NATIONAL BUREAU OF STANDARDS, *U. S. Department of Commerce, Washington 25, D. C.*

New Alpha-Particle Counter

A new methane flow proportional counter designed for the efficient detection of alpha-particles is announced by Nuclear Instrument and Chemical Corporation, 223 West Erie Street, Chicago 10, Illinois. The outstanding feature of this new Model D45 Detector is its ability to count alpha-particles in the presence of high beta-activity with 50 percent geometry and low coincidence losses.

When this detector is used with a high gain linear amplifier and a "fast" scaler, it is possible to count alpha-particles in the presence of a beta-activity of 5 $(10)^9$ disintegrations per minute. Measurements of this type are particularly useful in chemical, physical, and biological research.

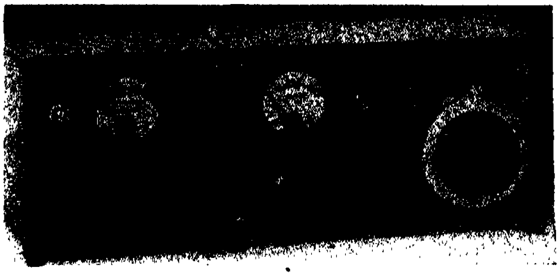
The counter chamber of Model D45 has a very highly polished cylindrical cathode. The anode is 0.002" diameter tungsten wire mounted between glass insulators. Construction is designed to permit easy decontamination both inside and outside. The sample holder, mounted on a stainless steel sample changer, is designed for standard one-inch diameter samples, with provisions for raising the sample up into the counting volume for improved geometry. Flow of methane gas through the chamber is controlled by means of valves and an attached bubbler. Connection of a coaxial cable is made to the center wire via a well insulated connector on rear of the cover.—NUCLEAR INSTRUMENT & CHEMICAL CORPORATION (formerly Instrument Development Laboratories, Inc.), *223–233 West Erie St., Chicago 10, Illinois.*



R-F Capacitance Meter

The Type 1612-A r-f capacitance meter is designed for rapidly measuring and testing small capacitors (up to 1200 micromicrofarads) such as are used in radiofrequency equipment. It is equally useful in the laboratory and in production testing and, for the latter use, a simple test jig can be devised to facilitate connections.

Measurement is made by a substitution method in which the capacitance of a calibrated air capacitor is reduced to re-establish resonance after an unknown capacitor is connected. Resonance is indicated by maximum deflection of a meter. Two ranges are provided, 0 to 80 $\mu\mu$f and 0 to 1200 $\mu\mu$f, and range switching is accomplished automatically as the dial is rotated. Measurements are made at a frequency of one megacycle.



Maximum meter deflection can be also used as an indication of loss, and hence as a basis for rejection of high loss capacitors when compared to a standard sample.

The instrument operates from a 115-volt power line, either a.c. or d.c. Dimensions are $12\times6\frac{5}{8}\times7\frac{3}{4}$ inches over-all.

Weight is 11 pounds.—GENERAL RADIO COMPANY, *275 Massachusetts Avenue, Cambridge 39, Massachusetts.*

Manufacturers' Literature

High Stability Carbon Resistors—8-page catalog describes high stability carbon film resistors, normally supplied to 1 percent tolerance up to 50 megohms, and pyromatic resistors in ranges up to 10^6 megohms. Technical data and price schedules are given.—WELWYN ELECTRONIC COMPONENTS, INC., *234 East 46th Street, New York 17, New York.*

Errors in Second-Order Measuring Instruments

ELLIOT T. BENEDIKT
North American Aviation, Inc., Inglewood, California[1]

(Received July 19, 1948)

The various types of error which affect the result of a measurement performed by an instrument behaving as a second-order linear instrument are defined.

The theoretical systematic error is shown to be caused by the (dynamical) lag with which the instrument responds to the signal. If the damping is high, this type of error turns out to be proportional to the rate of change of the signal.

The accidental error resulting from input noise and accidental changes of the instrument constants is considered. It is shown that all these effects can be represented by an effective input noise. A formula for the mean square error in the indication of the instrument is given in terms of the correlation function of the above effective noise.

Related theoretical questions on random functions are discussed in the Appendix.

1. INTRODUCTION

CONSIDER a device used for the purpose of the determination of a quantity $F(t)$ variable with the time; we shall assume this device to behave as a second-order system having a (generalized) mass M, resistance R, and elastance S. The (generalized) coordinate θ (usually an angle or a displacement), in terms of the value of which the quantity $F(t)$ is determined, would satisfy the differential equation,

$$M(d^2\Theta/dt^2)+R(d\Theta/dt)+S\Theta=F(t), \tag{1}$$

if there were no accidental effects superimposed upon the quantity to be measured, and no accidental variation in the coefficients M, R, S would occur. If such variations occur, an erroneous value θ' will be determined by the equation:

$$M'(d^2\Theta/dt^2)'+R'(d\Theta/dt)'+S'\Theta=F'(t), \tag{1'}$$

where

$$M'=M+m(t), \tag{2}$$

$$R'=R+r(t), \tag{2'}$$

$$S'=S+s(t), \tag{2''}$$

$$F'=F+f_0(t). \tag{3}$$

The quantities $m(t)$, $r(t)$, $s(t)$, $f_0(t)$ are of the nature of random functions[2] and small in absolute value so that their square can be considered negligible.

Accidental variations of the instrument constant of the considered type can be caused, e.g., in an electrical instrument by deformation of the geometry of its parts which would cause a change in its inductance and elastance, by a temperature fluctuation which would change its resistance, etc. Accidental variations in the input (or effective input) of such instrument could be caused by stray magnetic fields, fluctuations of e.m.f.'s in the circuit, shot-effects in vacuum tubes, etc.

2. ERRORS

Under static conditions and in the absence of any accidental errors, Eq. (1) becomes

$$S\Theta=F. \tag{4}$$

The quantity F is usually determined, assuming this relation to be true, even under dynamic conditions and in the presence of random effects; that is, the incorrect value

$$\mathfrak{F}(t)=S\Theta', \tag{5}$$

---

[1] Now at U. S. Naval Ordnance Test Station, Pasadena, California.

[2] For a definition of the concept of random function, see James, Nichols, and Phillips, *Theory of Servomechanisms* (McGraw-Hill Book Company, Inc., New York, 1947), p. 266.

is assumed for F,[3] so that the error

$$\varphi = \mathcal{F} - F = S\Theta' - F, \tag{6}$$

in its determination is committed.

Subtracting (1) from (1′), taking into account (2), (2′), (2″), and (3), and putting

$$\theta = \Theta' - \Theta, \tag{7}$$

we obtain, neglecting infinitesimals of second order, the differential equation:

$$M(d^2\theta/dt^2) + R(d\theta/dt) + S\theta = f(t), \tag{8}$$

with

$$f(t) = f_0(t) + f_1(t), \tag{9}$$

$$f_1(t) = -m(t)(d^2\Theta/dt^2) - r(t)(d\Theta/dt) - s(t)\Theta. \tag{9'}$$

Using (7), expression (6) can be written in the form

$$\varphi = S(\Theta + \theta) - F = \varphi^0 + \varphi', \tag{10}$$

where

$$\varphi^0(t) = S\Theta - F, \tag{11}$$

represents the systematic error due to the dynamical lag of the instrument, and

$$\varphi'(t) = S\theta(t), \tag{12}$$

represents the accidental error due to the presence of random phenomena in the components of the instrument.

3. SYSTEMATIC ERROR

Assuming

$$\Theta(0) = (d\Theta/dt)_{t=0} = 0, \tag{13}$$

we shall obtain, integrating Eq. (1)

$$\Theta(t) = (1/M\omega_0)\int_0^t F(\tau)e^{\gamma(t-\tau)} \sin\omega_0(t-\tau)d\tau, \tag{14}$$

where

$$\gamma = R/2M,$$
$$\omega_0 = [(S/M) - (R/2M)^2]^{\frac{1}{2}}.$$

If the constant γ is large, the factor $e^{\gamma(t-\tau)}$ will be negligible for non-negligible values of $t-\tau$. Expanding $F(t)$ in series we shall have, then, with sufficient approximation:

$$\int_0^t F(\tau)e^{-\gamma(t-\tau)} \sin\omega_0(t-\tau)d\tau$$

$$\simeq F(t)\int_0^t e^{-\gamma(t-\tau)} \sin\omega_0(t-\tau)d\tau$$

$$-\dot{F}(t)\int_0^t (t-\tau)e^{-\gamma(t-\tau)} \sin\omega_0(t-\tau)d\tau$$

$$= [F(t)/(\omega_0^2+\gamma^2)][\omega_0 - e^{-\gamma t}(\gamma \sin\omega_0 t + \omega_0 \cos\omega_0 t)]$$

$$-[\dot{F}(t)/(\omega_0^2+\gamma^2)^2]\{2\omega_0\gamma + e^{-\gamma t}[(\omega_0^2-\gamma^2)\sin\omega_0 t$$

$$-2\omega_0\gamma \cos\omega_0 t] + (\omega_0^2+\gamma^2)te^{-\gamma t}[\gamma \sin\omega_0 t$$

$$+\omega_0 \cos\omega_0 t]\}.$$

Neglecting in the last result terms in which $e^{-\gamma t}$ appears as a factor, we have:

$$\int_0^t F(\tau)e^{-\gamma(t-\tau)} \sin\omega_0(t-\tau)d\tau$$

$$\simeq [\omega_0/(\omega_0^2+\gamma^2)]F(t) - [2\omega_0\gamma/(\omega_0^2+\gamma^2)]\dot{F}(t).$$

Replacing this result in (14) and (11) we obtain:

$$\varphi^0(t) = -(R/S^2)\dot{F}(t).$$

4. ACCIDENTAL ERRORS

Integrating (8) under the assumptions:

$$\theta(0) = (d\theta/dt)_{t=0} = 0, \tag{15}$$

we obtain

$$\theta(t) = \int_0^t K(\tau,t)f(\tau)d\tau, \tag{16}$$

where

$$K(\tau,t) = (1/M\omega_0)e^{-\gamma(t-\tau)} \sin\omega_0(t-\tau). \tag{17}$$

Squaring both members of (16) we obtain:

$$\theta^2(t) = \int_0^t\int_0^t K(\tau,t)K(\tau,'t)f(\tau)f(\tau')d\tau d\tau'. \tag{18}$$

For the ensemble average of θ^2 we shall have then:[4]

$$\langle\theta^2(t)\rangle = \int_0^t\int_0^t K(\tau,t)K(\tau,'t)\Lambda(\tau,\tau')d\tau d\tau'. \tag{19}$$

---

[3] The rigorous determination of $F(t)$ from the observed response $\theta(t)$ would imply the solution of an integral equation of the first kind [Eq. (14) of the following article].

[4] We shall indicate with

$$\langle A(t)\rangle = \lim_{N\to\infty}\left[\sum_{i=1}^N A_i(t)/N\right],$$

the *ensemble average* of a quantity $A(t)$ (whose repeated measurement under the same controllable conditions at the time t yields results A_i, and with

$$\langle A(t)\rangle = \lim_{T\to\infty}\left[\int_{-T/2}^{T/2} A(t)dt/T\right],$$

its time average. The ensemble and time averages of quantities which depend upon measurements performed at the times t_1, $t_2\cdots t_m$ are respectively defined by

$$\langle A(t_1, t_2\cdots t_m)\rangle = \lim_{N\to\infty}\left[\sum_{i=1}^N A_1(t_1, t_2\cdots t_m)/N\right],$$

$$\langle A(t_1, t_2\cdots t_m)\rangle = \lim_{T\to\infty}\left[\int_{-T/2}^{T/2} A(t_1+t, t_2+t, \cdots t_m+t)dt/T\right]$$

A_i being the result of measurements performed at the times t_1, $t_2\cdots t_m$.

where

$$\Lambda(\tau,\tau') = \langle f(\tau)f(\tau')\rangle, \tag{20}$$

is the (auto-) correlation function of the random process represented by $f(t)$.[5] φ'^2 can be obtained immediately from the value of $\langle\theta^2\rangle$ through Eq. (12).

5. EMPIRICAL DETERMINATION OF THE CORRELATION FUNCTION

Predictions of $\langle\theta^2\rangle$ with the above method can only be obtained if $f(t)$ (that is, all the random processes involved), are independent of the response $\Theta(t)$ of the system. We shall assume this condition to be satisfied in what follows.

The determination of the correlation function (20) for a random function of the type (9) can then be obtained in general, with the method outlined in Appendix I. For the case under consideration, this would involve the determination of the ensemble average of the error in the output of the system for at least 16[6] different, appropriately chosen, responses. Such a procedure, of course, would be extremely lengthy.

A much more rapid determination of Λ can be obtained if the process represented by $f(t)$ is stationary.[7] In this case we shall have:

$$\Lambda(\tau,\tau') = \Lambda(\tau'-\tau) = f(\tau)f(\tau'), \tag{21}$$

which can be approximated numerically from an experimental determination of the function $f(t)$ over a sufficiently long period of time.

It should be noted that, for all practical purposes, the function $f(t)$ will be stationary only if $f_0(t)$ is stationary and $m(t)$, $r(t)$, and $s(t)$ are zero or negligible. Even if these last functions are stationary, their linear combination (9′) will, in general not be stationary. (See Appendix II.)

Once $\Lambda(\tau,\tau')$ is determined, $\langle\theta^2(t)\rangle$ can be determined by numerical integration from formula (19). Usually, however, an approximate evaluation of the integral (19) defining $\langle\theta^2(t)\rangle$ is sufficient, the purpose of which can be reached by approximating the experimentally determined correlation function by an appropriate analytical expression.

6. THEORETICAL METHODS

Further methods can be applied to the problem treated in the present paper if the random function $f(t)$ describes a process of a better specified nature.

If this process is Gaussian,[8] a method due to Rice can be applied; for a Markoffian[9] process, the method of Fokker-Planck-Kolmogoroff can be used with advantage. Details of these methods can be found in the original papers of Rice[10] and of S. Chandrasekhar[11] and Ming Chen Wang and Uhlenbeck.[12] In the latter two papers, a detailed treatment of the statistical properties of the solution of an equation of the type (8) can be found if $F(t)$ is the type of a force acting on a colloidal particle undergoing Brownian motion. An extensive bibliography can be found in these papers.

Due to the fact that the main purpose of the present work was to examine instrument errors from an empirical point of view, and since a comprehensive treatment of the theoretical aspects of the above special cases can be found in the cited publications, no further discussion of these matters will be given here. We shall, however, apply the methods previously established to the case in which the errors are stationary and of a type having considerable theoretical and practical importance.

If the error is simultaneously Markoffian and Gaussian, its correlation function must be of the form[13]

$$\Lambda(\tau,\tau') = \alpha^2 e^{-\beta(\tau'-\tau)} \quad (\tau' \geqslant \tau).$$

Replacing this into (19) and making use of (17) we obtain

$$\begin{aligned}\langle\theta^2\rangle &= (\alpha^2/M\omega_0^2)\int_0^t\int_0^t e^{-\gamma(t-\tau)}\sin\omega_0(t-\tau)e^{-\gamma(t-\tau')} \\ &\qquad\times\sin\omega_0(t-\tau')e^{-\beta(\tau'-\tau)}d\tau d\tau' \\ &= (\alpha^2/M\omega_0^2)\int_0^t\int_0^t e^{-(\gamma-\beta)\sigma}e^{-(\gamma+\beta)\sigma'}\sin\omega_0\sigma \\ &\qquad\times\sin\omega_0\sigma' d\sigma d\sigma' \\ &= \alpha^2 J(\gamma-\beta)J(\gamma+\beta)/M\omega_0^2,\end{aligned}$$

---

[5] I am indebted to S. O. Rice of the Bell Telephone Laboratories for suggesting the above method of determination of $\langle\theta^2\rangle$.

[6] This number can be reduced (to not less than 4) if some of the random processes involved in $f(t)$ can be considered uncorrelated a priori.

[7] A process defined by a random function $x=x(t)$ is said to be stationary if

$$\langle X(x_1x_2\cdots x_m)\rangle = \langle X(x_1x_2\cdots x_m)\rangle,$$

where X is an arbitrary function of the quantities $x_i=x(t_i)$. A relation of this type cannot in general be established on theoretical grounds and is, therefore, assumed whenever this seems justified. Such an assumption made for a given system is referred to as ergodic hypothesis.

[8] The process is said to be Gaussian if the probability of the simultaneous occurrence of the values $x_1,x_2,\cdots x_N(x_i=x(t_i))$ is given by a (pluridimensional) Gaussian function.

[9] A discontinuous random process defined by the series $x_1, x_2\cdots x_N$ is said to be Markoffian if the probability of occurrence of a given term x_i depends only on the value of previously occurred term x_{i-1}. A continuous Markoff process is the limiting case for $t_i-t_{i-1}\to 0$ of a discontinuous one.

[11] S. Chandrasekhar, Rev. Mod. Phys. **15**, 1 (1943).

[12] Ming Chen Wang and G. E. Uhlenbeck, Phys. Rev. **17**, 323 (1945).

[13] This result was established by J. L. Doob, Ann. Math.; **43**, 351 (1942).

where

$$J(\xi)=\int_0^t e^{-\xi\sigma}\sin\omega_0\sigma d\sigma$$
$$=[\omega_0-e^{-\xi t}(\omega_0\cos\omega_0t+\xi\sin\omega_0t)]/[\xi^2+\omega_0^2].$$

Making use of the above identity, we obtain

$$\begin{aligned}\langle\theta^2\rangle=[\alpha^2/M\omega_0^2P(\beta)]\{&\omega_0^2+\omega_0^2+\gamma^2-\beta^2/2e^{-2\gamma t}\\&-\omega_0^2[e^{-(\gamma-\beta)t}+e^{-(\gamma+\beta)t}]\cos\omega_0t\\&-\omega_0[(\gamma-\beta)e^{-(\gamma-\beta)t}+(\gamma+\beta)e^{-(\gamma+\beta)t}]\sin\omega_0t\\&+e^{-2\gamma t}[\omega_0^2-\gamma^2+\beta^2/2\cos2\omega_0t\\&+\omega_0\gamma\sin2\omega_0t]\},\end{aligned}\tag{22}$$

where

$$P(x)=x^4-2(\gamma^2-\omega_0^2)x^2+(\gamma^2+\omega_0^2)^2.$$

If the source of the error is a monochromatic disturbance, that is, represented by a sinusoidal function with angular frequency ω_1, amplitude a, and random phase, the correlation function will be of the form![14]

$$\Lambda(\tau_1\tau')=(a^2/2)\cos\omega_1(\tau'-\tau),$$

which replaced into (19) gives:

$$\langle\theta^2\rangle=(a^2/2M\omega_0^2)\int_0^t\int_0^t e^{-\gamma(t-\tau)}\sin\omega_0(t-\tau)e^{-\gamma(t-\tau')}$$
$$\times\sin\omega_0(t-\tau')\cos\omega_1(\tau'-\tau)d\tau d\tau'.$$

The latter expression can be written in the form

$$\langle\theta^2\rangle=(a^2/2M\omega_0^2)\mathcal{R}e\int_0^t\int_0^t e^{-(\gamma-i\omega_1)\sigma}e^{-(\gamma+i\omega_1)\sigma}$$
$$\times\sin\omega_0\sigma\sin\omega_0\sigma'd\sigma d\sigma'$$
$$=a^2\mathcal{R}eJ(\gamma-i\omega_1)J(\gamma+i\omega_1)/2M\omega_0^2,$$

where $\mathcal{R}e$ indicates the operation "taking the real part of." Applying formula (22) we obtain

$$\begin{aligned}\langle\theta^2\rangle=[a^2/2M\omega_0^2P(i\omega_0)]\Big\{&\omega_0^2+\frac{\omega_0^2+\omega_1^2+\gamma^2}{2}e^{-2\gamma t}\\&+\omega_0\exp[-\gamma(t)](\omega_0+\omega_1)\cos(\omega_0-\omega_1)t\\&+(\omega_0-\omega_1)\cos(\omega_0+\omega_1)t+\omega_0\gamma\exp[-\gamma(t)]\\&\times[\sin(\omega_0-\omega_1)t+\sin(\omega_0+\omega_1)t]\\&+e^{-2\gamma t}\left[\frac{\omega_0^2-\omega_1^2-\gamma^2}{2}\cos2\omega_0t+\omega_0\gamma\sin2\omega_0t\right]\Big\}.\end{aligned}$$

Errors due to the superposition of uncorrelated random processes of known nature, as of the ones described above, can be evaluated by making use of the easily proved fact that the correlation function and, consequently, the mean square errors are in this case additive.

7. ACKNOWLEDGMENTS

The author wishes to thank Dr. S. H. Browne of North American Aviation, Inc., and Mr. S. O. Rice of Bell Telephone Company, for helpful discussion on this subject, and Dr. M. Neustadt of North American Aviation, Inc., for assistance in the preparation of the present paper.

APPENDIX I

On the determination of the auto- and inter-correlation functions of a system of random functions.—Consider the linear combination

$$y(t)=\sum_{i=1}a_i(t)x_i(t),\tag{I}$$

of the random functions $x_i(t)$, the coefficients $a_i(t)$ being (deterministically) known functions. We shall assume the x_i's to be independent of the a_k's. The ensemble average of the product

$$y(\tau)y(\tau')=\sum_i\sum_k a_i(\tau)a_k(\tau')x_i(\tau)x_k(\tau'),$$

will be

$$\Lambda(\tau_1\tau)=\sum_i\sum_k a_i(\tau)a_k(\tau)\Lambda_{ik}(\tau_1\tau'),$$

where Λ is the (auto-) correlation function of y and

$$\Lambda_{ik}(\tau_1\tau')=\langle x_i(\tau)x_k(\tau')\rangle,$$

are respectively the auto- and inter-correlation* functions of the x_i's, according as to whether $i=k$ or i k. It should be noted that unless the random functions x_i, x_k are stationary, $\Lambda_{ik}\neq\Lambda_{ki}$.

The functions Λ_{ik} can then be determined from the experimental determination of ensembles of values $y^{(l)}(t)$ of the linear combination (I) for at least n^2, (or not less than n^2 if some of the processes represented by the x_i's are uncorrelated), properly chosen sets of coefficients $a_i^{(l)}(t)$.** If data for a larger number of sets are taken, the consistency of the hypothesis of the independence of the x_i's upon the a_k's can be verified, and the values of the functions Λ_{ik} can be determined by means of the least square method.

APPENDIX II

On the non-validity of the ergodic hypothesis for the process represented by a linear combination of stationary random functions.—Let $x(t)$ be a stationary random function, that is, a function necessarily satisfying the relation

---

[14] See James, Nichols and Phillips, (reference 2), p. 275.

* This terminology seems more appropriate to the author than the term "cross-correlation function" frequently used.

** The choice is, of course, restricted by the relations to which the members of the sets $a_i^{(l)}(t)$ are subjected.

$$\langle x(t)\rangle = x = \lim_{T\to\infty}\left[\int_{-T/2}^{T/2} x(t)dt/T\right].$$

Consider now the random process defined by the function $a(t)x(t)$, $a(t)$ being a known function. We shall have

$$\langle a(t)x(t)\rangle = a(t)x(t) = a(t)\bar{x},$$

which is, in general, different from

$$\langle ax\rangle = \lim_{T\to\infty}\left[\int_{-T/2}^{T/2} a(t)x(t)dt/T\right].$$

The process represented by $a(t)x(t)$ is therefore not stationary.

It follows that a time dependent linear combination of stationary random functions is not generally stationary.

Design and Performance of a Multicellular Geiger Counter for Gamma-Radiation

David A. Lind
California Institute of Technology, Pasadena, California

(Received October 28, 1948)

The design problems for Geiger counters which have a high gamma-radiation sensitivity are discussed. A description of a Geiger counter consisting of nine individual counters in the shape of pillboxes mounted inside a single envelope is given. The individual pillboxes are 3 inches in diameter. The anode has the shape of a four-pronged spider which is centered in the box. The nine section counter has a flat plateau of about 150 volts, and intrinsic sensitivity of 25 percent. Its lifetime is better than 10^7 counts.

INTRODUCTION

THE problem of a detector with high intrinsic sensitivity for gamma-radiation has not been solved satisfactorily, although, recently the development of the scintillation counter by Deutsch[1] and others has shown considerable promise. Sometime before these developments took place, the same problem presented itself in connection with the curved crystal gamma-ray spectrometer[2] developed in this laboratory. Since the radiation detector was a very important part of the whole apparatus, it was decided to attempt to construct a counter of the Geiger-Muller type but with enhanced sensitivity.

The requirements of the counter were as follows: It must have high sensitivity for gamma-radiations in the energy range 0.025 to 1.0 Mev, and accept an approximately parallel beam about two inches square. Furthermore, a very low background would be desirable, but extremely short counter recovery time would not be necessary on account of low counting rates. It was doubtful if even the scintillation counters could satisfy these requirements, especially the large beam cross section, without considerable development work.

DESIGN

The problem of intrinsic sensitivity of a Geiger counter to radiation is discussed by several authors.[3,4] The intrinsic sensitivity[*] may be represented by the expression:

$$\epsilon(E) = C(\tau R_\tau + \sigma \bar{R}_\sigma + 2\chi \bar{R}_\chi). \tag{1}$$

τ, σ, χ represent, respectively, for photo, Compton, and pair production, the linear absorption coefficients for radiation of energy E in the cathode material. R_τ, $\bar{R}_\sigma$, $\bar{R}_\chi$ represent the mean electron ranges, respectively, for the three corresponding processes. These ranges must be evaluated for the electron energies which result when the initial quantum of energy E interacts with the material. The constant C must be determined experimentally. The expression further assumes that the cathode wall thickness is such that other absorption effects may be neglected. Bradt *et al.*[4] show curves of the dependence of ϵ on E, the quantum energy, and Z, the atomic number of the cathode material, for the optimum design in each case, i.e., when the cathode wall thickness is just equal to the range of the most energetic secondary electrons. Since τ varies as Z^4

[*] By intrinsic sensitivity is meant the fraction of all photons passing through the counter which register counts.

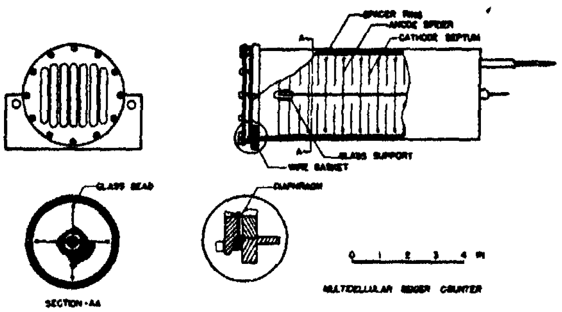

FIG. 1. Schematic drawing of the multicellular Geiger counter showing the main features of construction.

it is advantageous to use plates of high atomic number. On the other hand, if the quantum energy is low, the range of the electrons becomes very small. In this case, it is better to rely on the gas for absorption where every secondary electron produced will register a count.**

It is evident that the efficiency of a counter will vary by a considerable factor especially at low quantum energies. It is impossible to design a single counter of the conventional type, which will have reasonably good efficiency for a wide range of quantum energy, if one must rely only on the cathode for ejection of secondary electrons. Hence, separate counters are used for different energy ranges. In each case the cathode wall thickness is adjusted to some optimum value. The nature of the cathode surface also has an effect on the sensitivity. Evans and Mugele[5] showed that there was considerable advantage in the use of wire gauze for the cathode. This is primarily on account of the increased mass of cathode material effective for production of secondary electrons which penetrate the active volume of the counter. Considering all factors, lead appears to be the best cathode material, providing the natural radioactive contamination can be eliminated. To decrease the effect of this contamination, the plates were silver plated to a thickness of 0.001 inch. The counter designed for optimum sensitivity at 0.5 Mev used a lead cathode of 450 mg/cm^2 surface density. The cathode surface was embossed by rolling it between pieces of 80 mesh wire gauze to increase the surface area.

The counter geometry was such that the sensitive volume had a projected area of at least the cross section of the incident beam of radiation. Consequently, each counter section had the shape of a pillbox approximately three inches in diameter. The anode consisted of a four-pronged spider mounted so the plane of the wires lay midway between the end plates of the box and parallel to them. Electrostatically, the geometry represents a straight wire spaced midway between parallel plates to a fair approximation. A calculation of the field about such a wire leads one to expect a reasonable plateau from this geometry.[6]

The increased sensitivity of the counter is obtained by merely connecting a number of these pill-box counters in parallel in the same envelope. Of course, this arrangement requires that the threshold voltages of the individual sections shall coincide closely enough so that the multicellular counter may exhibit a plateau. This was indeed accomplished by the construction and treatment described below.

CONSTRUCTION

The constructional details of the counter are shown in Fig. 1. The case is made of Shelby tubing, 3 inches inside diameter and 8 inches long, to which an end plate was silver soldered in a hydrogen furnace. The end plate carried the pumping lead and a Stupakoff glass insulator bushing for the central wire. The opposite end was fitted with a flange and a grill to support the 2 mil nickel foil window. The seal was made with an aluminum or lead wire gasket in a vee groove as shown in the detail view. The clamping ring was a grill identical to the inside one. This furnished support to the window which allowed the unit to be pressure tested for leaks. This method of construction permitted rapid opening and resealing of the unit and has given no trouble whatsoever.

The counter sections themselves consisted of circular disks of silver-plated wire gauze or lead sheets 3 inches in diameter. At the center a $\frac{3}{8}$ inch hole was punched to allow the supporting rod for wire spiders to pass down the axis. The spiders

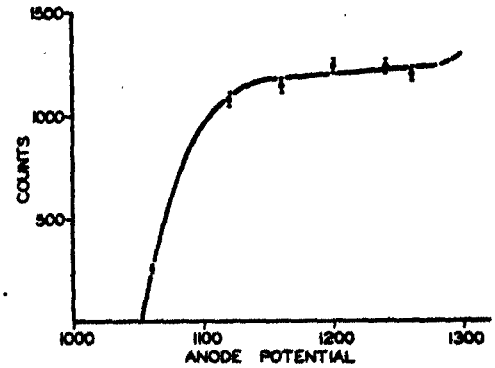

FIG. 2. The counting characteristic for a counter of nine sections.

** Mr. W. West of this laboratory has succeeded in making xenon-argon petroleum ether filled counters operate satisfactorily with high quantum efficiency up to about 0.070 Mev energy.

[5] R. D. Evans and R. A. Mugele, Rev. Sci. Inst. 7, 441 (1936).

[6] S. C. Curran and J. M. Reid, Rev. Sci. Inst. 19, 67 (1948). In this paper several different counter geometries and the plateau to be expected are discussed.

consisted of four radial 0.01 inch tungsten wires, silver soldered to a monel tube 0.050 inch outside diameter. The tips of the wires were beaded with glass to prevent discharge at these points. Each spider was etched by a.c. electrolysis in NaOH solution to clean the wires of all scale and sharp points. A 0.040 inch drill rod was soldered in the Stupakoff bushing and extended down the axis of the counter. As each disk was set in the counter, a spider was slid on this central rod and centered between each pair of disks. In this manner, a maximum of nine complete sections was built up in the cylindrical envelope. The free end of a central rod was supported in a glass bushing to keep the spiders centered on the axis.

No special treatment was given the counter once it was assembled. Of course, during assembly great care was taken to exclude any foreign matter. The counter was merely pumped out and tested to assure that no leaks were present and then filled with a 3 percent mixture of petroleum ether and argon to 20 cm of mercury. It was necessary to wait several hours at least before the counter became stable, but thereafter, the threshold and plateau were quite constant. Furthermore, the characteristics of several counters of this type could be made nearly identical.

PERFORMANCE

The threshold of the counter was about 1100 volts. As Fig. 2 shows, the plateau was flat to about 5 percent per hundred volts and had a length of 150 volts. These characteristics are independent of whether a quench circuit was used or not. The lifetime of the counter was of the order of 10^7 counts, at least.

The efficiency of two of the nine section counters was measured by a coincidence technique using annihilation radiation (0.51 Mev) and found to be approximately 25 percent averaged over the whole face of the counter. Tests made with a collimated pencil of gamma-radiation from a radium source showed that the sensitivity was almost constant over the entire face with the exception of the axis of the counter where the cathode plates were punched out.

The pulses from the nine section counter are not uniform in height, but over the plateau they have a certain minimum height which, of course, increases with the over-voltage. Because of the relatively large capacity of the wire, it is desirable to use a circuit which is a little more sensitive than those ordinarily used. An interesting observation was made on the pulses from a single counter section. The pulse heights are distributed as 1:2:3:4; the interpretation is that the pulse height is just proportional to the number of wires which discharge. The methods by which the discharge spreads are two. The initial ionizing event may produce ions in the vicinity of one or more wires, or the discharge which is propagated by photon emission[7] along one wire may also be propagated from one wire to the others by the same mode. The number of pulses of each height decreases as the height increases.

FIG. 3. Photograph showing the multicellular counter and a bank of six anticoincidence counters in the lead housing.

In the application for which the counter was intended, it was important that the background be as low as possible. If cosmic-ray counts are subtracted by means of a battery of six conventional counters, placed in an arc situated immediately above the gamma-ray counter and connected so as to operate the scaling circuit in anticoincidence with the latter, the background per counter section, when shielded by four inches of lead, is about 11 counts per minute. Figure 3 shows the counter and its anticoincidence counters in the lead housing. There could be some decrease in this rate if the axial dimension of the individual counter sections could be decreased. Spacings of 0.375 inch between the cathode plates have been used but, as would be expected, the operation is somewhat more satisfactory with the larger spacing.

The counter has a sensitivity for gamma-radiation comparable with a good scintillation detector. However, its greatest advantage is that the sensitive volume has a relatively large cross-sectional area. The construction is rather easy and the performance comparable with Geiger counters of more conventional geometry.

The author wishes to acknowledge the assistance of Dr. J. W. M. DuMond under whom the work was carried out. The work was supported by the Office of Naval Research under Contract N6onr-244 Task Order IV.

THE REVIEW OF SCIENTIFIC INSTRUMENTS VOLUME 20, NUMBER 4 APRIL, 1949

The Maxwell Bridge at Low Frequencies

Vinton A. Brown and B. P. Ramsay
Naval Ordnance Laboratory, Silver Spring, Maryland

(Received August 2, 1948)

The Maxwell bridge has been found useful for measuring inductance L and a.c. resistance R_{ac} at periods from 0.01 sec. to 200 sec. In some applications, the inductors had solid ferromagnetic cores and inductances of several hundred henries. The effect upon the bridge circuit of induced currents in the ferromagnetic material is expressed as a first approximation in terms of the equivalent mutual inductance M. The resulting equations expressing the frequency dependence of L and R_{ac} are in qualitative agreement with experiment. Because of harmonic frequencies generated by magnetic hysteresis, the bridge cannot be completely balanced when measuring L and R_{ac} of ferromagnetic-cored inductors. Analysis of the precision of measurement indicates that the effect of the residual voltage at best balance is a reduction in bridge sensitivity. Factors determining the choice of bridge resistors and of balance indicator are discussed, and typical graphs of L and R_{ac} as functions of frequency are presented.

INTRODUCTION

THE Maxwell bridge (Fig. 1) is a well-known circuit for the measurement of capacitance or inductance and a.c. resistance. The series combination of inductance and resistance in one arm is balanced by the parallel grouping of resistance and capacitance in the opposite arm. The equation of balance of the general four-arm bridge,[1] of which the Maxwell bridge is an example, is

$$Z_1Z_4=Z_2Z_3, \tag{1}$$

where the Z's are the complex impedances of the respective arms. Substitution of the appropriate expressions for the impedances of the arms of the Maxwell bridge yields the equation

$$(R_1+j\omega L_1)\left(\frac{R_4/j\omega C_4}{R_4+(1/j\omega C_4)}\right)=R_2R_3. \tag{2}$$

The real and imaginary components of this equation are the familiar equations of balance,

$$R_1R_4=R_2R_3, \tag{3}$$

$$L_1=R_2R_3C_4. \tag{4}$$

Thus inductance may be measured in terms of capacitance, or *vice versa* by means of Eq. (4). If the unknown is an inductance, Eq. (3) yields its a.c. resistance R_1, at the frequency and excitation of measurement. If R_1 and L_1 are independent of frequency and excitation, Eqs. (3) and (4) express the balance conditions for all frequencies and excitations. If not, R_1 and L_1 must be considered to be the effective series resistance and inductance at any particular frequency and excitation; Eqs. (3) and (4) then specify the conditions of balance at that frequency and with that excitation only. In either case the balance is complete; that is, an indication of null voltage is always obtainable by proper adjustment of R_2, R_3, R_4, and C_4.

In its usual application the Maxwell bridge is employed at audiofrequencies. Its proven range of usefulness has been extended in measurements at

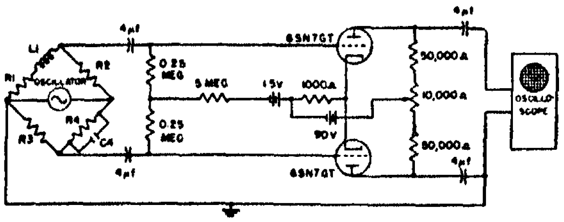

FIG. 3. Balanced amplifier for use with cathode-ray oscilloscope as balance indicator.

the Naval Ordnance Laboratory to frequencies as low as 1/200 cycle per second. In most of these applications, the unknowns were induction coils having solid ferromagnetic cores and inductances of several hundred henries. The effect of eddy currents in the ferromagnetic core upon the balance of the bridge is represented schematically in Fig. 2 by means of a coupled secondary circuit. The current i_5 in the secondary circuit consisting of inductance L_5 and resistance R_5 is a simplified representation of the continuum of eddy currents circulating in the solid core. The equations of balance of this circuit are derived as follows.

EFFECT OF MUTUAL INDUCTANCE

Reference to Fig. 2 shows that the voltage e_1 across the inductive arm is

$$e_1=(R_1+j\omega L_1)i_1+j\omega M i_5. \tag{5}$$

Application of Kirchhoff's law to the secondary circuit gives

$$0=(R_5+j\omega L_5)i_5+j\omega M i_1. \tag{6}$$

Hence the impedance Z_1 of the inductive arm is

$$Z_1=\frac{e_1}{i_1}=R_1+j\omega L_1+\frac{\omega^2M^2}{R_5+j\omega L_5}. \tag{7}$$

Thus Eq. (1) becomes

$$\left(R_1+j\omega L_1+\frac{\omega^2M^2}{R_5+j\omega L_5}\right)\frac{R_4/j\omega C_4}{R_4+(1/j\omega C_4)}=R_2R_3. \tag{8}$$

Separation of reals and imaginaries yields the equations of balance,

$$R_5(R_1R_4-R_2R_3)=\omega^2R_4[L_5(L_1-R_2R_3C_4)-M^2], \tag{9}$$

$$L_5(R_1R_4-R_2R_3)=-R_4R_5(L_1-R_2R_3C_4). \tag{10}$$

It is evident that the conditions of balance for the Maxwell bridge will satisfy Eq. (10). Equation (9), however, becomes

$$0=-M^2\omega^2R_4. \tag{11}$$

Thus, Eq. (9) is not satisfied by Eqs. (3) and (4) except under the trivial condition described by Eq. (11).

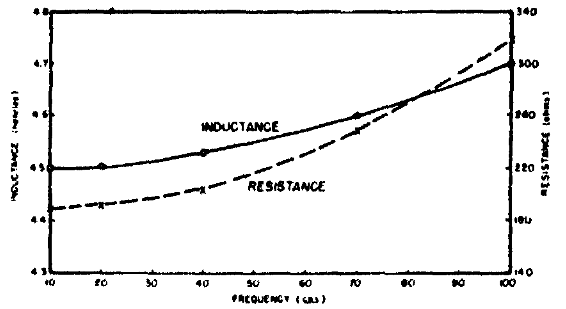

FIG. 4. Inductance and a.c. resistance of a 20-ft. square Helmholtz coil system. 300 turns per coil.

The condition which prevails when the trivial solution is eliminated from consideration can be clarified by separating the adjustable bridge parameters R_2, R_3, R_4, and C_4 from those which are characteristic of the induction coil, namely, R_1, L_1, R_5, L_5, and M. Simultaneous Eqs. (12) and (13) in which this separation is effected follow directly from Eq. (8).

$$R_1+R_5(\omega^2M^2/R_5^2+\omega^2L_5^2)=(R_2R_3/R_4), \tag{12}$$

$$L_1-L_5(\omega^2M^2/R_5^2+\omega^2L_5^2)=R_2R_3C_4. \tag{13}$$

Since L_1 is the inductance and R_1 is the a.c. resistance of the coil in the absence of eddy currents, the effective inductance L and a.c. resistance R of the coil with a conductive core are shown by Eqs. (12) and (13) to be

$$R=R_1+R_5(\omega^2M^2/R_5^2+\omega^2L_5^2), \tag{14}$$

$$L=L_1-L_5(\omega^2M^2/R_5^2+\omega^2L_5^2). \tag{15}$$

This presentation indicates that the a.c. resistance R of a coil with a conductive core will increase with frequency more rapidly than R_1, the a.c. resistance of the coil exclusive of the effects of eddy currents in the core. However, the inductance L of the coil with conductive core is less than L_1, the inductance exclusive of the effects of eddy currents in the core. Equation (15) does not indicate that the inductance of a coil with a conductive core is less than that of an air-cored coil, but it does show that the inductance of a coil with a metallic core is reduced by the effects of eddy currents. Since only eddy-current effects are included in these equations, they are not sufficiently inclusive to describe all effects which are observed with coils having ferromagnetic cores. In particular, they do not take into account the generation of harmonics of the fundamental frequency which result from magnetic hysteresis. Because of hysteresis, a complete balance of the bridge cannot be effected by any adjustment of R_2, R_3, R_4, and C_4 in the case of coils with ferromagnetic cores.[2]

---

[2] A similar conclusion applies to A. T. Starr's bridge (Phil. Mag. 12, 265–280 (1931)), in which the mutual inductance is

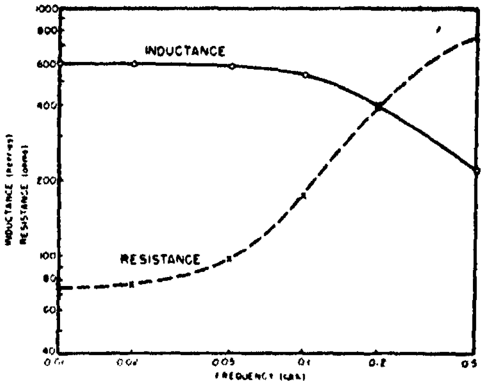

FIG. 5. Inductance and a.c. resistance of search coil with solid ferromagnetic core.

In spite of the impossibility of completely balancing the Maxwell bridge when magnetic hysteresis is present, the conventional Maxwell bridge has been employed for the measurement of L and R_{ac} of ferromagnetic-core inductors on the assumption that the equations of balance [Eqs. (3) and (4)] are applicable when the a.c. voltage drop across the indicator is a minimum. The justification for this assumption is the smallness of the hysteresis effect in comparison with that of inductance. For example, at a period of 10 seconds, the minimum peak-to-peak indicator voltage was 1/1000th of the voltage developed across the inductor. Hence it is concluded that the imperfection of the balance is not sufficient to materially affect the applicability of the usual equations of balance to the problem of determining L and R_{ac}. The precision of measurement is reduced, however, by the residual voltage at best balance, which reduces the sensitivity of the bridge, as shown in the following discussion.

BRIDGE SENSITIVITY

The definition of sensitivity of a Maxwell bridge for which a complete balance cannot be obtained may be developed along lines followed in treating the conventional bridges.[8] With R_4 and C_4 dials set at the positions of best balance, the voltage V_i across the indicator terminals is a minimum. If either dial is displaced from this position while the other remains at its position of best balance, the change ΔV_i in indicator voltage is directly proportional to the deviation in impedance Z_4 from the balance setting, provided this deviation ΔZ_4 is small. Hence,

$$\Delta V_i = SV_g\Delta Z_4, \tag{16}$$

where V_g is the generator voltage. The proportionality factor S, which is a function of frequency, is known as the sensitivity of the bridge. This relation, in the form

$$\Delta Z_4 = (\Delta V_i/SV_g) \tag{17}$$

determines the minimum detectable increments in R_4 and C_4, provided ΔV_i is here considered to be the least change in indicator voltage that can be distinguished from spurious fluctuations. Thus the minimum increments ΔR_4 and ΔC_4 depend upon the following factors:

(1) Sensitivity of the indicator, a factor in determining ΔV_i.
(2) Magnitude of spurious voltage fluctuations relative to V_g, which contributes to $\Delta V_i/V_g$,
(3) Bridge sensitivity S.

In practice, obtaining sufficient indicator sensitivity presents no problem. Experience indicates that it is the magnitude of spurious voltage fluctuations arising in electronic and mechanically driven oscillators at the low frequencies considered here which is the principal limiting factor in the determination of the accuracy of the measurements. If it were possible to obtain a perfect balance independent of frequency, the anomalies in generator voltage would not be detectable at balance. In the actual case, the imperfection of balance reduces the accuracy of measurements to a value determined by the magnitude of the fluctuations in indicator voltage at best balance. The accuracy attained is estimated to be ±2 percent at a period of 1 sec., and ±5 percent at 100 sec.

BRIDGE DESIGN

Choice of resistances for the bridge was based upon several considerations. (a) Since available variable condensers have small capacitance, the value of the product R_2R_3 by which C_4 is multiplied to obtain L_1 must be large to permit measurement of inductances in the range of interest, that is up to 800 henries. (b) It is of course desirable that the factor R_2R_3 have a simple numerical value, in order that inductance may be read off at once from the condenser setting. (c) For maximum bridge sensitivity, R_2 should be of the same order of magnitude as R_1 which, in the applications of greatest interest, was approximately 100 ohms. Such a small value of R_2 would require that R_3 be as large as several megohms. This would introduce leakage problems. To avoid such difficulties R_2 and R_3 were fixed at 20,000 ohms each. The value of the inductance in henries is then 400 times the capacitance in microfarads.

As constructed, the bridge incorporates a decade resistance box as R_4 and a decade condenser as C_4. For measuring inductances above 400 henries, capacitance C_4 is increased to a maximum of 2.11 μf by shunt connection of an auxiliary 1-μf standard condenser. A rheostat controls the current through the bridge, which is ordinarily limited to

---

balanced by modification of the opposite arm so that it becomes the inverse network of the inductive arm. In the presence of a ferromagnetic core, the capacitors in the inverse network do not compensate for the effects of magnetic hysteresis.

[8] See reference 1, pp. 81–85.

40 μa in order to avoid saturation of the ferromagnetic cores of induction coils under test.

The galvanometer need not be one of especially high sensitivity since a minimum deflection of appreciable magnitude, rather than a null, is obtained. The galvanometer's natural period of vibration, however, is fairly important. A portable spotlight galvanometer of 2-sec. period has been found satisfactory at a.c. periods up to 10 sec. For longer periods of the applied voltage, a ballistic galvanometer of natural period 30 sec. has proved more useful, as it smooths out the minor fluctuations in the mechanically driven power supply.

A type of indicator which has proved useful in a somewhat higher frequency range, namely from 1 to 100 c.p.s., is the cathode-ray oscillograph and an appropriate amplifier (Fig. 3). In order to permit the use of a grounded oscillator and a grounded oscilloscope, the input circuit of the amplifier is balanced relative to ground and one side of the amplifier output circuit is grounded. This apparatus has been used in measuring inductance and resistance of large magnetic generators[4] of which the conventional Helmholtz coil and the solenoid are familiar examples.

TYPICAL MEASUREMENTS

Figure 4 presents as typical results, the inductance and a.c. resistance of a 20-ft. square Helmholtz coil system. Both inductance and resistance, which are apparent values, increase with frequency as predicted from consideration of the effect of distributed capacitance.[5]

Figure 5 shows the inductance and resistance of a typical search coil having a solid ferromagnetic core. Resistance increases with frequency because of the effect of eddy currents, as predicted by Eq. (14), and also because of the effect of distributed capacitance. Inductance decreases with increasing frequency, in accordance with Eq. (15). The decrease in inductance is attributed to eddy currents, which delay the penetration of the magnetic field into the interior of the core so that the field strength in the interior is less than the field strength at the surface.[6] The magnetic induction and the inductance are thereby reduced. The agreement of the observed frequency dependence of inductance and resistance with the predictions of Eqs. (14) and (15) justifies the first approximation concept of eddy-current effects in terms of mutual inductance.

THE REVIEW OF SCIENTIFIC INSTRUMENTS VOLUME 20, NUMBER 4 APRIL, 1949

Methods for Reducing Insulator Noise and Leakage

F. M. Glass
Instrument Department, Oak Ridge National Laboratory, Oak Ridge, Tennessee

(Received December 14, 1948)

A recent study of the insulator problem involved in radiation detection instruments disclosed the fact that insulators, in high impedance input circuits, are the predominate source of background noise when subjected to high voltages and high humidities. Methods for eliminating this trouble in some of the commonly used circuit components, and new and superior insulating materials, were found.

SERIOUS insulation problems have arisen with the widespread use of radiation detection instruments. In certain types of detection devices such as alpha-chambers, proportional counters, and electrometers having high input impedances, the necessity for good insulators cannot be overemphasized. In many instances where background noise is of sufficient amplitude to make accurate counting difficult or impossible, the spurious counts can be traced to insulator noise. However, as a result of experience with past applications of insulators in the electronic field, engineers are prone to take the quality of insulators for granted. Even if the best insulating materials available are selected, the insulator may be made into a constant source of trouble by improper milling or molding technique. It is the intent of this article to point out some of the insulator troubles encountered and to suggest some preventive measures.

Let us consider some of the common circuit components that are a potential source of trouble as a result of poor insulation. Figure 1 shows a conventional preamplifier for use with an alpha-chamber or proportional counter. In the grid circuit we note that the filter condenser, C-1, the coupling condenser, C-2, and any other supporting insulators

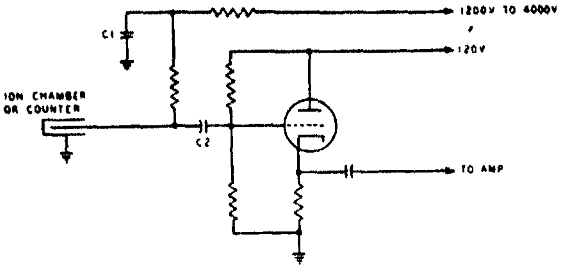

FIG. 1. Conventional preamplifier circuit for radiation counters.

in the chamber or cable and cable connectors are subjected to high voltage. All these components are possible noise makers, especially in the presence of high humidity. Since the humidity is not always a controllable factor in the use of radiation detection instruments, it is necessary to provide insulators which are noise-free at humidities approaching saturation.

DESCRIPTION OF TEST

In order to determine the pulse characteristic, frequency, and cause of insulator noise in such circuits as Fig. 1, a series of tests were made under simulated operating conditions. The equipment used in these tests consisted of an Oak Ridge National Laboratory A-1 amplifier[1] and preamplifier with a combined voltage gain of 300,000, a 5000-v power supply, a 248 DuMont oscilloscope, a Higinbotham scaler,[2] a Tobe line filter, and a humidity controlled test chamber (see Fig. 2). The test chamber was constructed with two compartments. One of these contained the high voltage filter in dry air to prevent surface noise on the $0.01\text{-}\mu F$ 10,000-v Glassmike filter condenser.[3] The other compartment, in which the insulator under test was placed, was humidity controlled. A special noise-free feed-through insulator that could take 5000-v at 96 percent humidity was used to feed the 5000-v through the partition. A hygrometer mounted on the side of the chamber and extending through the wall made it possible to keep a constant check on the humidity. The humidity was controlled by passing dry or saturated air through two valves provided for that purpose. A small fan motor on top of the chamber, with the shaft extending through an air-tight seal, drove a small fan which thoroughly mixed the incoming air. This arrangement provided a means for testing an insulator at any given humidity, and at the same time maintained a zero-count background.

It was observed that all insulator noise could be traced to one of four sources. The first and most annoying source of noise in good insulators is surface noise resulting from high humidity. When the insulator is subjected to high voltage, random pulses are produced with characteristics so nearly like those from ionization chambers, and with amplitudes of such height as to make it impossible to discriminate against them, when counting pulses of low amplitude. These pulses have a rise time of $\frac{1}{8}$ microsecond or less, and amplitudes as high as 3 millivolts.[4] Since shot effect and thermal noise in well designed amplifiers may be as low as 3 microvolts r.m.s. or lower, depending on band width, it is quite obvious that defective or noisy insulators may well be the determining factor in the effective sensitivity of the amplifier.

The second source of noise, although annoying, need not be a serious handicap. It is caused by a change in dielectric strain resulting from a sudden change in voltage across the insulator. This noise appears to be piezoelectric pulses resulting from discontinuity in the mechanical motion of the dielectric when seeking equilibrium. As a rule this phenomenon is more pronounced in materials of crystalline structure. However, ceramics, being comparatively free of this noise, are an exception. Only insulating materials considered suitable for radiation detection instruments were tested for this source of noise. Mica was found to produce the most pulses, while teflon[5] fluorothene[6] and polyethylene produced no pulses. This noise is relatively unimportant in any insulator if the high voltage is turned on one or two minutes before the instrument is put in use, and if no sudden changes of voltage greater than 100-v occur while in operation. (See Fig. 3.)

The third source of noise may offer some difficulty unless a few simple precautions are taken. It is most pronounced in polystyrene or polystyrene substitutes and results from stresses set up in machining. Annealing these materials at 65°C for an hour or more will sufficiently relieve them of stresses set up in the machining processes. These stresses can be visually recognized by use of crossed polaroids. After the insulator has been annealed, care should be exercised in mounting to prevent unnecessary mechanical strain. If these two precautions are taken, the insulator will be free of noise as a result of mechanical stresses.

The fourth source of insulator noise results from leakage through the insulating material. The chief offender among frequently used insulating materials is mica-filled Bakelite. This noise is not present in high grade insulating material such as polystyrene, mica, and teflon and fluorothene. Since it is assumed the designer will use only good insulating materials, this article will carry no further discussion on this type of noise.

CABLE CONNECTORS

Cable connectors head the list of trouble makers. Many of the commercially available connectors were tested and none of them were found satisfactory for pulse work when subjected to high voltages and high humidities. The results of these tests are shown in Table I. This table shows the average counting rate for five samples each of the connectors tested. Pulses were recorded over a period of ten minutes for each individual test. Each time the voltage was advanced, a two-minute delay was made before starting the next count. This prevented the recording of counts as a result of change in dielectric strain.

TABLE I. Table shows pulse repetition rate of cable connectors as a function of voltage and humidity.

Sample	Voltage	Pulses/min. at 5% humidity	60%	90%
Amphenol 93-C and 93-M	1500	0	0	7
	3000	0	0.2	420
	5000	0	2.5	>60,000
Amphenol-P. L. 259	1500	0	0.2	420
	3000	0	64	>60,000
	5000	0	498	>60,000
Cannon Q-1-22C and Q-1-SL	1500	0	0	68
	3000	0	0	>60,000
Q-1-22C with polystyrene insulation installed in place of original insulation	5000	0	>60,000	>60,000
Amphenol A.N. No. UG-58U	1500	0	0	4470
	3000	>60,000	>60,000	>60,000
	5000	>60,000	>60,000	>60,000
Amphenol 83-1SPY	1500	0	0	>60,000
	3000	8	8	>60,000
	5000	51	81	>60,000
Amphenol 83-1SPN with phenolic insulation	1500	50	571	704
	3000	25,600	>60,000	>60,000
	5000	>60,000	>60,000	>60,000

As a result of these tests, engineers at Amphenol, working with the Oak Ridge National Laboratory, developed a pulse fitting that is noise-free at 5000-v and 96 percent humidity. This cable connector has teflon insulation which can be successfully cleaned when it gets dirty. The minimum surface leakage path is ½″. The shell has spring fingers for low impedance ground connections, and the center connector is designed to give corona-free service. The Amphenol stock numbers on these connectors are 82-804 and 82-805.[7]

COUPLING CONDENSERS

The data obtained from tests run on coupling condensers were even more discouraging than that obtained from the cable connector tests. However, the noise was eliminated without design changes. Only two of the many condensers tested showed any promise of being satisfactory. Centralab's type #850 high voltage ceramic series[8] were by far the best condensers tested. They were found to be entirely satisfactory at low humidities but very unsatisfactory at high humidities. Table II shows some of the data obtained from this test. Since these condensers are noise-free in dry air, a search was made for a method of surface treating the ceramic shell to make it less hygroscopic.

Silicones were discarded because the temperature necessary for baking exceeds the melting point for the soft solder used in the condenser assembly. Since it had already been demonstrated that a good polystyrene surface produced no pulses, several attempts were made to coat the ceramic shell with polystyrene. A successful method was finally worked out, and is described as follows:

(1) The condenser is washed in petroleum ether, or benzene, then in 180-proof ethyl alcohol, and finally rinsed in distilled water.

(2) It is then baked in a vacuum oven for about one hour at 100°C, after this the oven is cooled to 60°C and dry air admitted.

(3) The condensers are removed from the oven and while still warm, dipped in Amphenol 912 coil dope that has been cut by adding an equal quantity of 916 thinner.

(4) They are then air-dried for 2 hours and baked at 60°C for one hour. The condensers can then be soaked in water for several hours and tested at 90 percent humidity at 5000 v and no pulsing will occur.

FILTER CONDENSERS

Another source of trouble has been filter condensers. The Glassmike, Plasticon ASG, silicon-filled, made by Condenser Products Company, seems to be the most promising condenser for high

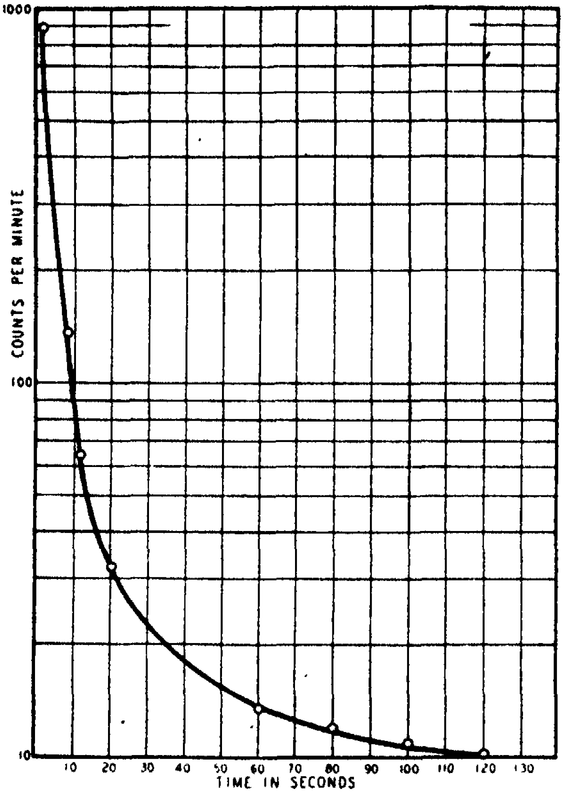

FIG. 3. Curve showing pulse frequency decay with time, resulting from a sudden 1000-v change in voltage across a 0.0001-μf, 2500-v silver-mica condenser.

voltage applications. These condensers produce no pulsing internally, but give considerable trouble on the shell surface at high humidities. However, if the shell is properly cleaned, no trouble will be encountered below 3000 v at any humidity. Alcohol alone will not do the job, as it is not a good solvent for the flux that is used in soft soldering the ends on the glass case. To clean these condensers properly, carbon tetrachloride should be used first to remove the flux. Then they should be washed thoroughly in alcohol. If voltages higher than 3000 v are used, the surface can be further improved temporarily by applying a very thin coat of ceresin wax. This is accomplished by dissolving a piece of ceresin the size of a pea in about four ounces of benzene and dipping the condenser in the solution. The condenser will then stand 5000 v at 90 percent humidity without pulsing. This surface, if not protected from dust, will soon be inferior to the plain glass surface that has been well cleaned. Therefore, if voltages lower than 3000 v are used, it is strongly recommended that no ceresin be applied.

TABLE II. Table shows pulse repetition rate of condensers as a function of voltage and humidity.

Sample	Voltage	Pulses/min. at 5% humidity	60%	90%
50-uuf Centralab ceramic not treated	1000	0	0	128
	3000	0	28	>60,000

0.01 microfarad 5000-v Glassmike condenser	1500	0	0	0
	3000	0	0	0
	5000	0	0	1

STAND-OFF INSULATORS

At the present there are no stand-off or feed-through insulators on the market that are noise-free. They should be machined from teflon or fluorothene, or molded from polystyrene, if possible. If molded from polystyrene, the molds should be so constructed that the use of wax is not required for unloading the mold. The mold should have an optical finish, and be kept immaculately clean. From the standpoint of surface noise, the insulator cannot be any better than any foreign materials that might be deposited on the surface. If teflon or fluorothene is used, it can be easily machined, and no polishing is required. The only precautions necessary are to use a clean cutting tool and to prevent the finished insulator from coming in contact with the hands or anything dirty or greasy. When machining and polishing polystyrene the following techniques will produce good insulators.

(1) When turning on a lathe, as little chuck pressure as possible should be employed, and the stock material within one-half inch of the chuck is not considered usable. With a milling machine one must use as little clamp pressure as possible and take only light cuts to prevent setting up mechanical stresses.

(2) A sharp cutting tool that has been thoroughly cleaned with alcohol must be used. Sapphire cutting tools are recommended.

(3) Polishing is done slowly with emerald or diamond powder and distilled water, using a clean lint-free rag. Chamois is not used as there is always some oil present. Slow polishing speeds are required to prevent surface heating and consequent imbedding of the polishing agent. Powdered carborundum may be used with extreme care to prevent overheating. *Note:* It is almost impossible to get a pulse-free surface using metallic oxide polishing agents.

(4) The insulator is then polished with talc until an optically polished surface is obtained.

(5) The insulator is then removed from the lathe with clean padded tongs and dropped in a container of distilled water until ready for use. The hands should never come in contact with the insulator during the milling or polishing process. Once dirty, no satisfactory method of cleaning polystyrene insulators has been found.

(6) When the insulator is ready for installation it should be removed from the jar of distilled water and rinsed thoroughly in fresh distilled water and dried in a vacuum oven.

Note: Almost all surface leakage is a result of poor polishing technique or mishandling the insulator after it leaves the machine shop.

SELECTOR SWITCHES

High input impedance electrometers place the same exacting demands on insulators as do the input circuits of high gain amplifiers. In addition to the circuit components already mentioned as sources of trouble, we have the problem of procuring a good selector switch for changing input resistors to the electrometer. These switches often must have a d.c. leakage resistance exceeding 10^{15} ohms at humidities as high as 90 percent. They must be comparatively free of contact and stress potentials. It is also often desirable that they be compact for use in portable test equipment. Efforts to obtain these switches commercially have been unsuccessful. Therefore an intensive study of the commercially available switches was made to determine the feasibility of altering or surface treating the most promising of these so that they would fulfill our needs. Centralab's ceramic series, the most promising of the commercially available switches, was studied first. These switches were found to be very good from the standpoint of contact and stress potentials. Tests were then run on leakage resistance, and very discouraging results obtained. Tests in a humidity controlled test chamber showed the resistance to vary from 5×10^{14} ohms at 2 percent humidity to 8×10^{12} ohms at 90 percent humidity. This indicated that if the switch were properly cleaned and sealed against moisture, the insulating properties of the ceramic would be satisfactory for our present needs. Other minor changes in the switch assembly made further improvement by lengthening the shorter leakage paths. After these switches had been treated according to the following process, the leakage resistances exceeded 10^{15} ohms and were independent of humidity.

(1) The switch assembly should be removed from the indexing assembly and cleaned thoroughly with carbon tetrachloride and a stiff brush, then rinsed thoroughly in ethyl alcohol, followed by a distilled water rinse.

(2) The assembly is then baked for 2 hours at 100°C under vacuum, after which dry air should be admitted.

(3) The switch is then removed from the vacuum oven and dipped while still hot in Amphenol 912 coil dope that has been thinned with two parts of Amphenol 916 thinner, agitating it until all the bubbles which form on the ceramic surface are gone. After dipping, it will be necessary to sling off all excess coil dope.

(4) After allowing the switch to dry for 20 minutes in clean, dust-free air, the rotor should be rotated with a clean screw driver to remove the coil dope from the contacts.

(5) After the switch has dried for three additional hours, the switch may be assembled using a polystyrene connecting link or shaft between the indexing assembly and the switch assembly. The metal spacers should also be replaced by spacers made from ¼″ polystyrene dowels ⅜″ in length, drilled and tapped for 5–40 screws. *Caution:* Do not drill all the way through the dowel or spacer as this provides another surface leakage path. Surfaces should be well polished. Also, the hands or anything that is greasy or dirty must not be allowed to come in contact with the ceramic insulation at any time after starting the cleaning process. Switches should be kept in dust-proof containers until such time as they are used. If these suggestions are followed carefully these switches will be found to have a leakage resistance exceeding 10^{15} ohms regardless of humidity. Some of these switches have been in service for ten months and still appear to be satisfactory.

METAL-TO-GLASS SEALS

Other insulators that play an important part in many detection devices are metal-to-glass (Kovar) seals. They are often used in metallic chambers to support the center electrode. Fortunately this type of glass is free of noise if properly cleaned and installed. One successful method of cleaning is to remove all traces of flux from the surface with Zapon #5 thinner, then wash in alcohol and rinse in distilled water. Dry in a vacuum oven, if available. Seals having a flash-over voltage rating of eight times the operating voltage, should be used to insure noise-free operation. If these precautions are taken, no trouble should be encountered with these insulators.

CONCLUSIONS

Insulator noise presents a difficult problem. Especially is this true when the counter voltage exceeds 1500 v and the humidity is above 60 percent. Under such conditions the problem becomes extremely difficult when counting pulses of amplitudes less than 150 microvolts. When accurate counting at low rates is required, it should preferably be done in an air conditioned room, with a humidity not exceeding 50 percent. The insulators should be designed to offer a minimum surface leakage path of ½″. The number of parallel leakage paths should be held to a minimum. From the standpoint of economy and performance, teflon or fluorothene insulation should be used. The labor cost for machining teflon or fluorothene is about 10 percent of that required for machining and polishing polystyrene. These materials produce fewer pulses as a result of mechanical or dielectric strain, and produce far less surface noise at high humidity. If a polystyrene insulator is accidently touched by the hand, it is ruined. Teflon and fluorothene, on the other hand, may be successfully cleaned many times. Neither type of insulator should be dried by rubbing with a cloth as this charges the insulator causing it to attract dust. Only extreme care and patience will solve the insulator problem in radiation detection instruments.

The author takes this opportunity to thank Mr. P. R. Bell of Oak Ridge National Laboratory for bringing to the author's attention the need for this investigation and for the many helpful suggestions which he contributed.

Conversion of a Motor Generator into a Low Noise Power Amplifier

H. S. Sommers, Jr., P. R. Weiss, and W. Halpern*
Department of Physics, Rutgers University, New Brunswick, New Jersey

(Received November 16, 1948)

The noise output of motor-generator sets is so large as to impair their use in precision control work. This paper describes a method for reducing this noise by incorporating a motor generator in an electronic feed-back circuit. The method is based on the use of a high frequency output channel in parallel with the generator to permit cancellation of the higher harmonics of the noise. Design, construction, and performance of an amplifier based on a ⅓-kw M-G set are described. The noise output of this unit is ⅕ percent of the normal noise of the generator.

A. INTRODUCTION

Problem

FOR certain types of physical measurements—for instance, in magnetic measurements requiring a controllable field and in calorimetry—it is necessary to hold a direct current constant to a high degree of precision. If the load impedance is sufficiently high and the power requirement not exorbitant, precision control can be achieved with feed-back circuits using vacuum tubes throughout.[1,2] No high fidelity feed-back control has yet been described in the literature for these cases where it is not practical to drive the load from vacuum tubes. Conventional controls for cyclotrons or mass spectrographs,[3,4] for example, are limited in both their precision of control and speed of response. This is because available high power sources are not suitable for incorporation in high gain, fast acting feed-back circuits. Generators or thyratrons give trouble because of their inherently large output ripple; this noise may produce unwanted fluctuations in the load current, but more important, it introduces large signals into the feed-back amplifiers which can overload and block them. This latter difficulty limits the possible feed-back gain and hence the quality of control achievable. On the other hand, the size, expense, and upkeep of a storage battery make it undesirable when the power requirements are high.

The present paper describes a practical method of converting a motor generator into a low noise, constant gain power amplifier. Our particular problem has been the development of a current regulator for a 40-kw electromagnet to facilitate its use in the study of the shape of the lines due to resonance absorption by nuclear magnetic moments. The circuits here described apply to a small pilot model generator which excites a magnet; however, they are being adapted to the generator for the large magnet. The method used and the bulk of the circuits have a much wider application than this, for they can be applied to other types of load and other power levels by appropriate scaling of the power stage and the filters.

TABLE I. Power amplifier—noise output.

Frequency	Generator output noise Without feedback	 With feedback	Reduction factor
30–60 c.p.s.	0.40 v r.m.s.	0.15×10^{-3} v r.m.s.	2500
below 1500	0.50	0.50	1000
all frequencies	0.65	1.3	500

Generator Noise

Table I gives the principal harmonic components in the output of the generator used in our pilot model. The largest components are nearly one percent of the generator output. The frequencies of the noise are harmonics of the rotational speed of the machine and are associated with assymetries in the armature and field and with the commutator segments and armature slots. The tolerable output noise is dictated by the gain required to achieve the desired degree of control. Our pilot model control requires the generator output noise be reduced by a factor of 500 at all frequencies below 1 kc/sec. The reasoning which determines the reduction factor will be explained in detail in a forthcoming paper describing the scaling of this power amplifier for use in the current control feed-back circuit for our 40-kw magnet.

Filtering of the generator output with an *LC* circuit is not a feasible means of reducing the noise. Aside from the expense of the filter elements capable of handling the high power, the design of a suitable filter is very difficult because of the high inductance and low resistance of the load. (For the large magnet, the load will have an inductance of 10 henries and a resistance of 2 ohms.) A matched filter requires impracticably large condensers, while an unmatched one either gives circuit instability or excessively long time constants. Shortening the time constants or damping the filter sections results in prohibitive power dissipation.

Our method of reducing the generator output noise was to incorporate it into an inverse feed-back amplifier and remove the ripple by dynamic filtering. This paper will give the design and performance of a feed-back amplifier, incorporating a 100-volt, 1-kw generator working into a 1-ampere magnet, which has been built as a pilot model for the 40-kw system.

Terminology and Symbols

The following conventions will be used in this paper. By transfer function of a component is meant the complex ratio of the output voltage delivered by the component into its load to the input voltage. In case there exists a feed-back channel external to the component, the transfer function is the voltage ratio when the feed-back path is broken. The gain at a certain frequency is then the absolute value of the transfer function at this frequency.

Figure 1 gives a block diagram of a typical feed-back loop. The symbol μ will be used for the forward transfer function, i.e., the voltage ratio without feed-back. β will be used for the feed-back transfer function due to the feed-back net. The loop transfer function will then be $\mu\beta$; it will be considered to be positive if, in the center of the band pass, the vector difference of input voltage and feed-back voltage is less than the input voltage. The quantity $K=\mu/(1+\mu\beta)$, the net transfer function, then describes the behavior of the degenerative amplifier treated as a black box, while $|K|$, the net gain, gives the amplitude of the response as a function of frequency. $|K_0|$ will mean the function evaluated at zero frequency.

B. DESIGN

The purpose of this design is to convert a standard motor generator set into a power source with low noise output and with precisely controllable and variable output voltage. The upper limit on acceptable output noise is 1 mv r.m.s. at frequencies below 1000 c.p.s. The output, working into an electromagnet, must be variable from zero to full voltage.

It is possible to degenerate the output noise (Table I) by incorporating the generator into an inverse feed-back power amplifier provided the section of the closed loop which contains the generator maintains its gain at high frequencies. The cut-off frequency of the loop transfer function can be estimated by the following rough calculation. Suppose the 200-c.p.s. noise is to be reduced by 60 db (i.e., the loop gain is to be 1000 at 200 c.p.s.), and the high frequency cut-off is to be at the rate of 10 db per octave.[5] Then the gain must exceed unity for all frequencies below $200\times 2^6=13{,}000$ c.p.s.

The generator by itself is not a suitable series element for a feed-back amplifier because of its narrow band and non-linear response. These two factors together prevent the generator from satisfactorily degenerating even the 30-c.p.s. component of its own noise output. The bad non-linearity gives serious frequency multiplication of the feed-back frequencies,[6] and the higher harmonics resulting from the multiplication are not attenuated because the generator will not respond to them. One attempt to feed the noise back through the generator illustrates the results to be expected. The generator was driven by a d.c. amplifier and the generator output fed back inversely to the amplifier input. With a rather small amount of degeneration ($\mu\beta$ small), the 30-c.p.s. component of the generator output noise was reduced by a factor of ten, but harmonics with amplitudes comparable to the original 30-c.p.s. noise were added to the output. Increasing the loop gain to remove these higher frequencies made the components well outside the band pass of the generator overload and block the amplifier. To prevent this overloading and blocking of the amplifier, the band limiting must occur in the early stages rather than in the power stage.

It thus becomes evident that a successful method of applying dynamic filtering to the generator output requires a drastic extension of the band width of the power stage. This extended band width has actually been obtained by paralleling the generator output with a hard tube as indicated in the block diagram of the power amplifier, Fig. 2. This tube serves as the high frequency output for the amplifier, while the generator retains its original function

of passing the d.c. and low frequencies. As shown in the theoretical analysis, Section C, the gain ($\mu\beta$) of the composite amplifier is the sum of the individual gains of the two outputs by themselves. This addition to the generator output maintains the gain of the power stage (Fig. 2) up to 100 kc/sec., in contrast to the generator itself, whose gain starts to drop at a few cycles/sec. In its essential features, the problem has now become equivalent to the design of a highly stabilized, hard tube power supply.

Components

The components discussed below are shown in detail in the power amplifier block diagram (Fig. 2) and the power amplifier schematic (Fig. 3).

Comparator

The comparator is an adding net which derives the difference between the input voltage and the feed-back voltage. Although pictured as a unit in the block diagram, it is physically integral with the first stage of the voltage amplifier; the difference is obtained by sending the input signal to the grid and the feedback directly to the cathode. This permits the comparison of the two voltages without loading down the input signal, which may come from a high impedance source.

Voltage Amplifier

The voltage amplifier has a gain of about 150,000 and a band pass of 100 kc. This insures the loop transfer gain ($\mu\beta$) will always exceed 1000, with the over-all d.c. transfer gain ($1/\beta_0$) of 55 while the band easily satisfies the requirement that the internal amplifier introduce no appreciable phase shift in the region of frequencies below the loop cut-off. The desired high frequency cut-off of the entire power amplifier can then be obtained by insertion of appropriate passive elements so that the tube characteristics will not influence the loop cut-off. This means the only effect on the amplifier of tube variations will be a change in over-all gain, not in stability. At the same time, the output noise must be kept low, below one part in 10^6 of the maximum signal, which gives an upper limit to the noise (referred to the input) of 20 microvolts in the band between 0.1 and 60 c.p.s.

Figure 3 gives the circuit diagram of the voltage amplifier. The required gain and band width and correct feed-back polarity are obtained by using four direct-coupled stages. The gain per stage is held to about 20 so that each stage can have a band of greater than 100 kc/sec. Even at that, to nullify stray capacities several types of high frequency compensation were incorporated. The largest stray capacity is introduced by the coupling batteries, and this was eliminated by isolating each battery from both the following grid and preceding plate by a pair of series resistors and then shunting the whole with a small condenser. Further compensation is provided by shunting the cathode resistor with a small by-pass condenser; the same scheme is used in the screens. Careful staggering of these various time constants will make the response as flat as one wishes. In this particular case, a slow change in gain has little significance and no special care was taken in choice of condensers. The actual response begins to rise somewhat around 50 kc/sec.

To keep down the noise level, certain standard practices are resorted to. The filaments are operated on d.c., wire-wound resistors are used on the input and first stage, and bias batteries are used to couple from plate to grid. The effect on the output noise of the time constants associated with the plate loads

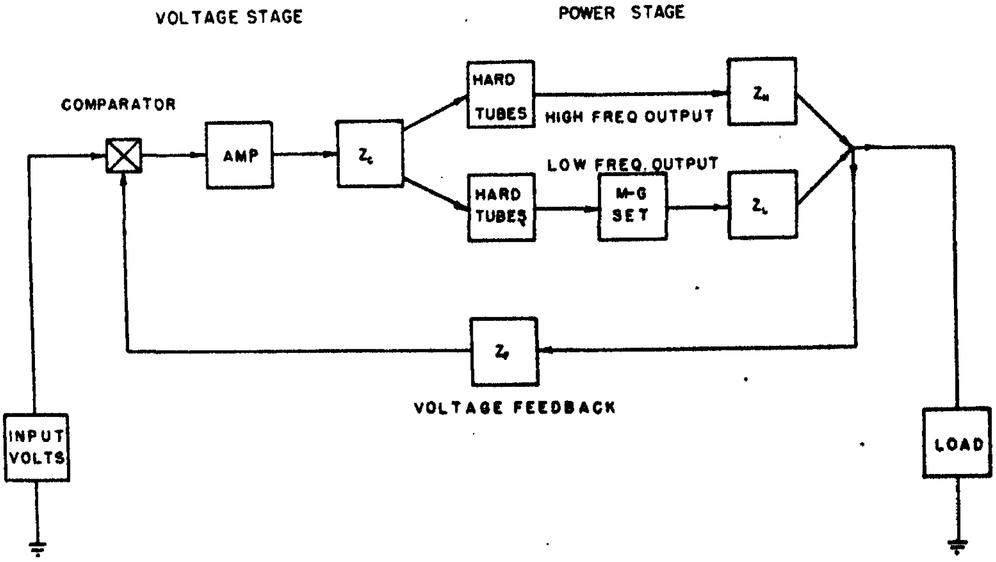

FIG. 2. Power amplifier—block diagram.

of the second, third, and fourth stages, which have been inserted for stability reasons, is discussed at the end of the section on components.

Feedback is derived from a potentiometer (Z_F) across the magnet with center tap feeding into the cathode of the first stage. The impedance of this potentiometer should be high to keep the power dissipation down to a convenient magnitude, while for servicing it is convenient to have an output from the generator when the input grid to the amplifier is grounded. These two conditions, plus the fact that the cathode resistor is specified and the factor $1/\beta_0$ must equal approximately 50, determine the values of the resistances[7] in the feed-back net. The 4-μf condenser makes β increase to about $\frac{1}{3}$ at higher frequencies, thus increasing the a.c. degeneration while maintaining the d.c. net gain.

Generator Branch

The generator field excitation, $\frac{1}{2}$ ampere at 100 volts, is supplied from a bank of hard tubes. Either a small motor generator set or an amplidyne would drive the generator field, but both of these introduce new complications to the problem because of the additional time constants and the high noise output of such units. Even less desirable is a thyratron driver, which is difficult to control over the range from zero to 100 volts output, has a large noise output, and has a considerable variation in characteristics with ambient temperature.

Details of the driver circuit are shown in Fig. 3. The generator field winding, 24 henries and 200 ohms, is the plate load for the five 6L6 driver tubes. These tubes have a common plate connection to the field winding, except for the 10 ohms parasitic suppressors, but each has its own cathode resistor and screen by-pass, which balance the plate currents in the various tubes and suppress parasitic oscillations between them. The separate grid resistors likewise help prevent parasitics besides preventing coupling between these tubes and the parallel output branch to the magnet.

The actual power source for the field is an unregulated half-wave rectifier and a π-section LC filter which delivers a nominal 400 volts. Ripple and lack of regulation have no undesirable effect, for the feedback gives high degeneration for noise introduced at the output of the amplifier, provided no interaction occurs between this supply and other elements of the circuits. Because of dangers of such interaction, the generator driver power supply is separate from the normal plate and screen supplies as well as from the supply for the hard tube output branch of the power amplifier.

The blocking reactor (Z_L), though schematically it enters in the generator output branch, is functionally a unit of the hard tube output branch and will be discussed in the next section.

Hard Tube Branch

The hard tube output branch of the power amplifier is a single 6Y6 cathode follower condenser-

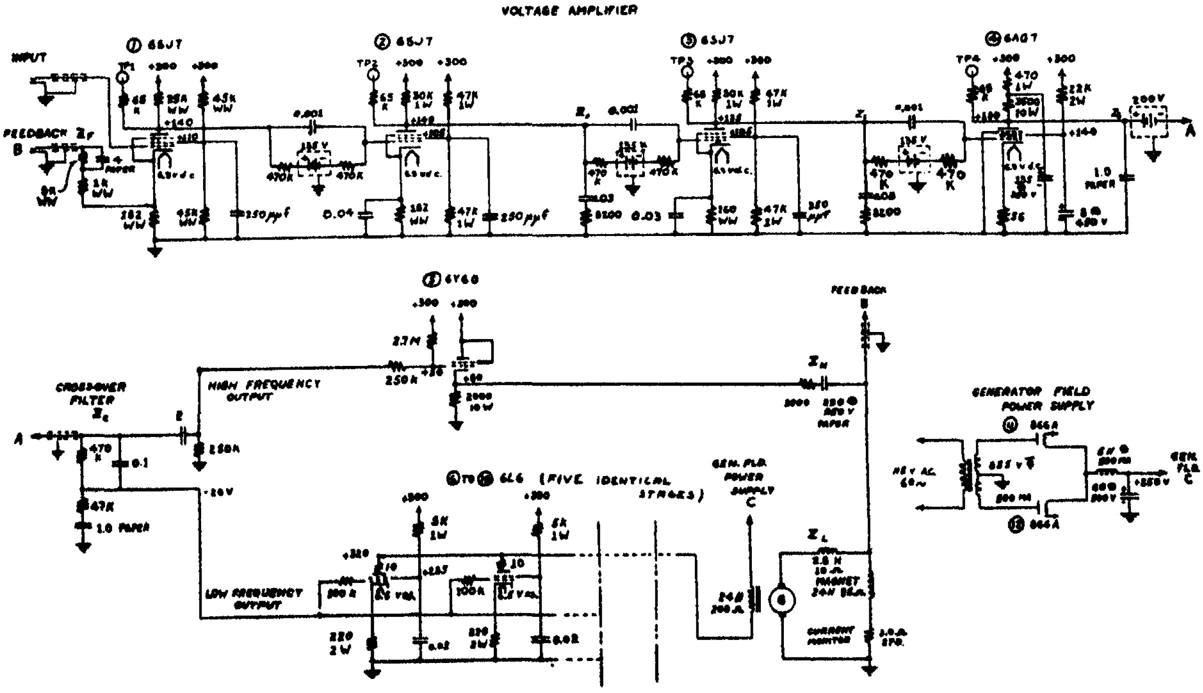

FIG. 3. Power amplifier—schematic.

---

[7] See E. L. Ginzton, Electronics 17, 98 (1944), for the method of calculating the resistances.

coupled directly to the magnet. The design is determined by two principal factors, voltage swing and stability.

1. Voltage swing.—The swing of the output of this branch must be greater than one-half volt r.m.s. at 30 c.p.s. in order to cancel the noise output of the generator. This half-volt must be developed across the load of the cathode follower, this load being the magnet in parallel with the generator output circuit. As the generator armature itself has negligible impedance, the blocking reactor is inserted between the magnet and the generator to increase the impedance presented to the cathode follower. This effectively makes the load into which the coupling net looks just the impedance of the blocking reactor, for its inductance and resistance are much less than those of the magnet.

The maximum voltage swing of the cathode follower is determined by the product of the current capacity of the tube and the inductance of the blocking reactor. Since the blocking reactor must carry the entire magnet current without saturating, it is expensive to make its inductance very large, and so the cathode follower must pass considerable current. However, in this case the magnet available utilized only 15 percent of the generator current rating and a single 6Y6 was sufficient to drive the 2.8-henry inductance of the blocking reactor.

2. Stability of the coupling net and magnet.—Since the coupling net (Z_H) and magnet form a series LC circuit, sufficient damping must be incorporated to prevent internal oscillations in the cathode follower output. Although direct coupling of the 6Y6 to the magnet would remove the possibility of oscillations, condenser coupling makes the design easier because it prevents the d.c. voltage across the magnet from changing the operating point of the cathode follower.

The 1000-Ω resister incorporated in Z_H overdamps the output circuit of the cathode follower. The value of 1000Ω is chosen here because it works well with the coupling condenser and reactor (Z_L) which happened to be available.

In a high power application, a smaller value for Z_L would be used because of the expense of the inductance. To maintain the low frequency response, the 1000-Ω damping resistor would likewise have to be reduced. Critical damping can still be maintained, however, if electrolytic condensers are used for coupling.

Location of Cut-Off Filters

The shapes of the desired loop transfer functions (Section D) determine the high and low frequency cut-offs of both the high frequency and low frequency output channels but do not specify how these cut-offs should be obtained nor where the necessary components should be located. A large part of the frequency response of the loops is inherent in the major components, such as the generator, the magnet, and the blocking reactor. Compensation for the response of these units to give the desired over-all frequency characteristic is accomplished by introducing appropriate RC high pass or low pass filters. Two factors are important in determining the best location of these filters, the actual location being determined by a consideration of the conflicting requirements of the two factors.

1. Because of their effect on noise, these filters should be located as late in the circuit as possible. Insertion of a filter narrows the band width of the amplifier. Since the signal passes through the entire amplifier, the attenuation of the signal is the same no matter where the band limiting occurs physically. The attenuator cuts down the noise band width only for noise originating before the filter; hence the output signal to noise will be best if all the filtering occurs in the output stage.

2. Because of blocking in the amplifier, the band limiting should be introduced at low level. Only those signals can block the amplifier whose frequencies lie outside the loop band width, for the degeneration of the closed loop keeps all extraneous signals inside the band at very low level. Blocking from out-of-band noise must be prevented by limiting the band pass of the feed-back loop at a sufficiently early stage to prevent this noise from overdriving any of the stages inside the amplifier.

A compromise between these two factors is achieved by inserting cut-off filters Z_1, Z_2, Z_3, on the outputs of the second, third, and fourth stages.

C. THEORETICAL ANALYSIS

The use of feedback to reduce the noise is particularly effective in the present instance since the noise source (the generator) immediately precedes the load. This permits the noise voltage across the load to be reduced by a factor equal to the loop gain, which can be made very large. A block diagram of the feed-back circuit is shown in Fig. 1 in which the noise voltage is appropriately shown as added separately immediately before the load. The entire voltage output V_0 is related to the input signal V_I and the noise N by

$$V_0=\mu(V_I-\beta V_0)+N, \tag{1}$$

so that

$$V_0=[\mu/(1+\mu\beta)]V_I+[N/(1+\mu\beta)]. \tag{2}$$

The expression (2) shows that when the loop gain, $\mu\beta$, is large the over-all gain is $1/\beta$, the reciprocal of the feed-back gain, and also the noise content of the output is reduced by the loop gain. If the noise source is situated earlier in the circuit, the noise is reduced by only a fraction of the loop gain.

To utilize this scheme, it is necessary that the over-all circuit have an extremely broad frequency

Table II. Power amplifier—transfer function elements.

response for reasons outlined in Section B. The addition of a high frequency channel to produce this response introduces, besides the possibility of instability in the entire circuit, the added possibility of near cancellation of the responses of the two channels in the frequency region where the gains are nearly equal. Were the latter to occur, the loop gain would be small in the stated frequency region and the noise there not filtered effectively. In addition, the circuit might become unstable with small changes in some of the parameters of the circuit.[7] It is possible, in other cases, for the circuit to be unstable even though the responses of the two channels add and maintain a high value of the gain. This occurs, for example, when the low frequency channel falls at −12 db/octave while the high frequency channel rises at +12 db/octave. The sum of the vector responses of the two channels gives a high value of the gain, but the over-all transfer function is such as to make the Nyquist diagram enclose the point (−1, 0), showing that the circuit is unstable. Incidentally, in the extreme situation described the individual channels are separately unstable. If the usual criterion of ±10-db/octave change rates were observed in order to make these channels separately stable, the over-all circuit would be unstable, nevertheless.

A simple criterion with respect to instability can be stated in terms of the relative phases of the transfer functions of the two channels at cróss-over. It can be expressed in terms either of the phases or of the rates of change of the amplitudes of the transfer functions, since phase and rate of change of amplitude are intimately connected.[**] If the amplitude changes as $6n$ db/octave over several octaves, the phase is $n(\pi/2)$ degrees at the center of the region on a log frequency scale. The criterion is: if the relative phase at cross-over is 180° or greater, the system is unstable. Moreover, if the relative phase is close to 180°, near cancellation takes place. A proper design is one in which the relative phase at cross-over is small.

Certain elements were introduced into the circuit to properly shape the high frequency cut-off and to obtain a suitable type of cross-over. These are the cut-off filters Z_1, Z_2, and Z_3 in the amplifier and the cross-over network Z_c, shown in the circuit diagram Fig. 3. The shaping of the high frequency cut-off followed standard criteria.[5] For a discussion of the location of these filters in the circuit, see Section B.

The proper design of the cross-over net, however, requires an analysis of the circuit. This is also true when any scaling is performed to adapt the circuit to loads different from that described here. It is necessary for this purpose, however, to include in the analysis only those time constants of the order of 3×10^{-3} sec. and larger since the cross-over region extends from about 3 to 50 c.p.s.

The voltage across the magnet V_M is a linear combination of the voltage output of the generator, V_L, (whose armature has essentially zero impedance) and the voltage on the grid of the hard tube (the 6Y6), V_H,

$$V_M = Y_H V_H + Y_L V_L. \tag{3}$$

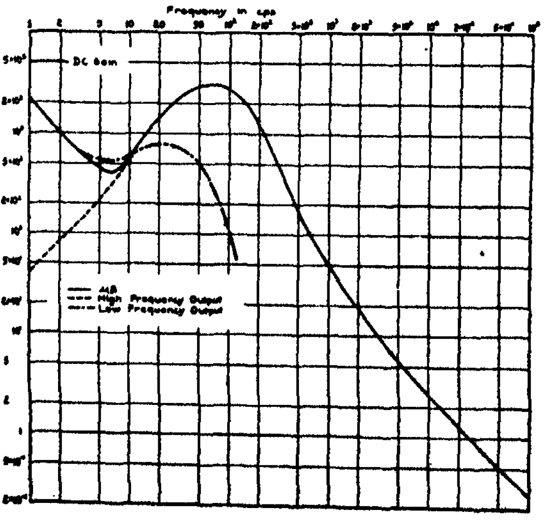

FIG. 4. Power amplifier—transfer function.

The transfer functions Y_H and Y_L refer to the load circuit as it affects the high and low frequency channels, respectively. They, like the transfer functions which follow, are described in Table II. Included in the table are simple equivalent circuits appropriate to the various transfer functions. The symbol "p" in the transfer functions denotes the complex frequency; the numerical values of the time constants and the gains are listed in the last column. Some of the transfer functions listed are only approximate but are sufficiently accurate in the stated frequency region for design purposes. The simplicity of the expressions listed for Y_H and Y_L arises from the fact that in the immediate vicinity of the cross-over point the two capacitances, 220 μf and 4 μf, have negligible impedances.

On tracing the voltages V_L and V_H back toward the comparator it is seen that

$$V_H = Y_{CH} V_A \tag{4}$$

and

$$V_L = Y_G Y_{CL} V_A, \tag{5}$$

where V_A is the voltage output of the amplifier. Y_{CH} in (4) is the transfer function of the cross-over net as it affects the high frequency channel. In the cross-over frequency region, as well as at higher frequencies, this is unity. Y_{CL} in (5) is the transfer function of the cross-over net as it affects the low frequency channel; it is described in Table II. Y_G in (5) is the transfer function of the generator, the ratio of the output voltage of the generator to the grid voltage of the 6L6 tubes.

The voltage amplifier and the feed-back network are common to both channels. The voltage output of the amplifier is

$$V_A = Y_A V_E, \tag{6}$$

where V_E is the output of the comparator and Y_A is the transfer function of the amplifier. When the input is zero,

$$V_E = Y_\beta V_M. \tag{7}$$

Here Y_β is the transfer function of the feed-back network.

On composing the various elements which are in series, the loop transfer functions of the high and low frequency channels are readily seen to be

$$\begin{aligned}(\mu\beta)_H &= Y_H Y_{CH} Y_A Y_\beta,\\ (\mu\beta)_L &= Y_L Y_G Y_{CL} Y_A Y_\beta.\end{aligned} \tag{8}$$

Finally, (3) shows that the over-all loop transfer function is the sum of these:

$$\begin{aligned}\mu\beta &= (\mu\beta)_H + (\mu\beta)_L\\ &= (Y_H Y_{CH} + Y_L Y_G Y_{CL}) Y_A Y_\beta.\end{aligned} \tag{9}$$

A plot of the transfer function $\mu\beta$ is shown in Fig. 4 where log amplitude is plotted against log frequency. Actually, this curve is an experimentally determined one; the graph of (9) agrees with it in all essential details. The cross-over frequency is 10 c.p.s., and the gain there is ~700. The lowest value of the gain in this region is ~500. In the region immediately about the cross-over point the low frequency channel rises at somewhat less than +6 db/octave while the high frequency channel rises at +12 db/octave. Consequently, the circuit stability is not destroyed by the behavior at cross-over. Also the gain remains high. These results are achieved by insertion of the cross-over network, which causes the low frequency channel to decrease its gain beginning at 0.3 c.p.s. and then to increase its gain at 5 c.p.s. The effectiveness of the cross-over net is brought out by considering the circuit without it; the transfer functions are obtained from (8) and (9) by deleting Y_{CH} and Y_{CL}. The cross-over now occurs at 20 c.p.s.; at the intersection $(\mu\beta)_H$ increases at a rate of roughly +6 db/octave and $(\mu\beta)_L$ at a rate of roughly −6 db/octave. The relative phase of the two channels at cross-over is just within the criterion for stability. A large degree of cancellation takes place so that $(\mu\beta)$ is small in spite of the individual gains at the intersection being 350. The near cancellation almost makes the system unstable and detracts seriously from the filtering action on the large 30-c.p.s. component of the generator output.

[**] See reference 5, Chapter XIV.

D. PERFORMANCE

Transfer Function

The performance of the unit as a power amplifier is determined by two factors, the circuit noise and the loop transfer function $\mu\beta$. The methods used to keep the circuit noise at a low level were discussed in Section B. The following paragraphs will discuss determination of the transfer function and its significance.

The amplitude of the transfer function, $|\mu\beta|$ of the composite amplifier is shown as the solid curve in Fig. 4. It is measured by opening the connection between Z_F and the comparator and feeding an input signal to the comparator in place of the interrupted feed-back voltage and measuring the output from Z_F. The ratio of this output to input is $|\mu\beta|$.

Figure 4 shows the measured transfer functions of the high and low frequency outputs as well as the composite one. The high frequency output was obtained in the same manner as the composite transfer function except that during its measurement the generator was shut off. Similarly, the low frequency output was measured with the input to the 6Y6 magnet driver removed.

The stability of the circuit is determined by the slope of the composite transfer function at the high frequency cut-off and the slopes of the two output functions in the region where their gains are equal (cross-over region). The high frequency cut-off will not render the closed loop unstable because the slope in the neighborhood of unity gain is −6 db/octave. Moreover, since this slope is maintained far on either side of the unity gain point (25 kc/sec.) the stability will be maintained in spite of wide variations in the gain of the amplifier. It was to achieve this reliability that the band width of the basic amplifier was extended to 100 kc/sec.

An attempt was made to keep the relative phase less than 120° in the cross-over region in order to maintain a large value for the amplitude of the composite transfer function. This was achieved in the region above 10 c.p.s. but just below this, where the composite curve is beneath the low frequency output, the phase somewhat exceeds 120°.

One of the features of this circuit is that a change in the gain of the voltage amplifier will have no effect on the stability in the cross-over region, for this amplifier is common to both outputs and will not change their relative phase. The gains of the sections of the amplifiers which are not common to both are small, being 2.5 for the low frequency output and 0.6 for the high. Hence, nothing but a major component failure can seriously disrupt the performance in this region.

The relative phase can be adjusted by a passive filter (Z_c) only if the gains at cross-over are high. This is achieved by making T_M large and T_{G1} small (Table II). At the same time, the coupling condenser in Z_H must be large enough to present a negligible impedance in this region.

The noise reduction when the loop is closed is given in Table I. The column labeled "Generator output noise without feedback," gives the measurements of the noise made between the blocking reactor and the magnet with the generator field excited from batteries, and so includes the static filtering provided by the blocking reactor. The next column, "Noise with feedback," shows the effect of the dynamic filtering produced by closing the feedback loop. The d.c. output was around 100 v for these measurements. The table shows the noise reduction factor for the 30-c.p.s. and 60-c.p.s. components taken together is 2500, which corresponds satisfactorily with the measured amplitude of the transfer function in this region (Fig. 4).

Besides this high frequency noise, there are low frequency variations of the generator output arising from other sources. One of them, the d.c. drift, is due to temperature changes affecting the resistances in the feed-back net. No temperature compensation was included in this model. The d.c. drift after warm up was 4×10^{-5} part/min. measured over a 6-minute interval. There was also present a low frequency fluctuation of about 0.1-c.p.s. frequency and 4-mv peak amplitude which was in some way associated with changes in the rotational frequency of the generator.

THE REVIEW OF SCIENTIFIC INSTRUMENTS VOLUME 20, NUMBER 4 APRIL, 1949

A Wide Range Capacitance-Conductance Bridge*

ROBERT H. COLE AND PAUL M. GROSS, JR.**
Metcalf Research Laboratory, Brown University, Providence, Rhode Island

(Received December 14, 1948)

The bridge described has been developed for reasonably accurate measurement by direct balance of capacitance and conductance in the frequency range 50 c/sec. to 5 mc/sec., and over most of this range is essentially direct reading in the two admittance components with negligible unbalance from lead effects or guard circuits of the unknown. These properties are realized by using two circuits developed from the work of others. The first employs inductively coupled ratio arms to minimize residual impedance effects and unbalance by guard circuits, the second, a conductance shifter wye network with good high frequency properties and an essentially linear conductance reading. Design considerations and limitations of these circuits are discussed, as are suitable test cells and auxiliary equipment.

I. INTRODUCTION

THE bridge described here has been developed for use in investigations of complex dielectric constants of polar liquids and solids over a wide frequency range, the primary objectives having been to obtain data of reasonable precision in as convenient and simple a form as possible. To achieve these ends, the circuit design has been arranged to achieve adequate precision on a direct rather than substitution balance, unwanted impedances can be neutralized to the extent that they do little or no harm, and the adjustments for balance are so arranged as to be essentially direct reading in both capacitance and conductance of the unknown.

The basic circuits by which these properties are obtained are by no means new, and all that can be claimed for the present work is their development into a tested instrument usable over a wide range of experimental conditions. The first of the characteristic features is the use of a closely coupled transformer with unity turns ratio as equal ratio arms in a Wheatstone bridge circuit, as shown in Fig. 1(a). This scheme was, so far as we know, first described by Starr[1] (hybrid coil method), and has the advantage over the conventional use of matched impedances that, because of the transformer action, any residual impedance or voltage developed across one coil is reflected across the other by the mutual inductance between the pair. By this arrangement, unbalancing effects in the bridge proper are largely neutralized, and, what is even more useful, unwanted admittances[2] which are necessarily associated with the unknown admittance or its connection to the bridge can likewise be made unimportant.

A typical unknown is indicated schematically in Fig. 1(b) as a three-terminal test condenser comprising test electrodes *D* and *R* and a guard electrode *E*, the latter to be maintained at the potential of *D* in order to prevent surface leakage and, if desired, provide a better defined geometric capacitance between *D* and *E*. The admittance between *E* and *R* ordinarily affects the balance conditions, however connected, and must be accounted for by a second balance with a different connection to the bridge.[3] In the present circuit, the admittance *ER* is connected to the correspondingly lettered terminals of the bridge in Fig. 1(a) and is across one transformer winding. To the extent that the transformer is ideal, no change occurs in balance conditions because the admittance is electrically reflected across the other winding and the ratio arms remain equal.

The third admittance of the three-terminal unknown, between *D* and the guard electrode *E*, appears across the detector, and hence the only effect is on the sensitivity of the detector. The final result is thus that only the direct admittance between *D* and *R* affects the bridge balance. The capacitance and leakage of necessary leads from the unknown to the bridge can also be taken care of in the same way by employing coaxial shielded leads from electrodes *D* and *R*, the shields being connected to point *E* (normally grounded). The cables, to the extent that they can be regarded as simple two-terminal admittances, then are connected across either the ratio arm *ER* or the detector, with the effects already described. The guard compensation effect was apparently first employed by Young[4] in a bridge designed for measurement of small vacuum tube interelectrode admittances with a working frequency of 465 kc/sec.

[4] C. H. Young, Bell Lab. Record 24, 433 (1946).

For dielectrics and electrolytic systems, the measures of admittance are most conveniently made capacitance and either conductance or dissipation factor. Suitable variable standards of capacitance are a relatively minor problem, but measurement of the dissipation components with convenience and accuracy has long been a serious measurement problem, particularly at radio frequencies. For the present bridge, a conductance shifter circuit has been developed on the basis of an arrangement in the vacuum tube bridge mentioned above.[4] Young does not describe the conductance circuit used by him in detail, but it was apparently not designed for precision measurement or for use at more than one frequency (465 kc/sec.).

The basic scheme from which our conductance network was evolved is shown in Fig. 1(c). The three terminal wye network is connected across the standard and unknown arms of Fig. 1(a). The conductance G sets the range of conductance unbalance between these arms which can be effected by shifting the tap on a low resistance divider between points L and R. The use of the divider thus splits the conductance G into two variable parts, one across each bridge arm. If the tap is moved to the left, the conductance across LD increases while that across RD decreases, the variation of conductance being nearly linear if the product of the total divider resistance $2r_0$ and conductance G is sufficiently small compared to unity. The range of conductance change which can be produced to compensate an unknown equivalent parallel conductance in the right arm is evidently the value of the conductance G, which can be chosen within quite broad limits to give desired ranges.

The advantages of this conductance shifter are: it is essentially direct reading in conductance; its range can be simply changed; the major residual errors are small and quite simply investigated. The nature and magnitude of residual errors in both this network and in the ratio arms must, of course, be considered, as is done in the next section and in Section III.

II. RATIO ARMS

A. Design Considerations

The compensation by inductive coupling of admittances or induced voltages across one coil of a transformer used for ratio arms is perfect only when the transformer is ideal, i.e., when the two coils are identical with unity coupling and no losses. As discussed below, matching of the two coils to better than 0.1 percent is readily possible, and the discussion here is confined to the effects of imperfect coupling and losses.

As is well known, inductances in general and mutual inductances in particular are in practice far from ideal, owing to distributed capacitances and dissipative losses resulting from skin effect, core losses, dielectric leakage, etc., as well as ohmic resistance. The effects are not accurately described by any simple equivalent circuit containing only fixed, simple impedances, but a sufficient approximation to the properties of coupled ratio arms for this discussion is shown in Fig. 2. The coils are represented by an inductance L and resistance r in series, and a common mutual inductance M. Distributed capacitances are represented by the admittances y_1 and y_2 across L and r, which can also represent any other shunting admittances, such as guard to ground admittance of an unknown. If y_1 and y_2 are not equal, the point E will not be the electrical midpoint between points L and R and the admittances Y_L and Y_R in the standard and unknown arms must be different if the bridge is to balance (potential of D equal to that of E).

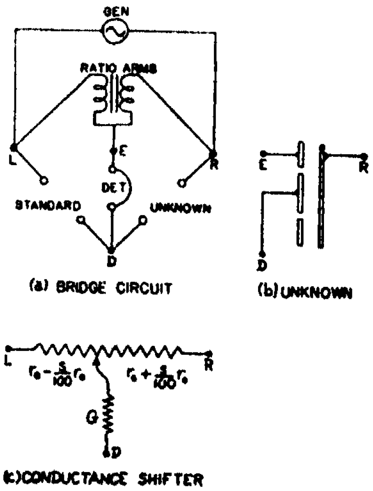
The effect of dissipation ($r>0$) and imperfect coupling ($M<L$) is conveniently expressed by the difference between Y_L and Y_R necessary to obtain balance. Letting $Y_L-Y_R=\Delta Y$ and $\frac{1}{2}(Y_L+Y_R)=Y$, we obtain by standard methods the result in complex notation that at balance

$$\frac{\Delta Y}{Y}=(y_1-y_2)\frac{r+j\omega(L-M)}{1+\frac{1}{2}(y_1+y_2)[(r+j\omega(L-M)]}, \quad (1)$$

if the approximation is made that $L+M=2M$, i.e., the coupling is good, but not so good that the difference $L-M$ can be neglected.

At sufficiently low frequencies, distributed capacitance is unimportant and only resistive unbalance of the shunting admittances y need be considered. If $y_1-y_2=1/r'$ and the second term of the denominator in Eq. (1) can be dropped, we obtain

$$\Delta Y/Y=r/r'+j\omega[(L-M)/r']. \quad (2)$$



(a) BRIDGE CIRCUIT (b) UNKNOWN

(c) CONDUCTANCE SHIFTER

FIG. 1. Basic bridge circuits.

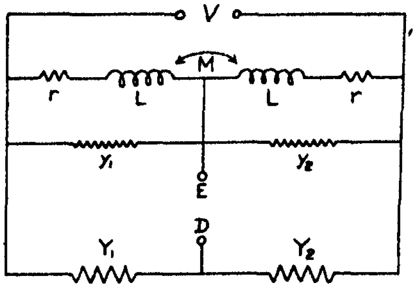


FIG. 2. Equivalent circuit of ratio arms and balancing admittances.

If the unknown admittance Y_R is a pure conductance G and the balance error ΔY is written as $\Delta G+j\omega\Delta C$, we obtain from Eq. (2) the two conditions

$$\begin{aligned}\Delta G/G&=-r/r',\\ \Delta C&=-(L-M)G/r',\end{aligned}\tag{3}$$

the assumption being made that $\omega C\ll G$ and hence $Y\cong G$. These results can be conveniently used to verify experimentally the adequacy of the equivalent circuit of Fig. 2, as shunting one ratio arm by a known resistance r' should require conductance and capacitance changes independent of frequency, the former only to the extent that the equivalent coil resistance is independent of frequency. This has been found true at audiofrequencies for suitable ratio arms, except that the conductance change ΔG increased slowly with frequency, as would be expected because of non-ohmic losses.

At high frequencies, a capacitative shunt admittance has the most serious unbalancing effect on the ratio arms. Consider a difference of shunting admittance given by $y_1-y_2=j\omega C'$ and assume that the unknown is primarily capacitative so that to a sufficient approximation $Y=j\omega C$. Then the balance errors are from Eq. (1) given by

$$\begin{aligned}\Delta G&=-\omega^2rCC',\\ \Delta C&=-\omega^2(L-M)CC',\end{aligned}\tag{4}$$

the second term in the denominator of Eq. (1) again being neglected.[5] The coil resistance r at high frequencies increases with frequency roughly as a fractional power of the frequency. The conductance error ΔG will thus increase somewhat more rapidly than frequency squared, and the capacitance error roughly as the square of frequency. These conclusions have been verified at radiofrequencies by placing a fixed condenser across one ratio arm, with results consistent with Eqs. (4).

B. Construction and Performance

A number of ratio arms have been wound, and the details of three of these, which together cover the range 50 c.p.s. to 5 mc/sec., are given in Table I. The use of several pairs of ratio arms for the entire range of frequencies simplifies design, although it might be possible to wind a single pair of coils sufficiently well balanced and of sufficient inductance.

For the lowest frequencies (50 c/sec. to 20 kc/sec.), the core of a small audio transformer was used. The final winding was balanced to less than 0.05 percent by removing two turns from one coil and adding about 0.07-ohm resistance to this coil. The values of equivalent series resistance r at 1 kc/sec. and the inductance coupling defect $L-M$ were determined from Eqs. (3) as described in Section II-A. The self-inductance of either coil was estimated from its impedance variation with frequency and voltage resonance. At the low frequencies for which this pair of ratio arms is intended, distributed capacitance effects are not important, and

TABLE I. Constants of inductively coupled ratio arms.

Ratio arms, range	Form	Winding	$L(\mu h)$	$C(\mu\mu f)$	r(ohms)	$(L-M)(\mu h)$
A. 50 c.p.s.–20 kc/sec.	Laminated iron core. Winding space, 1.6 cm square by 0.7 cm deep	250 turns each coil, No. 30 dcc wire, wound in opposite directions from center top	4300 (1 kc/sec.)		5.9 (1 kc/sec.)	17

---

[5] This approximation is not necessarily a good one if both shunt admittances, y_1 and y_2, are large. If, for example, these y's are capacitative, a resonance denominator of the form $(1-\omega^2(L-M)C)$ results. Equations (4) must therefore be used with some caution.

no attempt was made to estimate the equivalent shunt capacitance.

The ratio arms for the frequency range 5 kc/sec. to 500 kc/sec. were made by winding a pair of wires in two complete layers on a toroidal powdered iron core, the turns and dimensions being as indicated. The equivalent circuit parameters r and $L-M$ were obtained by the effect on bridge balance of unbalanced capacitance across one coil and use of Eqs. (4). The self-inductance L and shunt capacitance C were estimated by voltage resonance with and without an added known capacitance in parallel. The large value of 1500 μμf for C may seem surprising, but it is to be expected from the method of winding which puts turns with a large potential difference in close proximity. The unbalance of the two coils was found to be less than 0.02 percent without adjustment. Two remarkable features of such toroidal windings in practice are the closeness of balance obtained if the coils are wound as a pair, and the fact that considerable maltreatment by displacing and squeezing turns makes only trivial, barely measurable changes.

The ratio arms for the range 200 kc/sec. to 5 mc/sec. are a small scale version of the second coil already described, with a smaller form and fewer turns. The initial balance was off less than 0.2 percent up to 5 mc/sec. The parameters r, $L-M$, and L were determined in the same way as for the preceding ratio arms but at higher frequencies as indicated in Table I. This coil is the least satisfactory of the three, as its coupling is decidedly poorer, and it cannot be used as generally to compensate guard and lead capacitances as can the other two at lower frequencies. This type of use is, however, increasingly academic at frequencies much above 1 mc/sec. because of distributed impedances in connections to an unknown.

Examples of the accuracy to which the ratio arms can be balanced have already been cited, and it remains to illustrate the effectiveness of compensation for unbalanced admittances across these arms. Representative data for each of the ratio arms described in Table I are given in Table II. In this table are listed the changes in conductance ΔG and capacitance ΔC which are necessary to rebalance the bridge after shunting one ratio arm with the impedance stated. These changes, of course, depend upon the admittances in the standard and unknown arms, and these are also stated. The calculated unbalance values were computed from Eq. (1) using these initial values of G and C and the values of the ratio arm resistance r and uncoupled inductance $L-M$ given in Table I.

The effectiveness of the ratio arms in minimizing undesired unbalance from guard or lead admittances across one coil is evident from Table II. At 200 kc, for example, a capacitance of 1000 μμf so placed changes the balance for a direct capacitance one-third as large by less than 1 μμf (<0.3 percent). The compensation is least effective at the highest frequencies, owing to the relatively larger uncoupled inductance of ratio arms C. The conductance unbalance for a shunt of 1000 ohms is even at 2.5 mc/sec. about one-thirtieth what it would be if this resistance were placed in one of the working arms of the bridge.

TABLE II. Effect on bridge balance of shunting one ratio arm.

Ratio arms, frequency	Ratio arm shunt	Initial admittance G(μmho)	Initial admittance C(μμf)	Admittance unbalance ΔG(μmho) Obs.	Admittance unbalance ΔG(μmho) Calc.	Admittance unbalance ΔC(μμf) Obs.	Admittance unbalance ΔC(μμf) Calc.

	1000 ohms	50	300	34	38	0.50	0.3
	50 μμf	50	300	3.0	4.0	1.8	1.9

An equally interesting result is the generally good agreement between observed and computed unbalances, which gives one confidence in the use of the simple equivalent circuit of Fig. 2 and of the unbalance expression, Eq. (1), to predict the effect of residual impedances on measurements.

III. CONDUCTANCE SHIFTER NETWORK

This circuit is subject to a number of limitations, the more important of which are a non-linear scale for too large values of the range conductance G, failure of this element to be a pure conductance of constant value, and residual effects causing the tapped low resistance not to act as a simple divider at high frequencies.

A. Non-Linearity

If the divider is made up of resistances so as to give a linear change of resistance with tap setting,

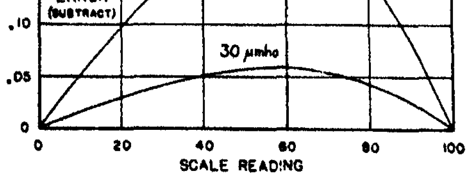

FIG. 3. Corrections for non-linearity of conductance shifter network in 100- and 30-μmho ranges. The scale error is referred to a full scale reading of 100 divisions.

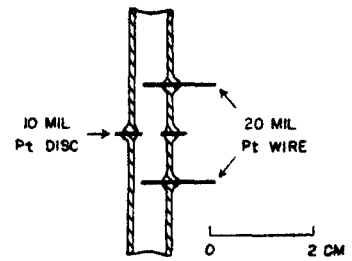

FIG. 4. Vertical section of electrolytic cell for conductance network tests. The body of the cell is 10 mm o.d. tubing. Cell constant approximately 10 cm^{-1}.

the resistances to left and right of the tap in Fig. 1 can be expressed as $r_0 - r_0(s/100)$ and $r_0 + r_0(s/100)$, where the setting s varies from 0 to 100. The equivalent conductances thrown across the standard and unknown arms are readily shown from the wye-delta-transformation[6] to be

$$G_L = \tfrac{1}{2}\frac{1+(s/100)}{1+\tfrac{1}{2}Gr_0(1-(s/100)^2)}G,$$

$$G_R = \tfrac{1}{2}\frac{1-(s/100)}{1+\tfrac{1}{2}Gr_0(1-(s/100)^2)}G.$$

The conductance difference for a given s is then

$$G_L - G_R = \frac{1}{1+\tfrac{1}{2}Gr_0(1-(s/100)^2)}(s/100)G. \quad (5)$$

If the product $\tfrac{1}{2}Gr_0$ is neglected, this reduces to

$$G_L - G_R = (s/100)G, \quad (6)$$

and the conductance difference is linear with setting s of the resistance divider, the range being from zero to G.

The departure from linearity increases with the value of the product Gr_0. In the present circuit $r_0 = 100$ ohms, and the largest value of G used is 100 μmho, whence $Gr_0 = 0.01$. From Eq. (5), the maximum absolute error in G is 0.19 μmho at a setting of 57 μmho and the maximum fractional error 0.5 percent at small settings.

This non-linearity becomes negligible for sufficiently small values of G (10 μmho or less for less than 0.05 percent error) and the small correction for somewhat larger values of G is simple to make. The procedure adopted by us has been to calculate and plot a series of differences to be subtracted from observed readings so that the corrected reading s_1 gives the actual change in G when used in Eq. (6). The formula for the purpose is readily shown from Eqs. (5), and (6) to be

$$s - s_1 = \frac{(1-(s/100)^2)}{1+\tfrac{1}{2}Gr_0(1-(s/100)^2)}(\tfrac{1}{2}Gr_0).$$

Values of the correction $s - s_1$ as a function of s for the values $r_0 = 100$ ohms, $G = 100$, 30 μmho are plotted in Fig. 3.

B. Effects of Residuals

Neither the range conductance G nor the divider circuit can be assumed to be purely dissipative elements because of their distributed inductance and capacitance. The resistances used for G in our applications exceed 10,000 ohms in value and for such resistances the dominant residual is shunt capacitance. If the divider were a pure resistance, small compared to $1/G$, a change of its setting would merely "split" the capacitance of G in proportion to the setting and a simple correction to the apparent measured capacitance would suffice.

Actually, of course, any divider must have residual impedances. In our case, this divider is made up of constant, low inductance one- and ten-ohm decade resistors, a 100-ohm fixed resistor and a one-ohm slide wire, as shown in Fig. 5. The major residual effect is from the series inductances of these elements, the total series inductance L being about 1.7 μh. Because of the constant inductance feature of the decades, the primary effect of inductance is to increase the total impedance of the divider by the factor $1+(\omega L/2r_0)^2$, where $2r_0$ is the total divider resistance. This factor makes the apparent conductance of the unknown larger than the true value, the error being 2.5 percent at 3 mc/sec. for the values $L = 1.7$ μh, $r_0 = 100$ ohms of the circuit used.

The second important residual limiting the accuracy of the conductance network has been found to be the increase in value of the conductance G at high frequencies. The conductances used by us were Western Electric Type 170,176A deposited carbon resistors. The tests described below indicate that, as stated by the makers, the frequency for a given percentage increase varies inversely with the value of G. For a one percent effect the ratio f/G was found to be 0.07, where f is expressed in mc/sec. and G in μmho, and the error at lower frequencies varied roughly inversely as the frequency. Thus a resistance of 10^4 ohms can be used up to 7 mc/sec. with less than one percent effect, while for a resistance of 10^6 ohms the corresponding limit is 70 kc/sec.

A number of other residuals should be considered: the variation in inductance of the slide wire with setting, skin effect in the divider resistances, incipient LC resonance of the divider inductance and the capacitance of G, and various direct or mutual impedances of connecting leads. Rough calculations for the components used indicated these effects to be unimportant compared with the residuals discussed above. This conclusion was verified by three types of tests, as follows:

---

[6] See, for example, reference 3, p. 128.

(a) Conductances of several ½-watt carbon resistors were measured at several frequencies for each of two or more values of range conductance G. Comparison of these data established the effect of frequency on the values of these conductances.

(b) Conductances of several pairs of ½-watt resistors were measured singly and in parallel. The agreements between the measured and calculated conductance series at frequencies up to 5 mc/sec. established that there were no significant errors depending on slide wire and decade settings.

(c) Conductances of KCl solutions of various concentrations were measured as a function of frequency. This was done using the simple cell shown in Fig. 4, the function of the grounded disk between the platinum electrodes being to eliminate dielectric losses of the glass walls from the direct admittance measurement. On the assumption that ionic relaxation effects were negligible at the frequencies and concentrations used, the measured conductance should be frequency independent. The observed variations were found to be accounted for by a divider inductance of 1.7 μh and the previously found dependence of range conductance value on frequency. This inductance value is in fair agreement with a value of 2.0 μh estimated from manufacturers' specifications for the divider decades and other tests of the slide wire (estimated inductance, 0.07 μh).

The errors in conductance measurements are evidently determined mainly by the frequency dependent values of the range conductance G below about 1 mc. For dielectrics, the effect is conveniently described by errors in the dissipation factor $G/\omega C$, which does not exceed 0.0003 for a capacitance of 100 $\mu\mu$f or more over the range 50 c/sec. to 1 mc/sec. About 1 mc/sec., the divider inductance gives rise to larger errors, the effect amounting to several percent for conductances of the order 100 μmho at 5 mc/sec.

The conductance circuit residuals also cause small errors in capacitance measurement. The first of these is due to the shunt capacitance of the range conductance, which is about 0.8 $\mu\mu$f as the circuit is arranged. The measured capacitance error is not necessarily this great as it is partially compensated by the series divider inductance, which has the effect of a negative shunt capacitance of magnitude approximately given by $(LG/2r_0)$. For the circuit constants employed by us, this compensating capacitance is -0.85 $\mu\mu$f for $G=100$ μmho and on this range thus almost exactly balances the real capacitance of G. This was found experimentally by measuring the capacitances of the electrolytic cell of Fig. 4 for different concentrations of KCl. No dependence of apparent capacitance on conductance setting was observed for the range $G=100$ μmho, as would be true for small dielectric constant changes of the solution and no net capacitance effect of the divider. The apparent capacitances of the smaller range conductances were determined by obvious methods of intercomparison and gave values increasing to 1.1 $\mu\mu$f for the smallest value of G used (0.1 μmho).

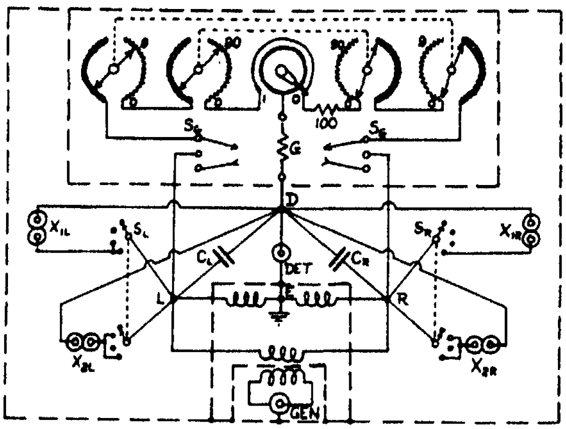

FIG. 5. Schematic wiring diagram of the bridge. Long dashes indicate shielding, short dashes ganged switches.

IV. BRIDGE CONSTRUCTION AND USE

A. Circuit Components and Arrangement

A schematic circuit of a bridge employing the circuits already described is shown in Fig. 5, the components being arranged in roughly the same relative positions as in the instrument. A view of the bridge is shown in Fig. 6. The conductance shifter network is mounted in a shielded box at the top between the precision condensers C_L and C_R, and the coupled ratio arms and input transformer are plugged into a lower box through the door visible in Fig. 6. The switches S_L and S_R connect either of two pairs of external terminals X_L and X_R to twin arms of the bridge. The arrangement of parts has been made as symmetrical as possible.

The divider setting of the conductance network is accomplished by use of ganged pairs of General Radio Type 668 inductance-compensated decade resistance units with ten- and one-ohm steps, and a three-quarter turn slide wire of 26-gauge manganin wire with one-ohm total resistance. The decade resistances are so connected in the two sides of the divider that as one step is removed from one side an equal step is added in the other. A slider on the manganin slide wire makes contact also to an adjacent turn of copper wire connected to the conductance G.

The range conductances G are a set of Western Electric Type D-170176A deposited carbon resistors, chosen for their excellent high frequency characteristics. These conductances, with values of 100, 30, 10, 3, 1, 0.3, 0.1 μmho (10,000 ohms–10 megohms) are mounted on a drum type selector switch, and thus any one of these values can be made the full scale reading of the shifter network. In order to make divider settings from zero to 100 correspond to percent of full scale change, the connections and initial settings of the decades and slide wire are made as shown in Fig. 5. The fixed 100-ohm resistor in the right side is added to make the zero setting of decades and slide wire give the initial balance correctly. The switch S_G interchanges or removes the connections of the divider to the rest of the bridge.

The wiring of the network is made as short and direct as possible to minimize residual impedances, and the inductance of the slide wire has been reduced by running the lead from one end back as a copper strip parallel and close to the manganin wire. The opposing magnetic fields thus partially cancel and the total inductance of the slide wire is reduced to about 0.07 μh, a figure which could probably be improved considerably.

The balancing condensers C_L and C_R are National Type NPW precision condensers with a total capacitance of 650 $\mu\mu$f, which are driven by National micrometer dials. The capacitance change of these condensers is approximately logarithmic with dial setting over 450 $\mu\mu$f of the total range, and a very open scale for balancing small capacitance changes is thus obtained. The necessity for a non-linear calibration chart or graph is the accompanying disadvantage.

In order to avoid the conversion when desired and also provide higher ranges of capacitance and conductance, a supplementary admittance panel has been provided. This contains a 500-$\mu\mu$f variable linear condenser, also driven by a National micrometer dial with 500 divisions, and decades of capacitance and conductance. The former decade (General Radio Type 380-N) provides a total capacitance of 0.01 μf in steps of 0.001 μf and a 500-$\mu\mu$f mica condenser can also be switched. The two conductance decades provide conductance increments up to 0.011 mho in steps of 100 μmho and were assembled from General Radio Type 500 resistors compensated by trimmer condensers for excess inductance.

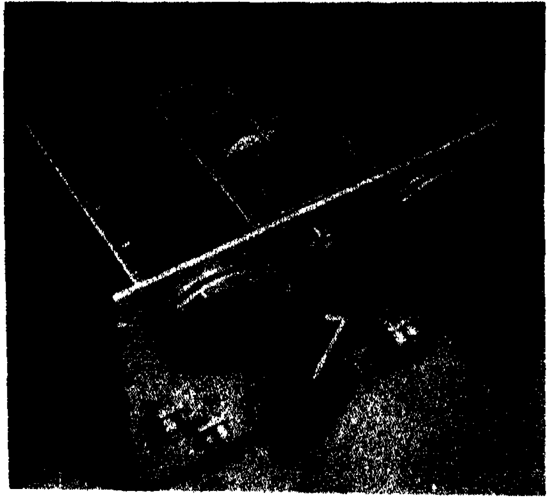

FIG. 6. View of the bridge showing conductance shifter circuit, standard condensers, and panel.

The generators and detectors so far used are conventional. At frequencies below 70 kc/sec. a Hewlett-Packard Type 200 DR oscillator is employed and a General Radio Type 805-C signal generator is used for higher frequencies. A DuMont Type 208B oscillograph preceded by an amplifier with a gain of 65 db and response flat to 100 kc is used at frequencies up to 200 kc. At higher frequencies, the modulated voltage of the signal generator is fed via the bridge to a Type 348-P receiver and the filtered 1000-cycle unbalance output applied to the oscillograph. Either a sweep or signal or modulation frequency can be used for horizontal deflection and the various desired combinations are selected on a switching panel.

Coupling of the generators to the bridge must be done with some care. As the circuit is arranged a balanced voltage about ground is required. This could be induced in the coupled ratio arms by a primary winding on the same core, as has been done by Starr[1] and by Young,[4] but we have preferred to use a separate transformer in order to provide greater flexibility in testing and use of the bridge. In either case, it is important that there be a minimum of electrostatic coupling between windings, as this acts to unbalance the ratio arms by asymmetrical leakage currents flowing from the generator. This effect is not as serious as in conventional bridges because the compensation action of the coupling between the ratio arms is effective for unbalanced voltages as well as admittances, as noted by Young.[4] As a result it has been found possible to use standard bridge transformers (General Radio) up to about one megacycle without appreciable error. At higher frequencies, however, small leakage capacitance and conductance between the windings can cause serious error. To minimize this effect, a special transformer, similar to one described by Field and Easton[7] was made with a carefully overlapped and insulated shield between windings. The leakage capacitance can be estimated from the change in bridge balance on reversing the connections of the primary winding to the generator and ground and was found to be of the order 0.01 $\mu\mu$f. With this small a value, the transformer works satisfactorily to 10 megacycles.

Another effect which must be considered carefully in the bridge design is that of direct coupling between the generator and detector either by induction or a common impedance. This is particularly true in the present circuit, as it is intended for measurement by direct balance, rather than by substitution balances which would minimize such effects. They have been reduced to negligible importance for frequencies up to several megacycles in the present circuit by suitable disposition of leads and grounds and use of coaxial leads.

B. Accuracy

The effects of residuals in the ratio arm and conductance circuits have been considered and it remains to discuss the accuracy at intermediate frequencies for which they are not important. The standard condensers used can be set consistently to one-tenth division out of five hundred total, which because of the roughly logarithmic scale permits an internal consistency of 0.1 percent or better for capacitances larger than 50 $\mu\mu$f, the range being 650 $\mu\mu$f. These figures are characteristic more of the condenser and drive than of the rest of the bridge.

The precision and reproducibility of settings of the conductance is often of the order 0.02 percent, but the accuracy is not as good. The main source of error is the temperature coefficient of about 0.03 percent/°C, which results in an apparent conductance difference of 0.3 percent for 10°C change in ambient temperature. A better performance in this respect might well be secured but some sacrifice has been tolerated in the present design in order to have the good high frequency properties of these resistors. A smaller but comparable source of error is in the lack of consistency of the divider resistance decades. The accuracy of these was found to be better than the tolerances of ±0.1 percent (10-ohm steps) and ±0.25 percent (1-ohm steps) quoted by the makers, and an error of not more than 0.1 percent results. Contact resistances of the decade switches cause variations of the order of 0.02 percent at most with reasonable attention to their cleanliness. (It is worth noting that the slide wire contact, an annoying source of noise in some bridge circuits, causes virtually no trouble here, as its resistance is in series with a resistance of at least 10,000 ohms.)

C. Measuring Cells

The bridge circuit as described has been developed and used primarily for studies of dielectrics and electrolytes. For such systems, the advantage of direct reading scales of both capacity and conductance together with elimination of separate balances and corrections for guard circuit and lead effects have proved very desirable. As the circuit is arranged, the direct admittance between the ungrounded terminals of a three-terminal admittance is measured. This value is not necessarily the same one obtained by a grounded point measurement in the case of a two terminal admittance, but it is the desired one in most designs of cells with guard rings, and the variety of such designs in the literature can be used simply with the present circuit.

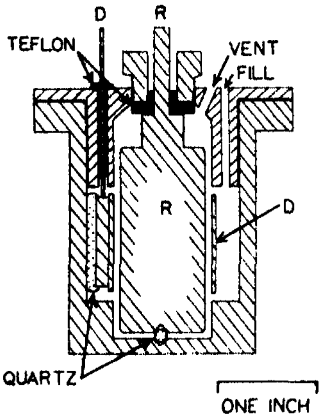

FIG. 7. Dielectric constant cell for liquids, $C_0 = 10$ $\mu\mu$f.

An example of a convenient cell for dielectric constants of liquids is shown in Fig. 7, this particular cell having been made for a study of dielectric constants of hydrogen peroxide-water solutions.[8] The central rod R is connected to terminal R of the bridge and insulated by washers of Teflon from the grounded case. Coaxial with this electrode is the guarded electrode D in the form of a tube with three raised axial slots on its outer surface. The tube is supported and insulated from the body of the cell by quartz rods sprung into the gap and positioned by the slots.[9] Capacitances in air of from 1 to 10 $\mu\mu$f are easily obtained by choice of central electrode diameter, a range readily extended in either direction by change in dimensions. This particular cell was made of stainless steel and electrolytically polished to prevent decomposition of the solutions studied.

It is important that the design of the cell should be such that there is no insulation other than air or the liquid dielectric between the high potential and guarded electrodes. With this arrangement and the guard compensation effect of the bridge, the desired dielectric constant of the sample is merely the ratio of measured capacitances when filled and empty. The specific conductance is also directly obtained from the observed conductance, as the conventional cell constant k defined in electrolytic conductance work is determined from the air capacitance C_0 by the relation

$$k\ (\text{cm}^{-1}) = 0.0885/C_0\ (\mu\mu\text{f}).$$

D. Other Applications

The bridge as described is naturally adapted to studies of dielectrics and electrolytes, but its characteristic features may well be useful for other purposes. Considerable simplification of measurement and reduction of data should be possible in systems for which guard circuits are necessary or desirable. The cancellation of lead effects might well prove valuable when leads must be subjected to unknown displacements which would otherwise cause errors, as in work at pressures other than atmospheric. The simplicity of the basic circuits and their use makes them adaptable to course demonstrations and experiments, and the compensation effect of the ratio arms is an interesting application of electromagnetic induction.

THE REVIEW OF SCIENTIFIC INSTRUMENTS VOLUME 20, NUMBER 4 APRIL, 1949

An Interferometric Study of Supersonic Channel Flow*

DANIEL BERSHADER
Palmer Physical Laboratory, Princeton University, Princeton, New Jersey

(Received December 14, 1948)

The Zehnder-Mach interferometer has been applied to the study of supersonic flow of air expanding from a pressure tank into the atmosphere through channels of rectangular cross section. This was made possible by using plane-parallel glass plates for a pair of opposite walls of the channel. Two such channels were used, each about one centimeter in width and two centimeters in depth, one being a divergent channel (half-angle$=4.0°$) and the other a Laval nozzle constructed by the "characteristics" method for $M=1.7$. It was found possible to measure the density distribution with a rather small estimated probable error (two percent or less). Knowledge of the stagnation temperature and pressure made it possible also to compute pressure, temperature, and velocity. Results obtained for the potential flow agree, for the most part, within one percent with the well-known theory of isentropic channel flow. The interferometric technique has been used also as a guide in improving the Laval nozzle, giving quantitative data on the inhomogeneities resulting from small errors in construction. Further quantitative data was obtained on the degree of non-uniformity of the flow in the throat regions of both channels. The boundary layers, which reach a thickness of about ten percent of the channel width near the orifice of the Laval Nozzle, introduce further accuracy problems into the study of channel flow by interferometry. These are taken up in some detail. Some of the considerations here will also apply to the interferometric analysis of flow in larger supersonic wind tunnels whose working sections are essentially channels of rectangular cross section.

I. INTRODUCTION

THE equations of isentropic expansion of a gas from a storage chamber through a convergent-divergent type nozzle into a receiver provide for a flow regime in which the gas moves with subsonic speed in the convergent portion, sonic speed at the throat, and supersonic speed in the divergent part.[1] The compressibility effects associated with the higher subsonic and especially the supersonic flows produce corresponding changes in the refractive index of the gas stream. It is then that optical methods become a powerful tool in flow analysis.

Early in the present century, the German physicists, Prandtl[2] and Meyer,[3] as well as Magin,[4] constructed channels (or nozzles) of the convergent-divergent type and of rectangular cross section in which a pair of opposite walls consisted of plane-parallel glass plates. By means of Toepler's striation ("schlieren") method,[5] they demonstrated the difference in nature of the flow downstream of the throat. This region was found to contain a pattern of stationary waves (Fig. 1) similar to those first observed by E. Mach in his studies on bullet flight and which are now known as Mach lines or Mach waves. The angle α between the Mach line and streamline at any point is simply related to the Mach number of the flow at that point by

$$M=\csc\alpha. \qquad (1)$$

The quantitative feature of these early experiments consisted in calculating the Mach numbers from angle measurements by means of the above equation.

Similar to the channels employed in the above-mentioned investigations, those used in the present study, also have rectangular cross sections and plane-parallel glass plates for one pair of walls. However, a method of optical analysis has been applied which is superior to others for accurate,

quantitative work—namely, interferometry. In this method establishment of the gas flow changes the optical path of one of two interfering light beams and produces a measurable shift in the previously adjusted interference fringe pattern. Values of density may be directly obtained from these fringe shifts. The interferometer used for studies in gas dynamics is the Zehnder-Mach type, named after the men who first developed instruments of this type in order to study problems in ballistics. A comprehensive bibliography on the instrument and its application to gas dynamics may be found in the paper of J. Winckler.[6]

The systematic study in this country of high speed gas flow by interferometry began at Princeton in 1943 with the program started by Professor R. Ladenburg. He suggested the present problem and the work was performed under his direction.** This paper is concerned firstly with establishing by experiment the validity of the application of interferometry to "enclosed flows" as represented by flow in a rectangular channel, and secondly with some useful information obtainable by the method.

II. APPARATUS AND EXPERIMENTAL PROCEDURE

A. Apparatus

The two channels used will be characterized by the names "divergent channel" and "Laval nozzle," the latter in honor of the Swedish engineer, de Laval, who made investigations of the flow of steam through nozzles. The channels are open at the downstream end so that the gas discharges into the atmosphere. For the divergent channel the supersonic section contains two plane steel walls, each making an angle of 4.0° with the axial plane of symmetry; in the Laval nozzle the walls, after an initial widening immediately following the throat, become parallel in such a way as to produce a uniform flow with constant Mach number and zero pressure gradient. The contours are shown in Fig. 2 while Table I gives the pertinent dimensions. The dimensions of the divergent channel are practically identical with those of Magin's channel.[4] The design of the Laval nozzle will be discussed in IV.

FIG. 1. Typical schlieren photo of channel showing Mach lines.

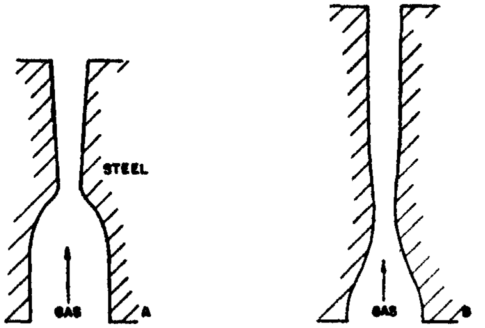

FIG. 2. Channel contours. A—divergent channel; B—Laval nozzle.

The assembled channel, ready for mounting on the pressure tank, is shown in Fig. 3. It is seen that the glass walls extend beyond the orifice of the channel proper. The design*** is such that the contact between the glass and steel walls is made air-tight by squeezing a rubber gasket which surrounds the glass plate, thus avoiding undesirable pressure on the glass by metal parts. If the junction is not air-tight, disturbances in the flow pattern are visible (see Fig. 4).

The position of the channel with respect to other components of the interferometer assembly is shown in Fig. 5. Notice the presence of a compensating chamber in the path of the second beam. This contains glass plates of thickness identical with that of the glass channel walls. All four pieces were cut

TABLE I. Channel dimensions in mm.

	Divergent	Laval
Orifice width	12.75	10.50
Throat width	7.33	7.65
Area ratio (orifice-throat)	1.739	1.372
Depth	19.05	19.05
Throat-orifice length	40.6	66.0

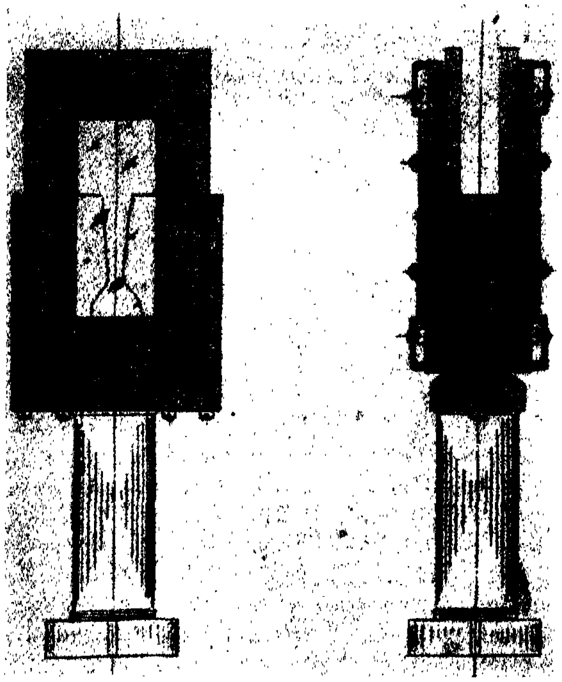

FIG. 3.

out of one ground and polished plate and installed in such an orientation with respect to each other as to minimize any inhomogeneities. Atmospheric conditions prevailed inside the chamber at all times during the present experiments.

The lens L-1 makes the light parallel before it enters the interferometer while the lens L-2 serves as a camera objective to focus the center of the channel on a photographic plate (not shown). The light source is a magnesium spark of about one microsecond in duration. A pressure switch causes the spark to flash at any desired pressure up to 100 lbs. above atmospheric. The photographic plates used were the Eastman 103-0 series, which are sufficiently sensitive in the region of the magnesium blue line, $\lambda = 4481$A, chosen by the monochromator. The interferograms were taken at a magnification of unity. The interferometer plates, on loan from Dr. R. B. Kennard, are the same ones used by Winckler[6] and by Ladenburg *et al.*[7] Further details on the interferometer and associated instrumentation may be found in these papers.

Since the interferometer plates were smaller than the region to be studied, it was necessary to take three pictures of different sections in order to include the whole of the supersonic portion of the divergent channel while for the Laval nozzle four pictures were required. Brass spacers were used to vary the position of the channel assembly with respect to the interferometer plates and thus to determine the section to be photographed. The spacer fits inside the lead-in tube of the channel until it comes up against a shoulder. This shoulder, the spacer, and the outlet-tube all have the same diameter so that the lead-in tube of the channel slides over the outlet tube of the pressure tank up to this shoulder or up to the bottom of one of the spacers. The lower part of the lead-in tube is threaded and accommodates a specially designed nut in such a way that as the latter is tightened, pressure is exerted on a rubber gasket preventing any sliding of one tube around the other. To solve the problem of aligning interferograms of different sections, wires (*w*-1, *w*-2, etc., in Fig. 5) were waxed to the outside of the glass in the overlap regions as reference marks for the fringe shift evaluation. These wires were set at slight angles with the horizontal to avoid the possibility of their being completely covered by one dark interference fringe.

B. Experimental Procedure

For adjustment of the optics, the green line, $\lambda = 5461$A, obtained from a mercury arc and filter was used. Horizontal fringes were established and adjusted to a width of 1.00 mm as a convenient separation. (The magnesium fringes would, of course, be closer together in the ratio 4481:5461.) This careful adjustment of the fringe width is important because only under these circumstances is it possible to align photographs of the different sections. Also important is the stability of the fringe system, for any changes in the pattern be-

[7] R. Ladenburg, J. Winckler, and C. C. Van Voorhis, "Interferometric studies of faster than sound phenomena. Part I. The gas flow around various objects in a free, homogeneous, supersonic air stream," Phys. Rev. 73, 1359–1377 (1948).

tween the time of adjustment and the time the picture is taken are undesirable.

First a photograph is taken of the stationary fringe pattern, quickly followed by a picture taken with air flowing. In some of the later experiments, a final photograph of the stationary fringes was made. Atmospheric pressure and temperature were recorded, as well as the temperature of the air in the tank.

Following the photography of the orifice section, the channel assembly had to be removed and a spacer added. The assembly was put back into place, the fringes again adjusted and the photography procedure repeated for the mid-section, and so on.

C. Evaluation Method

Atmospheric density prevails in the whole channel before the flow, while during the flow a density distribution exists which is, in general, different from atmospheric. If the direction of the light be z and the coordinates in a plane perpendicular to z are denoted by x and y, then in the case that the index of refraction n depends only on x and y, the fringe shift $S(x, y)$ is easily converted to the density $\rho(x, y)$. For if D is the distance between the glass walls, the index of refraction corresponding to a fringe shift S is

$$n = n_a + (S\lambda/D), \qquad (2)$$

where n_a is the index prevailing before the flow. (This assumes, of course, that the optical path through the compensating chamber remain constant in the meantime.) The relation between refractive index and density is given by the Gladstone-Dale formula

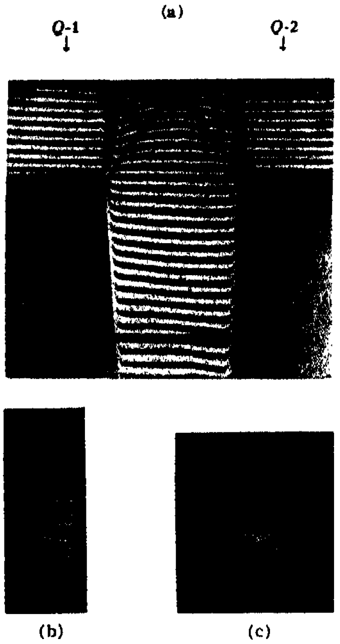
$$n - 1 = K\rho, \qquad (3)$$

where K is a constant over a large range of pressures for a given wave-length and a given gas. To get ρ from S, one may combine the two above equations:

$$\rho = \rho_a + (S\lambda/KD), \qquad (4)$$

ρ_a being the density in the channel when the stationary-fringe picture is taken (atmospheric density in the present experiments).

FIG. 5. Optical assembly.



(b) (c)

FIG. 6. Interferograms of (a) orifice section, (b) mid-section, and (c) throat section of divergent channel at $P_0 = 5$ atmospheres.

The interferograms were analyzed by numbering the fringes and measuring their positions with the aid of a comparator. A typical interferogram of the orifice section is shown in Fig. 6a. One of its features is the presence of undisturbed fringes in the regions labeled Q-1 and Q-2, The positions of corresponding fringes in the Q regions of the stationary and flow pictures were carefully compared as were the fringe positions in the overlap regions of the photographs of adjacent sections. When the necessary alignment corrections were made, the whole set of displaced fringes had been numbered and positioned from above the orifice to below the throat as if it were all on one interferogram. It was then possible to assign an undisplaced-fringe number to the position of each displaced fringe and so to obtain the fringe shift S.

D. Auxiliary Experimental Techniques

Additional valuable information was obtained from shadow and schlieren photography as well as from what may be called dynamic interferometry. The former two methods have been well known for some time,[8] and will not be discussed here except to recall that while interferometry measures the density, the photographic effects in schlieren are sensitive to the density gradient in a direction normal to the knife edge whereas the effects in shadow photography are concerned with the second derivative of the density.

---

[8] F. J. Weyl, *Analytical Methods in the Optical Examination of Supersonic Flow* (Navord Report 211–45, December 1945)

The technique of "dynamic interferometry"**** employs a camera with moving film in order to get a continuous record of fringe shifts. A picture of the camera used is shown in Fig. 7. Vertical fringes are focused on the horizontal slit so that each fringe is represented by a point on the film. As the film moves in a vertical direction past the slit, this point will trace a line on the film, the line curving when the fringe begins to shift. Following previous calibration with monochromatic fringes, an intense white light filament source was used and the shift of the central fringe measured. A spark source of light was also focused on the slit and made to flash at a desired tank pressure, marking the place on the film where the fringe shift was to be measured. A moving film trace showing the white light fringes shifting is seen in Fig. 8.

III. ACCURACY OF THE INTERFEROMETRIC METHOD

A. Sources of Error

The errors in the present experiment have been placed rather arbitrarily into four categories which are listed in Table II.

1. *Instrumentation Errors*

The atmospheric pressure and temperature were measured with a mercury barometer and thermometer, respectively, to a high degree of accuracy. The tank pressure P_0 was read to within 0.3 percent (at 60 pounds overpressure) from a gauge which had been cross-checked with other gauges. The tank temperature was taken to be the same as the atmospheric temperature. Later studies with a thermocouple revealed that this might give a value that was too high by one or two degrees, due to efflux of air between the time of the temperature reading and the flash of the spark.

FIG. 7. General radio continuous recording camera.

2. *Miscellaneous Errors*

Considered here was the possible existence of any deviations from steady-state conditions caused by transients, slowly shifting fringes, or oscillations. The only deviation from a truly stationary flow pattern appeared to be a small oscillation of the density about some equilibrium value with a rough periodicity of about 200 microseconds. This is 200 times as long as the duration of the magnesium spark—too long, therefore, to interfere with the sharpness of the photographs. Observation of the moving film record (Fig. 8) shows that the amplitude of these oscillations varies, reaching a maximum of 0.5 fringe. (In all of the present work, a shift of one fringe corresponds to a density change of approximately 0.1 mg/cc.)

The question of whether the Q-regions are truly quiescent during air flow merits consideration because these are used as reference regions for the fringe shift calculations. Results indicate that there is some small disturbance here caused by either a slight change in adjustment of the instrument or else by motion of air. The magnitude of the irregularity leads to the estimate given in Table II.

3. *Geometrical Errors*

The first of these involves the problem of reading the position of the reference wires w-1 and w-2, etc., accurately, for evaluations in lower sections of the channel are dependent on the sectional alignment procedure using these wires. Firstly, the wire was not in perfect focus since it was waxed on the *outside* of the glass; secondly, the fringe pattern sometimes interfered partially. The error in each alignment procedure was estimated at 0.1 fringe. Agreement between results of spark interferograms and moving film traces of a cross section near the throat (see Fig. 9) provided a check on the alignment procedure.

A precision estimate on the measurement of minimum channel width, or throat, is included in Table II because the channel geometry is important for theoretical calculations. The actual position of the throat is difficult to determine because of the small curvature of the walls in this vicinity. Repeated measurements of the throat width yielded the values shown in Table I with an estimated uncertainty of 0.5 percent in throat width and 1.0 percent in throat-orifice distance.

The evaluation of the divergent-channel interferograms was made on the assumption of constant physical conditions from glass to glass. This was investigated by taking an interferogram after having turned the channel through 90° with respect to its usual position. Then the light travels parallel to the glass walls. Of course, it is possible to view the flow field only above the orifice. Pictures of this sort are shown in Fig. 10. They illustrate the smaller density and higher temperature existing in the boundary layer along the glass as evidenced by the curvature of the fringes. Except for this glass layer, conditions are quite uniform from glass to glass up to about 5 mm above the orifice. It is reasonable to extrapolate below the orifice and assume that homogeneity exists there. For the divergent channel, the glass layer is evidently affected by the oblique orifice shock at about 5 mm above the orifice and begins to separate, with the result that the homogeneity in the direction of the light beam is destroyed (Fig. 10a) and fringe shift evaluations become impossible. A more detailed consideration of the glass layer and other boundary layer errors (category IV of Table II) will be given in connection with the discussion of the Laval nozzle where the boundary layers are thicker and therefore play a more prominent role. From these subsequent considerations it was possible to estimate that the error in density due to the boundary layer on the glass was, in the case of the divergent channel, less than 1 percent.

**** See p. 1367 in reference 7.

TABLE II. Survey of experimental accuracy.

	% Uncertainty	Basis for value in previous column
I. *Instrumentation*		
Tank pressure	0.3%	Fineness of graduations on gauge.
Tank temperature**	0.3%	Change in temperature due to efflux before photo is taken.
II. *Miscellaneous**		
Q-1, Q-2 mismatch.		
Effect on density:		
orifice	0.3%	Comparison of stationary and flow pictures.
throat	0.3%	Matching error of 0.1 fringe.
Oscillations.		Analysis of moving film traces.
Effect on density:		
orifice	1.5%	Estimated average displacement of 0.2 fringe from mean value.
throat	0.5%	
III. *Geometrical**		
Overlap alignment.		Study of comparator readings.
Effect on density:		
throat	0.5%	Estimate of a 0.1-fringe error per overlap, resulting in a 0.2-fringe possible error in throat section.
Width of throat	0.5%	Comparator studies on photographic plate.
Position of any wall	0.02 mm	
IV. *Boundary Layer****		
Boundary layer on glass.		
Effect on density at orifice of Laval nozzle, $P_t = 4.80$ atmos.	1.1%	Measurements on interferogram showing this glass-layer.
Corner effect:		
Maximum error—occuring at inner edge of boundary layer.	1.6%	Consistency of postulated corner effects of various magnitudes with other experimental results.
Refraction error—*maximum*	2.9%	Substitution of computed value of density gradient into the derived formula.

---

* Percentage uncertainties in ρ were calculated for divergent channel (ρ orifice $=1.29$ mg/cc, ρ throat $=4.00$ mg/cc). The percentage for the Laval nozzle are smaller since ρ is greater.

** Use of a thermocouple in the Laval nozzle work made this error negligible.

*** In the Laval nozzle work, the calculated ρ was corrected for the glass layer. The refraction error is an extreme case. For the average boundary layer, this was 1 percent or less.

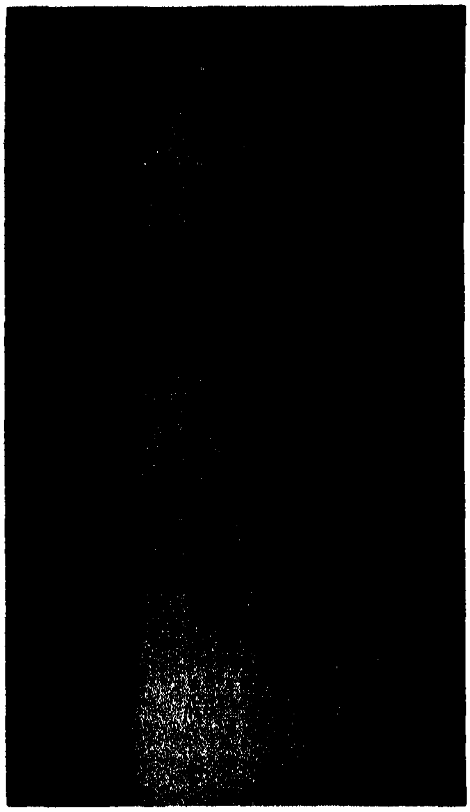


FIG. 8.

B. Potential Flow in the Divergent Channel

A set of interferograms covering the complete supersonic portion of the divergent channel was made and evaluated (Fig. 6). The results for the density were expressed graphically by drawing contours of equal density, known as isopycnals (Fig. 11). Examining this chart, we see first the decreasing density along the axis in the downstream direction, demonstrating the continued expansion. The gradient is largest in the region of the throat. The non-uniformity of the flow is greater in regions where the curvature of the walls is more marked; the homogeneity across the channel grows better as one approaches the orifice.

The isopycnic pattern can be confirmed, within limits, by photography. For if the fringes are made so wide that one fringe covers the entire field and an interferogram is then made, points of equal density will lie on the same fringe (Fig. 12). To do this, however, requires perfect interferometer plates. At least part of the discrepancies between this figure and the isopycnic chart are due to the inhomogeneities in the plates themselves, amounting to some fraction of a fringe.

Since there are no sources of energy dissipation in the channel except in the relatively narrow boundary layer regions, it was possible to obtain

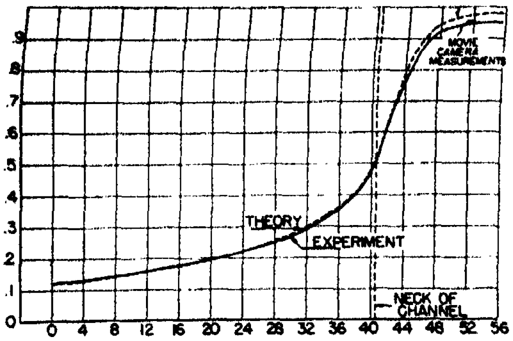

FIG. 9. Plot of P/P_0 *vs.* mm below orifice for divergent channel at $P_0=5$ atmospheres.

pressures and temperatures from the measured density using the well-known isentropic relations. If P_0, ρ_0, and T_0 are the known stagnation values of pressure, density, and temperature, respectively, then the pressure P and temperature T at some point in the channel are related to the density ρ by

$$P/P_0=(\rho/\rho_0)^\gamma=(T/T_0)^{\gamma/(\gamma-1)}, \tag{5}$$

where γ is the ratio of specific heats at constant pressure and volume. The velocity, u, and Mach number, M, may be conveniently calculated from the temperature by the energy equation:

$$u=[2C_p(T_0-T)]^{\frac{1}{2}}, \tag{6a}$$

$$M=[[2/(\gamma-1)][(T_0-T)/T]]^{\frac{1}{2}}. \tag{6b}$$

For comparison with theory, a relation between pressure at some point and the cross-sectional area, A, of the channel at this point was used. The one-dimensional theory of isentropic gas flow gives the relation as

$$(P/P_0)^{2/\gamma}-(P/P_0)^{(\gamma+1)/\gamma}=[(\gamma-1)/(\gamma+1)] \times[2/(\gamma+1)]^{2/(\gamma-1)}[A^*/A]^2, \tag{7}$$

where A^* is the throat area. In view of the small divergence angle of the walls, this one-dimensional theory was considered applicable. In Fig. 9, both experimental and theoretical pressure distribution curves are plotted. Agreement between theory and experiment is around one percent for most of the supersonic portion; deviations up to three percent may be observed in a small region around 32 mm below the orifice.

Schlieren pictures of the divergent channel gave Mach lines which permitted calculation of Mach numbers by Eq. (1). The definition of the lines was not as good as desired with the result that the calculated values of M are estimated as good to ±3 percent. The results for a few well separated places are given in Table III, which contains also the results obtained by interferometry together with results obtained from schlierens by Magin in 1908 with a practically identical channel. Under the heading "Theoretical" are listed Mach numbers *corresponding to the channel areas; the relation, obtained* from the one-dimensional isentropic theory, is

$$A/A^*=[1/M][[1+((\gamma-1)/2)M^2]/[(\gamma+1)/2]]^{\frac{1}{2}[(\gamma+1)/(\gamma-1)]}. \tag{8}$$

The discrepancies between columns 2 and 3 are within the estimated uncertainties of the measurements.

Flow of the gas through the orifice shock involves an increase of entropy and Eq. (5) must be replaced by the Rankine-Hugoniot relation which reads

$$P_2/P_1=[[(\gamma+1)/(\gamma-1)][\rho_2/\rho_1]-1]/[[(\gamma+1)/(\gamma-1)]-[\rho_2/\rho_1]], \tag{9}$$

where the subscripts "1" and "2" refer to opposite sides of the shock. By this equation, pressures downstream of the shock and at the inner edge of the vortex layer along the atmospheric boundary were calculated and found to be equal to 98 percent of the atmospheric value.

(a) (b)

IV. STUDIES WITH THE LAVAL NOZZLE

A. Construction and Revision

An interesting feature of channel flow, for whose study a channel design more suitable than the divergent channel was desired, is the viscous layer or boundary layer existing near the walls. The Laval nozzle was designed to obtain a more fully developed boundary layer with more uniform external conditions such as zero pressure gradient in the flow direction. The purpose of interferometry here was to provide a quantitative check on the proper channel construction.

The equation for two-dimensional steady potential flow may be written as follows:

$$\phi_{xx}[1-(\phi_x^2/a^2)]+\phi_{yy}[1-(\phi_y^2/a^2)] -2\phi_{xy}[\phi_x\phi_y/a^2]=0. \tag{10}$$

Here, ϕ is the velocity potential, a is the local velocity of sound, and the subscripts represent partial differentiation. Starting with certain given boundary conditions, the solution of this equation may be obtained by the "method of characteristics," first applied to supersonic flows by Prandtl and

Busemann[9] in 1929. The method makes it possible to determine the contour of a supersonic nozzle in such a way that the velocity finally becomes unifrom across the entire section. The Laval nozzle used in this work was designed by the "characteristics method" for a Mach number of 1.71. Figure 13 shows the graphical construction for this channel. One assumes $M=1$ at the throat (the validity of this assumption will be discussed later) and produces the expansion by curving the wall and inserting Mach waves in relation to the "wall bending" according to the rules of the method.[10] The quadrilaterals represent, to the approximation used, fields of constant velocity. The smaller the quadrilaterals, the closer the construction approximates the correct solution for the flow field. As the end of the expansion region is approached, the curvature of the walls is so designed as to cancel the reflected Mach lines. When this has been done, the walls of the channel are parallel and the flow field uniform.

A series of preliminary studies which included interferograms and shadow and schlieren pictures all showed the same phenomenon: oblique shocks within the channel (see Figs. 14a and 15a). These shocks are symmetrical and cross the axis at distances of 40.3, 27.4, 14.6, and 2.6 mm below the orifice. Interferometric study revealed that the density ratios varied from 1.01 to 1.03 across the shocks.

A slight revision of the original design and the removal of small machining errors gave an improved channel contour. In this revision the tolerance in the grinding operation was limited to 0.0003" (=0.1 percent of the throat width). The revised dimensions are given in Table IV. The polishing stone was not applied until preliminary shadowgrams were taken for the purpose of obtaining Mach lines. This is shown in Fig. 15b while 15c shows a shadow picture after the final polishing. A quantitative representation of the improvement in uniformity is given in Fig. 16 which shows Mach number distributions before and after improvement as obtained by interferometry. This figure also includes two values of M computed from Mach angle measurements on shadowgrams of the revised but unpolished channel. Agreement with the interferometric results is closer than one percent, itself the estimated degree of uncertainty in the shadowgram measurements. The observed decrease of Mach number with distance downstream, a feature of both curves, is associated with the growing boundary layer which decreases the effective cross section.

The degree to which the pressure gradient near the boundary layer in the direction of the flow was reduced (the main object of the channel revision) is shown in Fig. 17; these calculations were made from the same two interferograms whose axial Mach numbers are plotted in Fig. 16. It was felt that the improved channel gave a very good approximation to uniform flow, although residual non-uniformities are apparent from sensitive schlieren pictures (Fig. 18).

An interesting feature of a well constructed Laval nozzle is the degree to which the flow across the throat is uniform and of Mach number equal to one, inasmuch as the latter is an assumed boundary condition in the "characteristics" construction. In Fig. 19 are shown isopycnic photos of the throats of the two channels, illustrating the relative homogeneity of the flow. The evaluated interferogram of the divergent channel showed that the Mach number increased from 0.97 on the axis to 1.04 at 1.1 mm from the wall, a 7 percent change, whereas for the Laval nozzle the variation was from 1.01 on the axis to 1.05 at 1.0 mm from the wall, a 4 percent change. In the former case the curvature of the walls in the throat region is seen to be rather sharp but in the latter case a very gradual subsonic entrance was drawn with a French curve and a careful attempt was made to provide maximum con-

tinuity with the beginning of the supersonic portion. Figure 20 gives Mach number distributions across the throats of the two channels. From these results it appears quite evident that the assumption of uniform flow of $M=1$ at the throat of a rectangular nozzle is not justified unless the most extreme care is taken to reduce curvatures and discontinuities in this region to the barest minimum.

B. Boundary Layer on the Glass

The evaluation of the Laval nozzle interferograms included a correction for the deviation from truly two-dimensional flow due to the boundary layer along the glass. By taking an interferogram with beam parallel to the glass walls (Fig. 21) one can compute the amount of the necessary correction. In deriving this correction formula, the following notation is used:

S_1 = observed fringe shift in free stream on interferogram made with light beam perpendicular to glass.
Y = coordinate perpendicular to metal walls.
Z = coordinate perpendicular to the glass walls.
$\rho(Z)$ = density at a point in boundary layer Z mm from the glass.
ρ_a = atmospheric density existing in channel prior to gas flow.
ρ_1' = apparent free stream density calculated from S_1.
ρ_1 = true stream density.
$\Delta S(Z)$ = difference in fringe shift between a point in the boundary layer along the glass at Z mm from the glass wall and a point on the same horizontal level in the free stream as observed on an interferogram taken with light beam parallel to the glass walls.

TABLE III. Comparison of Mach numbers for flow in diverging channel.

Distance below the orifice mm	Interferometry	Schlieren	Magin	Area (theoretical)
2.2	1.98	—	1.96	2.01
16.3	1.77	1.79	1.74	1.79
25.6	1.60	1.64	—	1.64
30.7	1.48	1.53	—	1.47

$\Delta\rho(Z)$ = density difference corresponding to $\Delta S(Z)$.
W = width of channel.
D = depth of channel (= glass to glass distance).
δ = width of boundary layer along metal walls (along still air when above the orifice).
ϵ = width of boundary layer along glass wall
$\theta = D - 2\epsilon$.
$\tau = W - 2\delta$.
K = Gladstone-Dale constant.
λ = wave-length of light.

The apparent free stream density is obtained from the optical path change by the relation

$$S_1 \cdot \lambda = K \cdot D(\rho_1' - \rho_a).$$

Allowing for the layer on the glass, the correct expression is

$$S_1 \cdot \lambda = K(\rho_1 - \rho_a)\theta + 2K\int_0^{\epsilon} [\rho(Z) - \rho_a] dZ.$$

The boundary layer density $\rho(Z)$ is less than ρ_1; we put

$$\rho(Z) = \rho_1 - \Delta\rho(Z)$$

and removing ρ_1 and ρ_a from under the integral sign we get

$$S_1 \cdot \lambda = K(\rho_1 - \rho_a)D - 2K\int_0^{\epsilon} \Delta\rho(Z) dZ.$$

By equating the two expressions for $S_1 \cdot \lambda$, there results

$$\rho_1 = \rho_1' + (2/D)\int_0^{\epsilon} \Delta\rho(Z) dZ. \qquad (11)$$

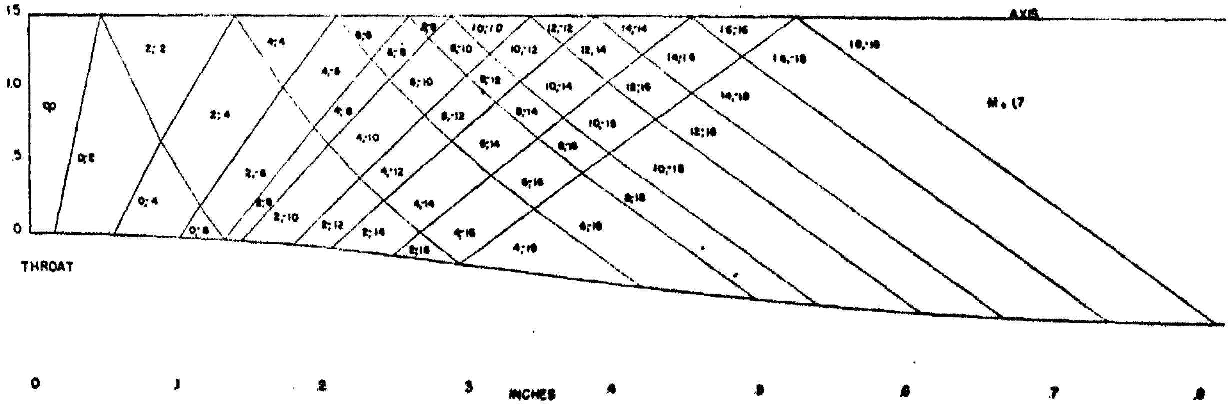

FIG. 13. Design of Laval nozzle contour by method of characteristics. Each pair of numbers gives the magnitude and direction of the velocity in the region indicated.

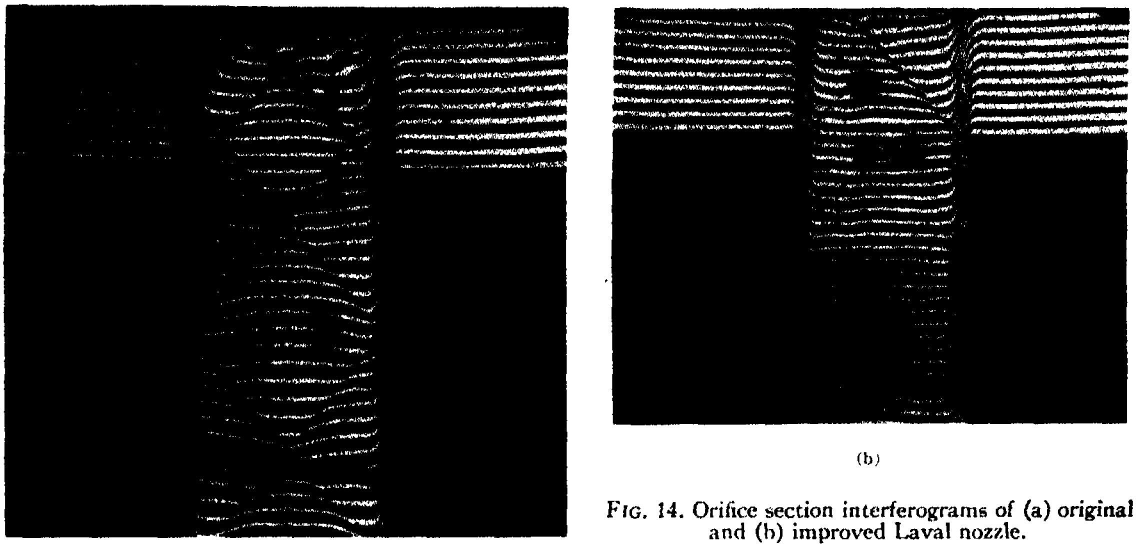

(a)

(b)

FIG. 14. Orifice section interferograms of (a) original and (b) improved Laval nozzle.

Referring to Fig. 21, we consider the two light rays A and B traveling perpendicular to the gas flow but parallel to the glass walls. For the ray A, $Z<\epsilon$ while for B, $Z>\epsilon$ so that the former passes through the boundary layer on the glass while the latter traverses the free stream. The two rays have different histories over a length of path $W\text{-}2\delta$ or τ. The relation between $\Delta\rho(Z)$ and $\Delta S(Z)$ is thus given by

$$\Delta\rho(Z)=(\lambda/K\tau)\Delta S(Z)$$

and the correction formula can be expressed in terms of the measured quantity $\Delta S(Z)$:

$$\rho_1=\rho_1'+(2\lambda/KD\tau)\int_0^{\epsilon}\Delta S(Z)dZ. \qquad (11a)$$

In practice, the correction integral is obtained by measuring the area under the curve of $\Delta S(Z)$ *vs.* Z. Measurements of the correction were made at 0.25, 2.8, 4.3, and 5.8 mm above (downstream of) the

orifice. The percentage correction for ρ at the orifice in the experiment at 4 atmospheres of tank pressure was

$$100[(\rho_1-\rho_1')/\rho_1]=1.3 \text{ percent.}$$

To obtain data on the correction at various cross sections below the orifice, the variation of the quantity

$$\int_0^{\delta} \Delta S(y)dy$$

along the metal walls was studied and the assumption made that the development along the glass wall was similar. Figure 22 is a test of this assumption. Superimposed on a density profile along metal at 0.50 mm below the orifice are points obtained from the boundary layer on the glass at 0.25 mm above the orifice. The agreement is rather good. All the calculations of the free stream density in the Laval nozzle experiments were corrected for the boundary layer.

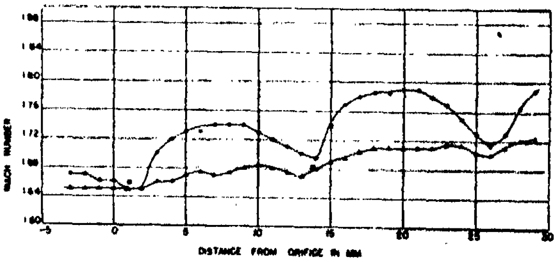

FIG. 16. Laval nozzle: Mach number distribution—

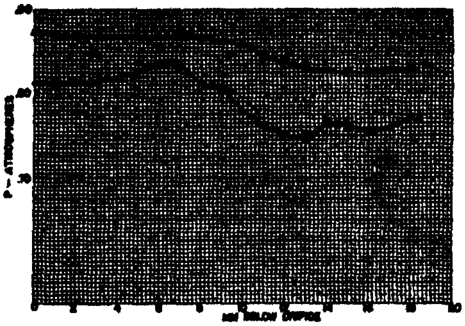

FIG. 17. Laval nozzle: Pressure distributions at 1.5 mm from the wall (a) before improvement and (b) after improvement. $P_0=4$ atmospheres.

The comparison of boundary layers on glass and steel was put on yet a more quantitative basis by replacing *one* of the glass walls with a plane steel plate and comparing directly the boundary layer on this wall with that on the other (glass) wall. Densities were compared at several corresponding points in the two layers. The steel wall showed a somewhat lower density along the whole layer but the average density difference for five cases was only 1.7 percent, too small to conclude that there is any real difference.

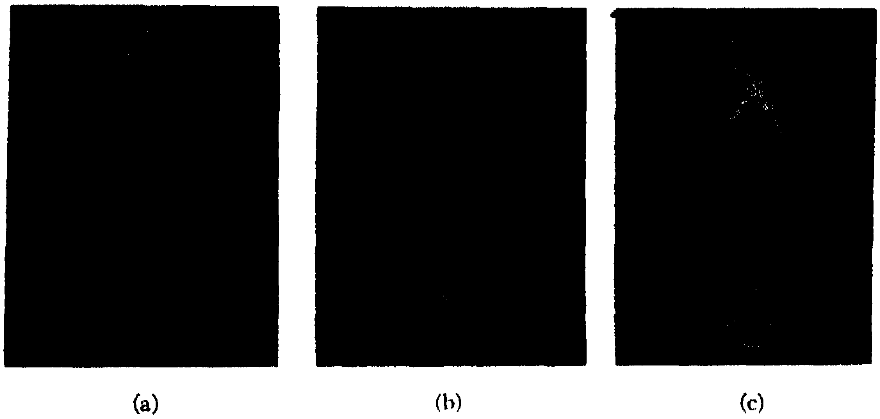
C. Refraction Error†

The presence of density gradients in the flow will, in general, cause the light beam to change its direction. This is illustrated schematically in Fig. 23 where a light ray entering the flow field at the point *E* would continue to the point *M* in the absence of a density gradient but actually takes the curved path *EF* in the presence of a downward gradient. This effect will be most marked in regions of high gradient such as boundary layers. Two questions arise:

1. Does the refraction introduce any distortion into the photographic behavior of the system?

---

† A more general and somewhat different treatment of this problem (unpublished) has been given recently by Dr. F. J. Weyl, Naval Bureau of Ordnance, Washington, D. C.



(a) (b) (c)

FIG. 18. Schlieren photographs of the improved Laval nozzle at (a) 4.07, (b) 4.80, and (c) 6.09 atmospheres.

I.e., is the center of the flow field on which the camera lens is focused still being mapped accurately on the screen or photographic plate?

2. By how much is the evaluated density at any point in error due to refraction?

In the following treatment, we make the following assumptions:

(a) The value of the radius of curvature R, of the path EF at E differs negligibly from its value at F so that EF is considered as the arc of a circle.

(b) R is much larger than D, the depth of the working section: $R \gg D$.

(c) The variation of grad$n$ (n = refractive index) between the lines EM and GF in Fig. 23 may be ignored.

(d) The pencil of rays coming from a point in the object plane is narrow enough so that variation of refraction effects between the extreme rays is insufficient to affect the sharpness of the fringes (i.e., optical path difference $\leq \lambda/4$).

(e) The density gradient lies in the plane of the diagram and is perpendicular to the incoming light.

In considering the first of the two questions, notice that under conditions of no flow, the ray shown in Fig. 23 would appear to the camera lens to be coming from point B in the object plane, whereas the presence of flow makes it appear to come from C. We wish to calculate the distance BC or ξ.

Since the tangents to the circle at E and F intersect at H, the line OH bisects the angle ϵ. The following exact relations hold:

$$\sin\epsilon = D/R; \quad \tan\epsilon/2 = EH/R = (D/2+\eta)/R;$$
$$\tan\epsilon = D/(R^2-D^2)^{\frac{1}{2}} = \xi/\eta.$$

From these one obtains

$$\xi = [D\cdot R/(R^2-D^2)^{\frac{1}{2}}][\tan\epsilon/2 - \tfrac{1}{2}\sin\epsilon].$$

Since $D \ll R$, it is possible to neglect D^2 compared to R^2 and to expand the terms in the brackets up to ϵ^3 which gives

$$\xi \cong \epsilon^3\cdot D/8 \cong D^4/8R^3 \cong [D^4/8][|\text{grad}n|^3/n^3].\dagger\dagger \quad (12)$$

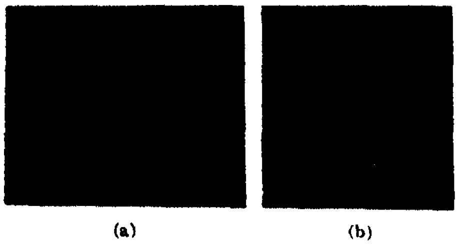
The value of ξ was compared with the radius of the "circle of confusion" due to diffraction by the camera lens itself. The half-width Ω of the central maximum of the diffraction pattern formed by the lens of a parallel bundle of light is given by $\Omega = 1.22\lambda f$, where f is the so-called f number, equal to the focal length of the lens divided by its diameter. Measurements of typical boundary layers and an expansion wave in the Laval nozzle gave values of ξ around 10^{-7} cm, whereas Ω was 6×10^{-4} cm. Thus in the fourth column of Table V, ξ is set approximately equal to zero and "photographic distortion" is considered absent. Agreement within the experimental error of 0.003 cm between measurements of channel width on an interferogram at a carefully adjusted magnification of 1:1, and accurate measurements made on the channel itself verified this result.

We now consider the second of the above questions. If ϕ is the angle between the direction of a light ray and the gradient of the refractive index, the radius of curvature of the path is given by

$$1/R = (\text{grad}n/n)\sin\phi.$$

Now, from Fig. 23 we see that

$$MF \equiv \Delta = R-(R^2-D^2)^{\frac{1}{2}} \cong D^2/2R.$$



(a) (b)

FIG. 19. Isopycnic photos (contour fringes) of throat sections of (a) divergent channel and (b) Laval nozzle.

---

†† Discussed in next paragraph.

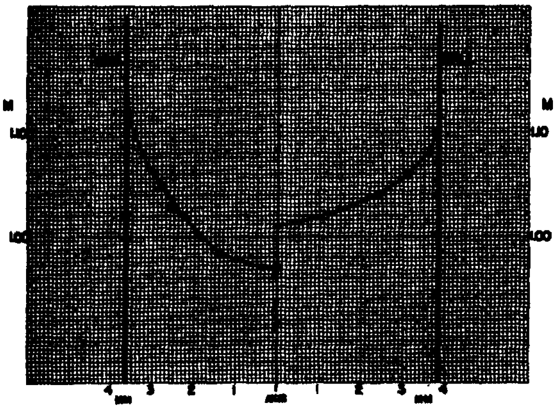


FIG. 20. Mach number distribution across the throat: ×—Divergent channel; ⊙—Laval nozzle.

More generally, if Z be the direction of the incident light with the line EG as the axis $Z=0$, then the deviation, $\delta(Z)$ of any point P lying in EF from the unrefracted path EM will be given by

$$PP'=\delta(Z)\cong Z^2/2R.$$

The average deviation, $\bar{\delta}$, over the path EF will be

$$\bar{\delta}=\frac{\int_0^D (Z^2/2R)dZ}{\int_0^D dZ}=D^2/6R.$$

The actual length of the path EF is

$$EF=R\cdot\epsilon\cong D+(R\epsilon^3/6).$$

Denoting the refractive index along EM by n, we find that the difference, Q, in optical path due to refraction is

$$Q=(n_1+\bar{\delta}\,\mathrm{grad}n)(D+(R\epsilon^3/6))-n_1D,$$

neglecting terms in ϵ^5 compared to ϵ^3. A very good approximate expression for Q may be obtained by allowing

$$\epsilon\cong D/R;\quad 1/R\cong\mathrm{grad}n\quad (\text{i.e., } n=1,\ \phi=\pi/2)$$

and using $\bar{\delta}=D^2/6R$. This gives

$$Q=(D^3/6)|\mathrm{grad}n|^2\cdot[2+(D^2/6)|\mathrm{grad}n|^2].$$

Where the last term in the brackets is much smaller than 1 (it was 10^{-5} or smaller in the present experiments), the expression becomes

$$Q\cong(D^3/3)|\mathrm{grad}n|^2=(K^2D^3/3)|\mathrm{grad}\rho|^2.\dagger\dagger\dagger \quad (13)$$

This extra optical path Q will produce an added fringe shift ΔS, given by $\Delta S=Q/\lambda$; i.e., the *observed* fringe shift will be too great by the amount ΔS. Because of the relationship between ρ and S, the error ΔS will be accompanied by an error $\Delta\rho$ given by

$$\Delta\rho=(\lambda/KD)\cdot\Delta S.$$

Expressing the desired result in fractional form we have

$$\Delta\rho/\rho=(KD^2/3\rho)\cdot|\mathrm{grad}\rho|^2. \quad (13a)$$

$\Delta\rho$ is the amount to be subtracted from the density supposed to exist at the point B according to the observed fringe shift.

Table V gives pertinent data for three cases among the highest gradients measured. The constants associated with these calculations are

$D=1.90$ cm, $\lambda=4.48\times10^{-5}$ cm,
$K=0.229$ cm^3/g, f-number of camera lens $=10$.

To understand the meaning of the bottom row of the table, it should be noted that, in the examples taken here, the higher the gradient, the narrower the fringes. On the present interferograms the narrowest accurately readable fringe width was 0.0080 cm, corresponding to a density gradient of 12.5×10^{-3} g/cc/cm as given in this row of the table. The second row of the table contains a higher gradient value and was included because it represents the highest gradient which was measured, but the data are less reliable. (It is estimated that for this case the uncertainty in gradρ is about 5 percent whereas for the other cases it is about 2 percent.)

The density gradients were computed by taking a region through which the fringe width remained reasonably constant (second column of Table V) and dividing by the total density change. In all cases this region was considerably larger than the maximum deviation, Δ, of the light ray from the unrefracted path so that the assumption of the constancy of gradρ is a valid one.

In boundary layer studies, the exact absolute values of the densities are less important than the shape of the density profile. Distortions of the latter would arise only from variation of gradρ, since for a constant gradient, the refraction error would merely displace the profile parallel to itself. Figure 24 shows a typical boundary layer profile; it is seen

that the curvature is small throughout most of the region.

D. Errors Due to Intersecting Boundary Layers

In the corners of a rectangular channel the boundary layers along the two intersecting walls themselves intersect. It is thought that a rounding-together occurs somewhat as shown in the schematic diagram of Fig. 25. The effect on the interferometric evaluation is illustrated by considering the rays labeled *A*, *B* and *C* in this figure. While it is clear that ray *B* does not traverse the boundary layer along the metal as does ray *C*, nevertheless it passes through the thickened "corner layer" and therefore its optical path is different from that of ray *A* (shorter). The difference between *A* and *B* may be mistakenly attributed to the passage of ray *B* through the entire boundary layer along the metal wall. Thus the apparent boundary layer would be thicker than the actual one.

There exists no experimental information on this sort of "corner effect." However, a knowledge of the density profiles in the boundary layers studied has made possible order-of-magnitude calculations which show that the effect of the corner thickening will be, in most cases, an extremely limited one. The first step is to take a typical profile and plot the fringe shift *relative* to the free stream. This was done for the case of a layer at 1 mm below the orifice on an interferogram of the Laval nozzle taken at 5 atmospheres of tank pressure, indicating an apparent boundary layer width of 1.0 mm. One next assumes that the actual boundary layer is thinner, choosing some definite value such as, for example, 0.7 mm and then proceeds to ascertain how much plausibility there is in assigning the remaining 0.3 mm to the "corner layer." It is now necessary to draw an assumed profile for the corner such as is shown in Fig. 25. Then, the procedure is to study a ray parallel to the wall, but somewhat outside the assumed true boundary layer (ray *B* in Fig. 25), say at 0.9 mm from the wall. After measuring the length of path of this ray in the corner layer and using the information given by the fringe shift plot that the difference in optical path was, in this case, equivalent to a relative shift of 0.5 fringe, it becomes possible to calculate an average corner density, ρ_c, which would account for the difference in path. For the example of the assumed 0.7-mm layer, this density was calculated as

$$\rho_c = \rho_1 - 0.5 \text{ mg/cc.}^{\dagger\dagger\dagger\dagger}$$

That such a result is extremely unlikely is apparent if it be noted that the density at 0.1 mm from the wall is only 0.45 mg/cc below the stream density ρ_1, and that the section of corner layer which plays

---

†††† A shift of 0.5 fringer was equivalent to a density difference of 0.5 mg/cc rather than 0.05 mg/cc because the extra length of corner layer traversed by ray *B* as compared to ray *A* was 0.2 mm, or about one-tenth of the channel depth.

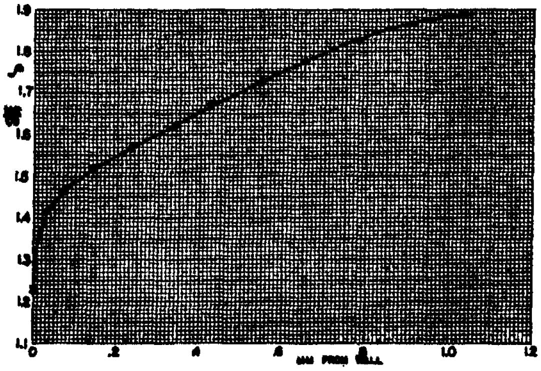

FIG. 24. Boundary layer density profile along channel wall ($P_0=4.80$ atmospheres). See appendix for other pertinent data.

the role in producing the 0.5-fringe shift relative to free stream is 0.9 mm away from the wall. The density must be, in reality, much closer to the free stream value.

One can then assume an 0.8-mm boundary layer and repeat the calculation. In the present case it was concluded that the effect of the corner layer would be limited to causing a relative shift of at most 0.3 fringes relative to free stream in a narrow region at the inner edge of the boundary layer. The result with the Laval nozzle of the dimensions used would be to cause an ambiguity of about 0.1 or at most 0.2 mm in the choice of boundary layer width.

V. SUMMARY AND CONCLUSIONS

This study indicates that the technique of interferometry applied to compressible channel flow is a feasible one which is capable of giving good accuracy in density determinations. Of course, the magnitudes of the various uncertainties depend on the particular apparatus geometry and experimental conditions. In the present experiments an analysis of errors as summarized in Table II leads to the conclusion that values of ρ directly obtained from the interference measurements possess an estimated probable error of about 2 percent. Comparison between interferometric results for potential flow in the divergent channel and the values computed from the one-dimensional theory of isentropic flow show a difference of 1 percent. Independent checks were provided by Mach angle measurements on schlieren pictures and by fringe shift measurements on moving film. In the case of the latter technique, agreement with the results of spark interferograms in the neighborhood of the throat showed that the procedure of studying density fields larger in size than the interferometer plates by aligning interferograms of adjacent sections is reliable.

The deviation from steady flow in channels of the type studied consists in small oscillations about a mean value of the physical variables. There would be corresponding inconsistencies in the absolute values of density calculated from successive interferograms taken at different parts of the oscillation cycle. The estimated uncertainty of this and other errors are given in Table II.

Interferometry can be usefully applied as a guide in nozzle construction since the results of the evaluated interferograms can be quantitatively compared with the desired properties of the nozzle. In particular, the uniformity of flow in the throat can be studied. The present experiments show that the attainment of uniform flow of $M=1$ across the throat is a difficult problem.

There are at least three different boundary layer phenomena which affect the interference pattern in channels having sizable boundary layers:

(a) Boundary layer on the glass.
(b) Refraction error.
(c) Corner intersection of boundary layers.

(a) The density obtained from the observed fringe shift has to be increased by:

$$\Delta\rho=(2\lambda/KD_T)\int_0^s \Delta S(Z)dZ$$

(for notation see Section IV). The percentage correction for the orifice region of the Laval nozzle at $P_0=4$ atmospheres was 1.3 percent. Except for this layer, homogeneity from glass to glass was excellent.

(b) In the presence of a density gradient normal to the light beam, a negative correction to the density will account for the refraction error. This is given by

$$\Delta\rho=(KD^2/3)|\mathrm{grad}\rho|^2.$$

In the present case, an extreme density gradient of 12.5×10^{-8} g/cc per cm was accompanied by a refraction error of 2.9 percent. The shape of a density profile is not altered appreciably by refraction unless gradρ varies strongly.

(c) Semiquantitative calculations give the result that, in the present Laval nozzle experiments, the

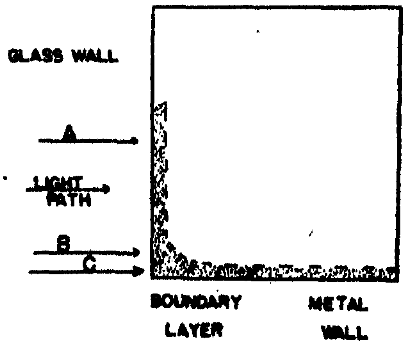

FIG. 25. Schematic diagram illustrating "corner effect."

"corner effect" introduces an ambiguity of about 10 percent in the choice of boundary layer width. Other parts of the interference pattern are unaffected.

ACKNOWLEDGMENT

The writer is indeed grateful to Professor Rudolf Ladenburg who suggested the subject of this research and gave constant guidance in the work. Sincere thanks are also extended to Miss Anne Kenny whose skillful and generous help in many phases of the work, particularly the computations, was of great assistance.

APPENDIX

Notes on boundary layer calculations.—In spite of the relatively small width of the boundary layers (1 mm or less), the sharpness of the interference fringes in these regions made possible an evaluation of density distributions, taking due account of previously mentioned correction factors.

Figure 24, a density profile at 4 mm upstream of the orifice of the Laval nozzle (62 mm downstream of the throat), is typical of many others. Conditions in the free stream near this layer are as follows:

$T_1 = 187°$ K. $\quad M_1 = 1.67$.
$P_1 = 1.02$ atmos. $\quad \rho_1 = 1.91$ mg/cc.
$u_1 = 459$ meters/sec.

The extrapolated value of ρ at the wall is calculated on the assumptions that the wall temperature equals the stagnation temperature of the gas (room temperature) and that the pressure across the throat is constant:

$$\rho_w = P_w/RT_w = P_1/RT_0 = 1.23\text{ mg/cc. } (T_0 = 293°\text{ K.})$$

The ideal gas law may further be used to calculate the distribution of temperature from the known pressure and densities.

As is evident from schlieren pictures (for example, Fig. 18), we are dealing here with turbulent boundary layer flows. Figure 26 shows a laminar-looking layer with an apparent transition to the turbulent form upstream of the uniform section of the channel. The evaluated layers were all considerably downstream of the transition region. The Reynolds number associated with the profile of Fig. 24 is

$$Re = \rho_1 u_1 l/\mu_1 = 4.3\times 10^6,$$

using the distance from the throat as a typical length l. The value of the viscosity coefficient μ_1 corresponding to the temperature T_1 was obtained from the Landolt-Börnstein Tables and found to be equal to 129 micropoises. The Reynolds number for the transition region was calculated to be

$$Re_{\text{trans}} = 1.2\times 10^6.$$

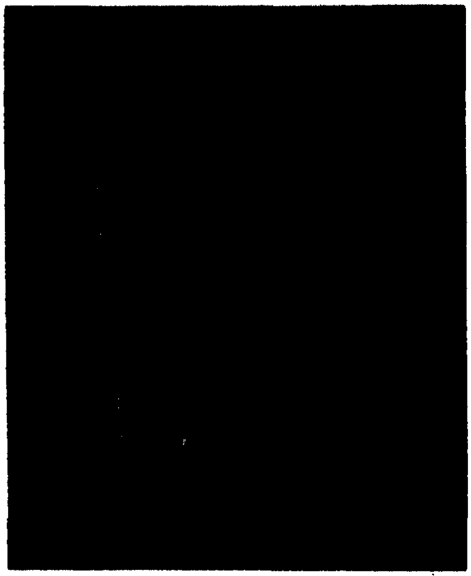

FIG. 26. Schlieren photo of throat region of Laval nozzle showing what appears like a laminar-turbulent transition in the boundary layer.

Of high interest are the velocity distributions in the boundary layers. Values of u were obtained from the energy equation:

$$u = [2Cp(T_0 - T)]^{\frac{1}{2}}.$$

The use of this relation is, in general, not justified for flows of the boundary layer type because of their non-isentropic character. Arguments exist, however, to show that it is applicable in the present case. Preliminary results have been obtained for the velocity distribution but a fuller investigation is planned before these are reported. An extension of the study to other Mach and Reynolds numbers is being undertaken using the larger intermittent supersonic wind tunnel recently constructed at this laboratory under the direction of Professor Ladenburg.

Cloud-Chamber Equipment for Study of Infrequent Cosmic-Ray Processes*

W. Y. CHANG AND J. R. WINCKLER
Palmer Physical Laboratory, Princeton University, Princeton, New Jersey

(Received January 3, 1949)

The cloud chamber described operates if a particle passes through a vertical telescope and stops before reaching anticoincidence counters under the chamber. The chamber is surrounded by a minimum amount of material, and a large number of the anticoincidence events consist of particles stopping in foils of aluminum, iron, and lead within the chamber. The expansion valve is of the fast electromagnetic type having a thin iron diaphragm which completes a magnetic circuit when closed. Six slow expansions for clearing the chamber occur immediately after each event. The chamber is housed in an insulated room kept within ±0.1°C. The Geiger counter coincidence circuits operate time delays for controlling the expansions, flash lamps, camera, clearing field, and recorders. The electronics is suitable for the study of very infrequent events. Several pictures of meson decay and shower events are presented.

I. INTRODUCTION

INTERACTION phenomena in cosmic rays are generally rare. For example, extensive showers, or showers produced by penetrating particles, or the processes connected with slow mesons occur particularly infrequently—about one in several hours for the usual solid angle of detection. The necessity of using a cloud chamber to observe these events does not need special mentioning. However, for these purposes the cloud chamber, which is of course counter-controlled, and its associated equipment, once adjusted, must be ready at all times to respond to the events. Essentially, the temperature and pressure,[1] in the first place, must be kept constant throughout the whole period so as to maintain the same expansion ratio. Second, the chamber must be cleaned periodically to remove any condensation nuclei so as to provide a clear background. Third, the delay control apparatus, etc., must operate reliably each time.

During the past two years we have built a cloud chamber and automatic control equipment for the study of meson absorption by thin foils.[2] This whole set of apparatus has been working satisfactorily for over a year—the cloud chamber and the counter units, etc., normally are checked only about twice a week (working continuously 24 hours a day). This set of equipment obviously can be used to study other infrequent cosmic-ray phenomena. It may be arranged so that two or more different types of cosmic-ray processes can be studied with the same chamber equipment at the same time, e.g., extensive air showers and meson absorption by thin foils. We feel, therefore, that it may be worth while to report the detailed construction of the cloud chamber and the electronic details of the control units, etc.

FIG. 1b. Chamber bottom with gear system.

II. THE CLOUD CHAMBER AND ASSOCIATED APPARATUS

A. The Cloud Chamber

The cloud chamber is in the rubber diaphragm type and has an inside diameter of about 12 inches. Figure 1a shows the assembly. For eventual use with a magnet, the back (dead) space has been made as small as possible. To accomplish this, the position of the perforated brass plate (with 4-mm holes), against which the diaphragm expands, and hence the expansion ratio is varied from outside at the bottom circumference by means of a system of three gears (see Fig. 1b). This brass plate is supported rigidly, by means of three screws, on to the threaded hub. From the plate there are three equidistant brass pins (perpendicular to the plate) which can move along in three brass tubes projected upward from the main gear. Hence, when the gear is turned, a moment is, by means of these pin-tube couplings, applied to the plate, which is thus turned forward or backward. The diaphragm is made of two rubber sheets, with a $\frac{1}{16}$-inch Bakelite plate in between. In this way the diffusion of alcohol from the chamber proper is much slower than without the Bakelite plate. Moreover, the expansion in the neighborhood of the circumference can be as near to that at the center as possible, i.e., more uniform expansion everywhere.

A brass ring (17) is held rigidly to the bottom ring (18) by using only four equally spaced brass cylinders ($\frac{7}{8}$-inch diameter, and with screws (19) inside). The glass window ($\frac{5}{16}$-inch Herculite glass) and the glass cylinder (cut from ordinary battery jar) are held together against the bottom ring (18) by the top ring (16) which can be screwed on to the ring (17). Neoprene gaskets are used for the vacuum seals. In this way we have the least amount of material surrounding the chamber proper. This is an advantage for studying certain cosmic-ray processes taking place inside the chamber, for the number of useless pictures due to the same process at the chamber walls is small. Moreover, the chamber depth can be easily varied (if desired) by simply changing the length of the four spacers and the height of the glass cylinder. The thickness of the over-all dead space at the back is about 2 inches. With argon gas saturated with alcohol-water mixture, the chamber depth can be increased up to 8 inches. Two depths have been used, namely 5 and 8 inches. The deeper chamber has been found to work with smaller turbulence.

Figure 1b shows the arrangement of the three gears, with the outside one in a vacuum-sealed box at the circumference. The expansion ratio can be read from a scale above the box (cf. Fig. 1a, left-hand side). The air passage to the expansion valve is smoothly constricted.

In operating the chamber it is advantageous to employ a back chamber pressure so that the rubber diaphragm is quite clear from the front perforated disk (which is covered with a piece of velvet for the purpose of photography). Thus, the turbulence, which may be created in the neighborhood of the diaphragm during expansion and be transmitted to the chamber proper, can be as small as possible. All

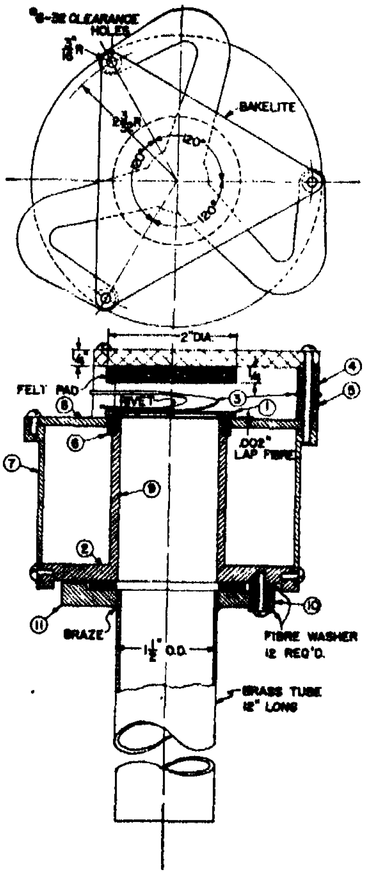

FIG. 2. Expansion valve. The iron diaphragm (1) supported on a Bakelite spider completes the magnetic circuit when closed.

the materials inside the chamber must be very clean, not soluble in the liquid mixture of alcohol-water, and not giving off disturbing volatile substances. Synthetic rubber for the diaphragm and gaskets is found to give a smaller background than gum rubber, for presumably the former does not dissolve in the alcohol-water mixture easily. In using lead foils as absorbing material inside the chamber, the oxide layers found on the surfaces must be carefully cleaned with steel wool and then washed thoroughly with alcohol. No water is used for the cleaning purpose, for lead is oxidized very easily by water. Thus the background at expansion ratios, smaller than the ion limit, will be very small.

B. The Fast Expansion Valve

The fast expansion valve is of a solenoid type. Figure 2 shows its assembly. The inner cylinder ((9) in Fig. 2) is made of steel, with the flange at the lower end, and the solenoid (No. 18 copper wire) is wound upon it. The outer cylinder (7) and the cover ring (8) are also made of steel. The magnetic circuit is thus completed except at the circular gap where the Bakelite ring (6) is. The Bakelite ring (6) provides a fiber seat for the iron disk (1), which may be attracted against the seat by the magnetic field so as to make a vacuum seal. The iron disk (1) is held in position by a thin Bakelite spider (3) (canvas base 0.01 inch thick). As shown in the top sketch, the legs of the spider are fixed so that the iron disk can only move along the axis of the valve. The brass tube (1½-inch diameter), which is to connect the expansion valve to the cloud chamber, is insulated electrically from the valve by means of the fiber washers (10) so that the eddy currents induced in the metal parts of this valve will not flow to the chamber metals when the solenoid current is cut off at the instant of expansion. The operating circuit is described in a later section.

In order to keep a constant expansion ratio for many days, the air pressure behind the diaphragm of the cloud chamber has to be maintained the same for each expansion. This is accomplished satisfactorily by a Mason-Neilan No. 40 reducing valve with the top compartment of the valve sealed against the atmosphere. In this way the air pressure behind the diaphragm is regulated against a constant pressure but not the atmospheric pressure, which varies. Better regulation is obtained with a small leak provided in the back chamber.

C. The Photographic Equipment

A Recordak Micro-File Model E camera and a pair of xenon flash lamps have been used for taking photographs. Each lamp is connected across a bank of condensers of about 50-microfarads capacity, charged at a voltage of about 2500. Two ways of focusing the illuminating beams have been adopted. In one case where the chamber depth was 5 inches, each lamp (General Electric 126, 4 inches long) was focused with a parabolic mirror of 1-inch focal length and 4-inch width, while in the other case (chamber depth 8 inches) a lamp of 8-inches length was focused with a Plexiglas lens. The lamps used in this latter case were manufactured by Amglo Corporation of Chicago and were found to work satisfactorily. Each of these lenses is about 4 inches wide and 8 inches high and has a focal length of about 2 inches. Such lenses have been found to give a better defined beam of light than the parabolic mirrors—sharper edges of the beam and more intense and uniform distribution of light intensity across the depth of the cloud chamber. The cloud chamber is illuminated from both sides—cross illumination. The two beams of light are pointed slightly toward the camera, the angles made with the camera axis being about 70 degrees. The duration of light is only a few hundred microseconds, and therefore a large screen of zinc sulphide is used to test the focusing of the light beams. A front-coated mirror is put perpendicular to the chamber at one edge for the purpose of stereoscopic photography.

In order that the ion clusters can grow up to a large enough size for future condensation, the chamber is delayed to expand at 5 to 10 milliseconds after the particle has entered the chamber. Again to have the liquid drops large enough to be photographed, the lamps are made to flash at 50 to 100 milliseconds after the particle entry. Eastman Linagraph Ortho films have been used in most of the cases.

D. Slow Expansion Device

If each fast expansion is followed by a series of slow expansions, the background of the chamber is found to be much smaller and more uniform, especially when the chamber contains many foils and has a very low rate of expansion. We have used a slow expansion unit by which a sequence of four or eight slow expansions can automatically follow each main expansion. This unit consists of a clock motor, lock-in switches, and delay relays, as shown in Fig. 3. When the incoming pulse locks the lock-in switch #1, the motor drives a circular disk. This rotating disk (not shown), which has 4 studs fixed to its lower face, closes the microswitch #1 four times in a revolution, and hence the chamber undergoes four slow expansions. Near the end of the revolution microswitch #2 is closed by another stud of the disk, and this operation unlocks the lock-in switches #1 and #2 after a certain time interval determined by the delay relay #1. The motor then stops. When the switch *S* is on position 2, the motor repeats another revolution before it stops, and eight slow expansions then follow each main expansion.

E. Constant Temperature Control

It is found that if the room temperature changes by about one degree centigrade, the chamber does not work satisfactorily. In order that the chamber can be continuously ready to record cosmic-ray tracks, the room temperature must be maintained constant. The small insulated room (8′×8′×8′) containing the cloud chamber, is first cooled to a few degrees lower than the outside room temperature. This is done by circulating pipe water through an ordinary car motor radiator. The room is then heated by a heater, which is then controlled by some suitable device.

Two devices have been used. When one goes wrong, the other is used as a substitute. The first one is an ordinary mercury switch. The change in the height of a mercury column is used to switch the heater on or off. The mercury switch is connected in the starter anode of an OA4 tube. The anode current of the OA4 operates a relay which then controls the heater. Since in this way the current through the mercury contact is extremely small, the contact surfaces of the mercury and the pointer can be preserved for a long time.

The second method is an electronic one employing a resistance bridge, as shown in Fig. 4. A small a.c. voltage is applied to the bridge. The temperature-sensitive element made of fine iron wire has a resistance of about 100 ohms and is kept inside the cloud-chamber room. The unbalanced voltage, the phase of which corresponds to, say, a temperature lower than the working temperature, is applied to the grid of the 6J6 tube after being amplified by the two 9001 tubes in cascade. This voltage controls the

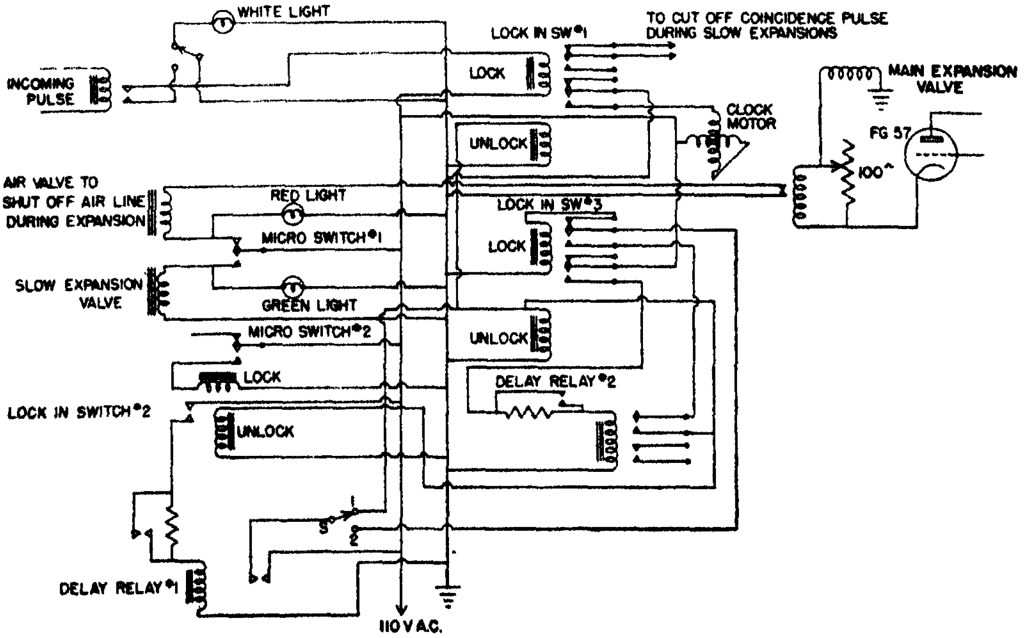

FIG. 3. Slow expansion unit.

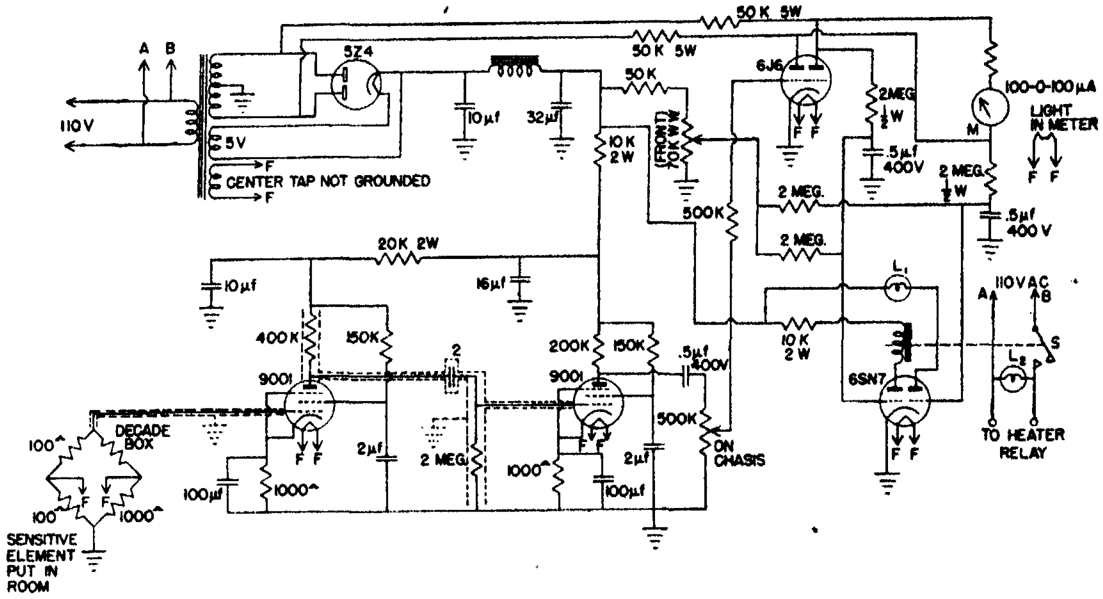

FIG. 4. Electronic temperature control circuit.

6J6 tube against the corresponding anode voltage of the appropriate phase. When the temperature gets lower, the needle of the meter *M* moves to one direction, and the relay in the left anode circuit of the 6SN7 tube closes the heater switch *S*. The indicating lamp L_2 is then lighted. When the temperature becomes higher, the needle of *M* moves to the other direction. The indicating lamp L_1 in the right anode circuit of 6SN7 is lighted. The advantage of this arrangement is that it controls a cooling device (if desired) as well as the heater.

III. ELECTRONIC CIRCUITS

The block diagram of Fig. 5 illustrates the electronic control system. A cosmic-ray particle actuating the three-fold telescope, but not the anticounters below the chamber, begins the cycling process through the coincidence circuits and the electronic gate. The expansion valve, clearing field removal, flash lamps, camera shutter and film advance, mechanical counter, and finally the reset of the gate proceed according to the time schedule, determined by electronic flip-flop circuits with adjustable recovery times. Thyratron-controlled current holds and releases the diaphragm-type expansion valve (cf. Section II-B).

The individual circuits are not shown completely, but some details are presented here, as the task of combining the many units in a reliable manner—especially for use with a very low expansion rate chamber—is time consuming, and many unexpected difficulties with stray pulses, etc., have been overcome in the present work.

A. Counter Circuits

Each tray of the three-fold coincidence counter array is coupled by a conventional cathode follower to a line leading to a pulse sharpener (univibrator), and to a conventional Rossi-type coincidence circuit. The anticoincidence counters are connected in groups to cathode followers which are coupled by crystal diodes to a similar pulse sharpener. This method of rectifier coupling permits paralleling large numbers of counters without undue individual loading. A section of the circuits including the final mixer tube is shown in Fig. 6. The discharge of one of the anticounters, along with the telescope, results in a negative pulse being applied to the control grid of the second section of the mixer tube, thus preventing the transmission of the signal from the telescope.

B. Gate Circuits and Time Delays

A 75-volt negative pulse of a few microseconds' duration from the mixer tube of the coincidence circuits serves to trip the gate (Fig. 7), which is a fast d.c. coupled "flip-flop" circuit, so arranged that it is stable with either tube #1 or tube #2 conducting. The coincidence pulse from the mixer tube causes tube #2 to conduct, and the negative pulse from its plate is led out to the various time delay circuits. Further coincidence pulses have no effect until a reset pulse occurring at the end of cycling again puts tube #1 in the conducting state instead of #2. The gate is insensitive to small pulses because of the method of triggering on the screen grid of tube #1. Triggering on the control grid of tube #1 was found to be unsatisfactory, as in this case the

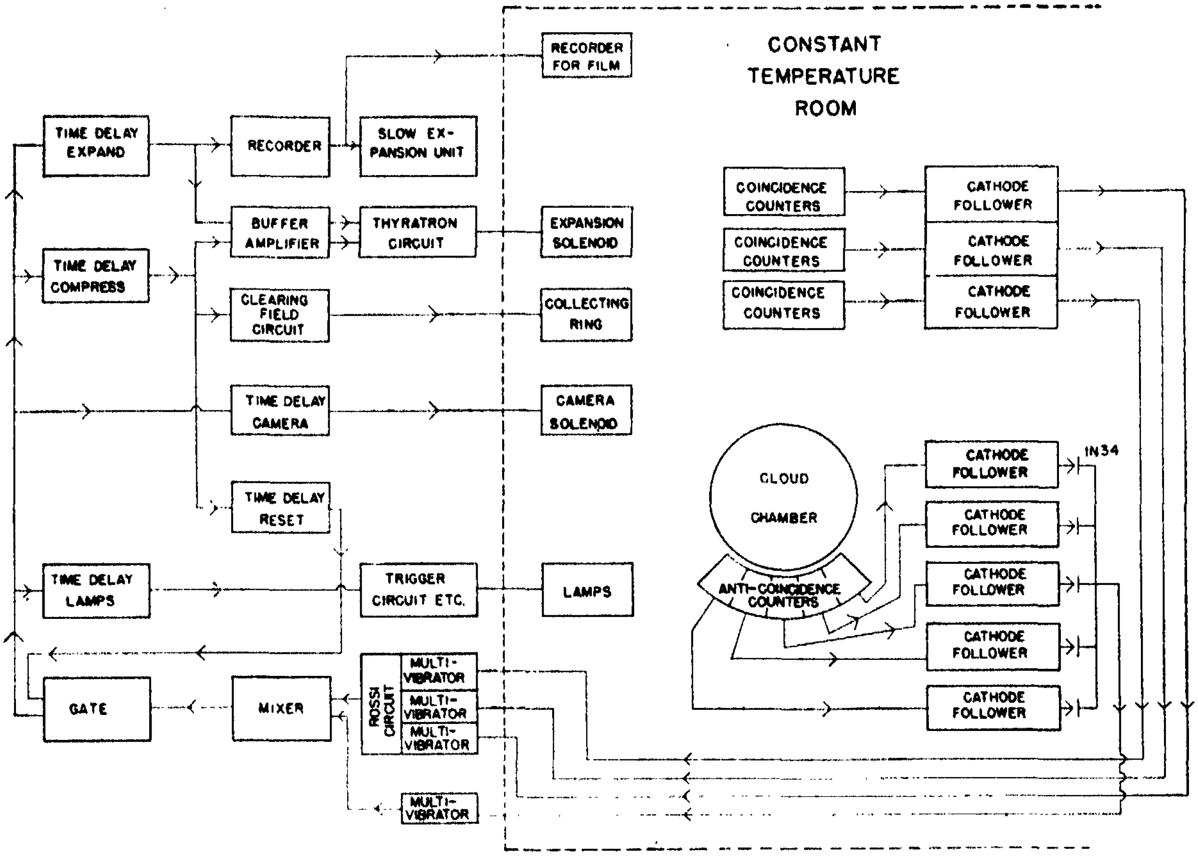

FIG. 5. Block diagram of electronic units.

triggering pulse appears on the output and begins cycling even though the gate is "closed." If the suppressor is used for triggering, the plate-suppressor capacity transmits the pulse to the grid of tube # 2, and the gate may be reopened prematurely before cycling is completed. The input and output connections are electrically isolated, and filtering is provided liberally on power connections. Manual

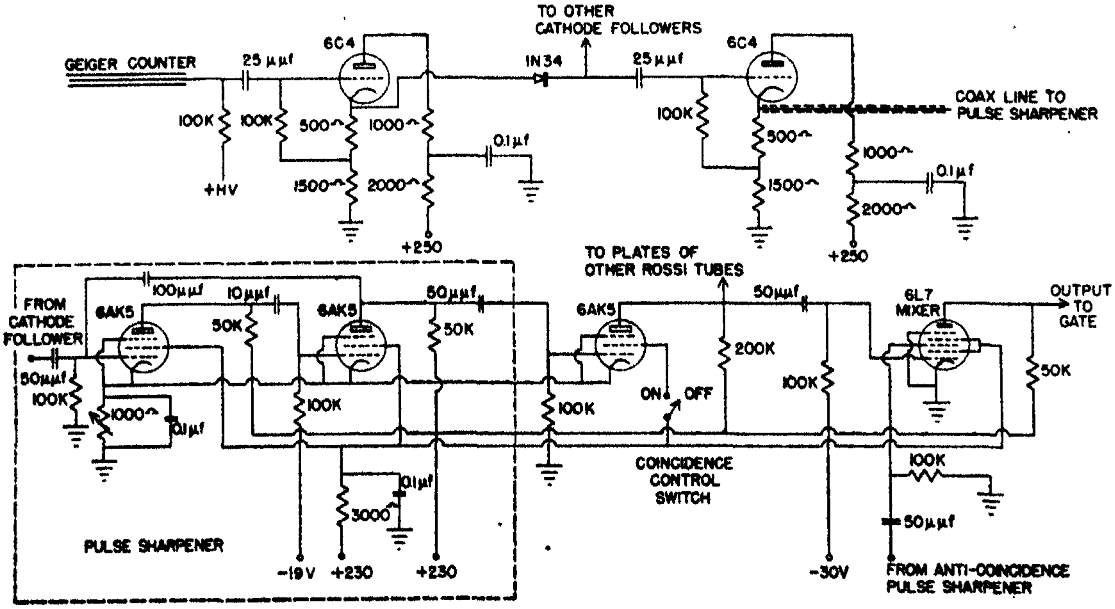

FIG. 6. Cathode follower, coincidence, and anticoincidence circuits.

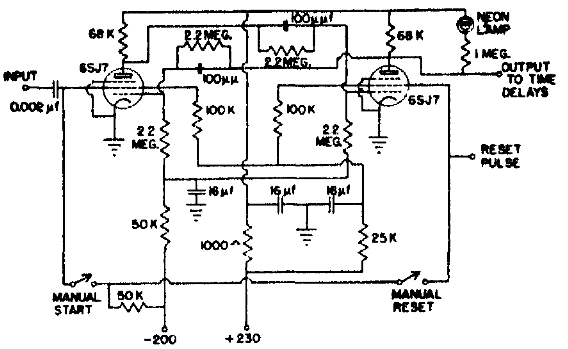

Fig. 7. Gate circuit. This circuit remains closed until cycling is completed.

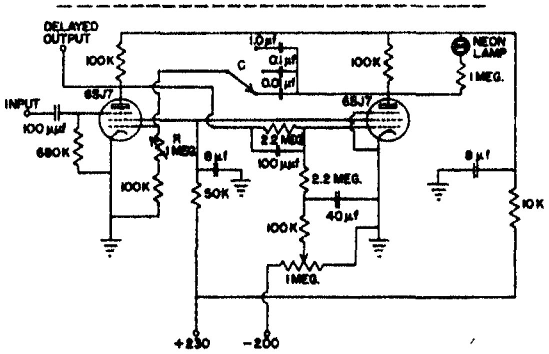

Fig. 8. Typical time delay circuit.

buttons permit operation of the gate by hand when conducting tests of the chamber.

The time delay circuits (see Fig. 8) are conventional univibrators, the period being controlled by the $R-C$ coupling network. The circuit is actuated through the suppressor grid of tube #1, to reduce sensitivity and isolate the input and output circuits.

C. Expansion Valve Circuit

The release of the expansion valve is accomplished by extinguishing the FG57 thyratron which carries the valve current by reducing its plate voltage to zero (see Fig. 9). A second thyratron, type FG17, is used for this purpose, discharging a condenser C through the common load resistance R of the two thyratrons when ignited by a pulse from the time delay expand circuit (see Fig. 5).[8] A pulse from the time delay compress circuit fires the first thyratron and closes the valve. The action is quite rapid, the valve opening with a miniature explosion. With a magnetizing current of about two amperes, the valve is able to sustain one atmosphere over pressure with negligible heating. It was found necessary to isolate the thyratrons from the time delay circuits by a buffer amplifier to prevent the feedback of spurious pulses into other delay circuits.

D. Lamp Circuits

As described in Section II-C, xenon-filled flash lamps (General Electric 126 and Amglo Corporation lamps) are used for illumination, fired from a capacitor bank of 50 or 100 microfarads charged to about 2500 volts. A fine wire wrapped about the capillary of the lamp and excited by the secondary of an automobile ignition coil serves to start the discharge. The coil is energized by a small thyratron which discharges a capacitor through the primary (Fig. 10). The charging and firing circuits must be carefully shielded, and the input from the lamp time delay filtered, as shown, against radiofrequency interference from the discharge circuits. The strong inductive pulse generated when the lamps discharge is an especially bad source of interference, not only to the cloud-chamber circuits, but to other high gain equipment within a radius of 25 feet or more.

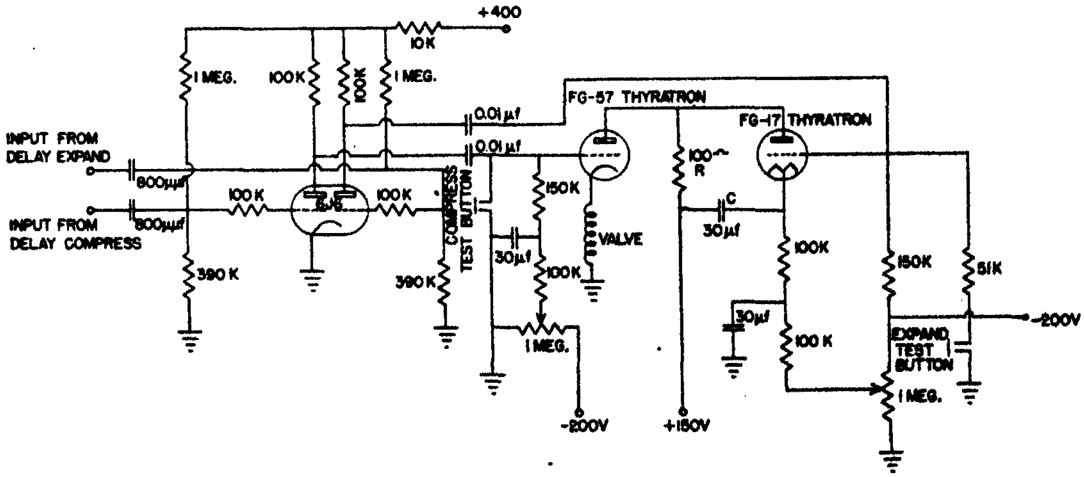

Fig. 9. Valve operating circuit.

---

[8] F. L. Allen, Rev. Sci. Inst. 19, 24 (1948).

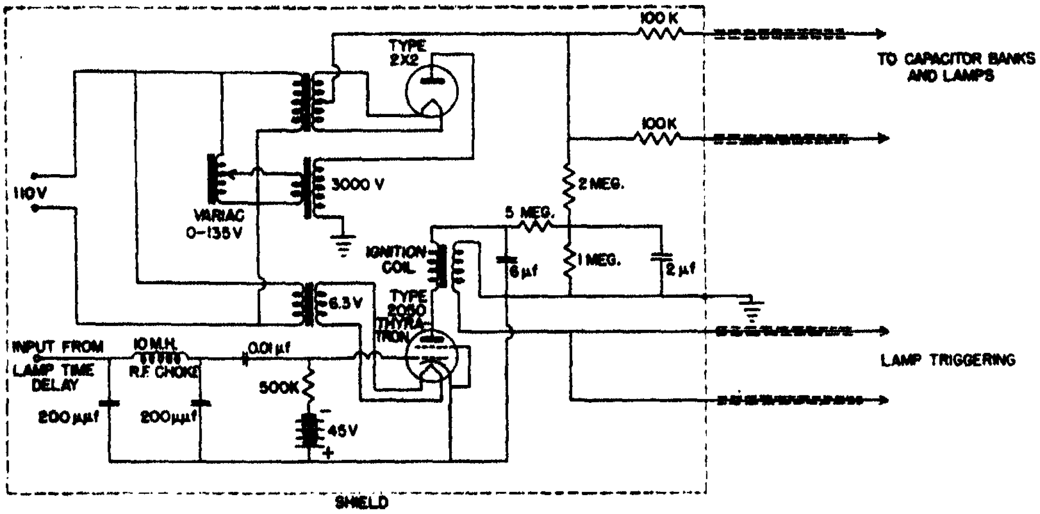

FIG. 10. Lamp firing circuit.

E. Clearing Field and Recording Circuits

The chamber clearing field is applied constantly, and removed at the earliest possible moment after the passage of the particle, by means of a d.c. amplifier connected to the time delay compress circuit. This time delay circuit triggers with the coincidence (see Fig. 5) and returns to normal at the time of compression, when the clearing field is reapplied.

The mechanical counter which is photographed along with the illuminated chamber in each exposure is turned by a simple cold-cathode thyratron circuit (Fig. 11).

IV. SOME CLOUD-CHAMBER PICTURES

In conducting the experiments on meson absorption by thin foils, a three-fold coincidence telescope has been used on the top of the chamber, and many anticoincidence counters in the form of an arc have been employed to surround the bottom circumference of the cloud chamber (see Fig. 5). Eleven (sometimes less) thin foils of thickness approximately equivalent to the range of a 12-Mev (or 2-Mev for Al) proton have been rigidly supported on a Lucite frame inside the chamber. The vertical beam of mesons before entering the telescope has to pass through a lead block of about 30-cm thickness. This lead block has two purposes: to filter off the electronic components of the incident beam, and to increase the intensity of the slow mesons. The whole setup for these experiments is shown schematically in Fig. 12.

In principle, the chamber expands only when a particle after passing through the telescope is absorbed by a foil or by the chamber and counter

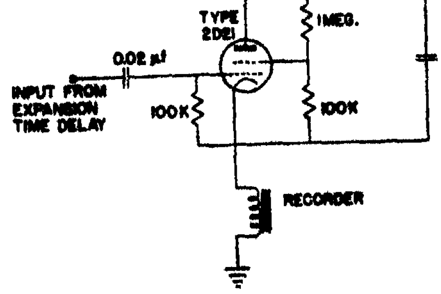

FIG. 11. Mechanical recorder. *Note:* The number under TYPE in the figure should read: *1D21*.

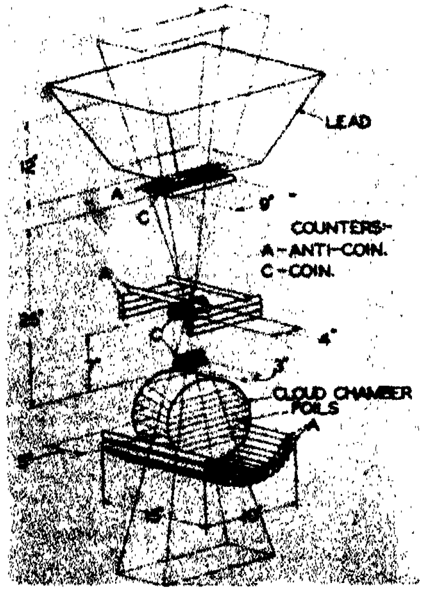

FIG. 12. Apparatus—meson absorption experiment.

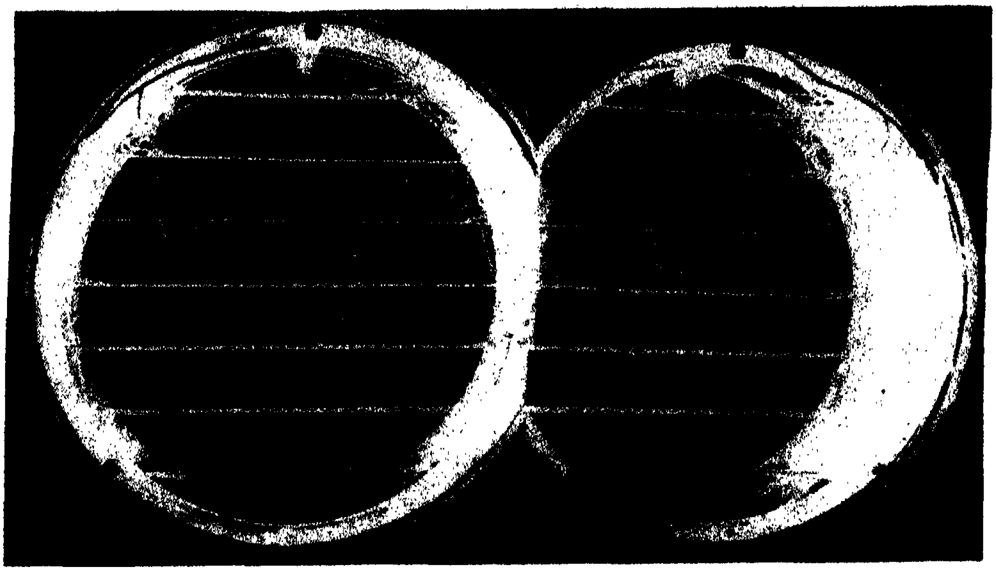

FIG. 13. Side showers covering whole chamber (Fe foils).

walls. To reduce stray coincidences, each tray of the telescope is protected against side showers by anticoincidence counters, and the bottom anticoincidence counters are arranged to cover a solid angle larger than geometrical necessity so as to receive scattered particles. On the average the chamber was triggered about once per 40 minutes, and one useful picture (a particle stopping at a foil) was obtained in about 35 pictures. The variation of ionization from foil to foil has been used to identify a proton, a meson, or an electron. Multiple scattering has been used for reference also.

Here we have presented some pictures of general interest. Figure 13 shows a large shower, which must have been produced in the back of the chamber. Here the chamber is seen to contain many short but straight tracks. The frame on the right-hand side is the stereoscopic picture, and the foils are iron foils (0.028 inch). In Fig. 14, simple cascade showers are produced at the iron foils by some vertical incident particles, presumably electrons. A meson decaying into a light particle, presumably an electron, is shown in Fig. 15. Here the meson stops in the last Al foil (0.002 inch) and the decay electron is emitted upwards to the right (see the direct picture on the left).

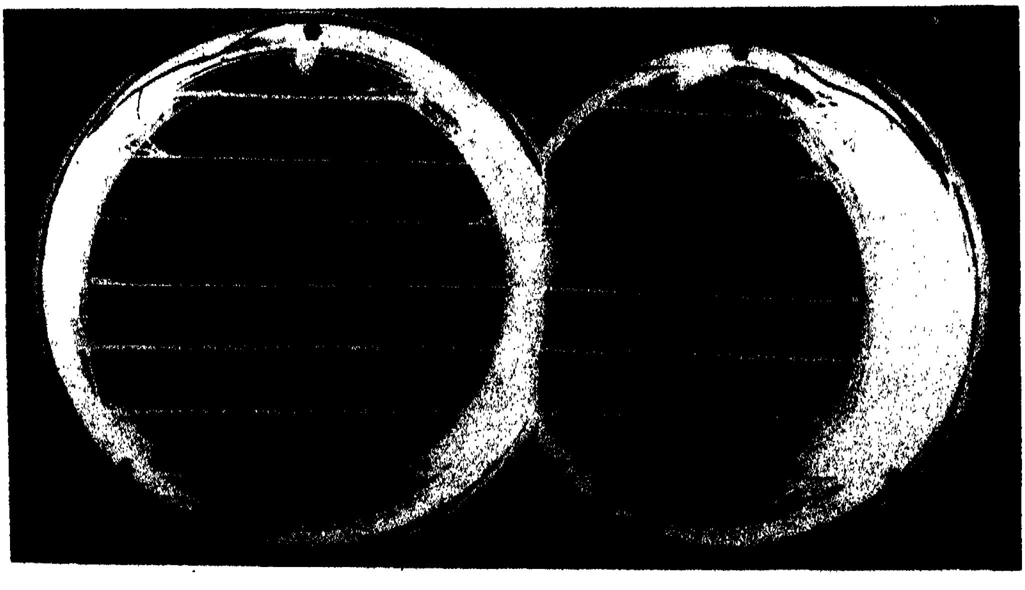

FIG. 14. Simple cascade showers (Fe foils).

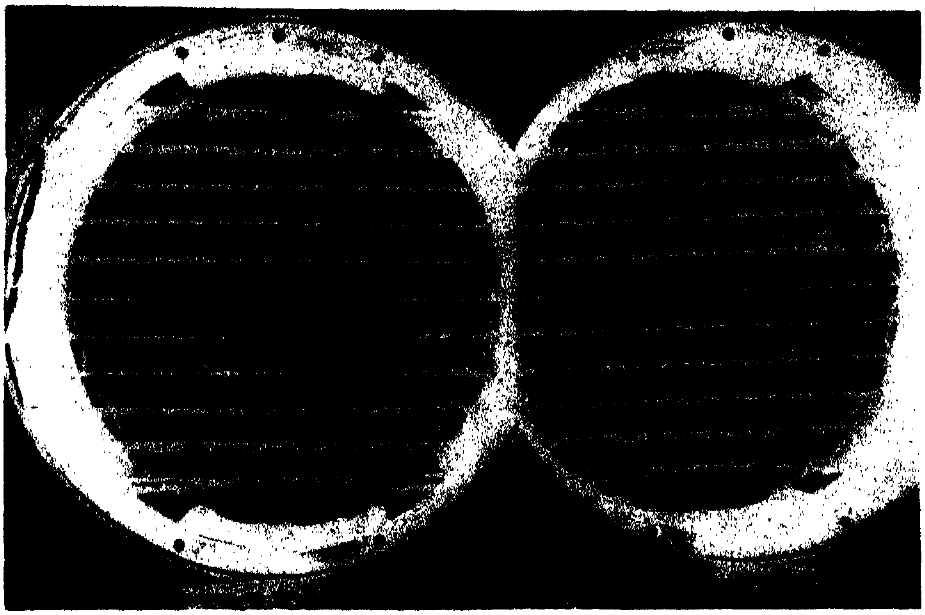

FIG. 15. A meson decaying in a 0.002-inch Al foil.

In conclusion, we should like to express our sincere thanks to Mr. D. B. Davis and his staff for building the cloud chamber and the control equipment, to Dr. T. Coor and Mr. F. J. Darago for their help in designing the electronic temperature control, and to Dr. L. G. Lewis for the valve design.

THE REVIEW OF SCIENTIFIC INSTRUMENTS VOLUME 20, NUMBER 4 APRIL, 1949

Magnetic Deflector for Mesons Produced in the 184-Inch Cyclotron

WOLFGANG K. H. PANOFSKY AND ERNEST A. MARTINELLI
Department of Physics, Radiation Laboratory, University of California, Berkeley, California

(Received January 3, 1949)

A magnetic deflector has been constructed which makes the mesons artificially produced in the 184-inch cyclotron by alpha-particle bombardment available outside the cyclotron tank. The deflector consists of a magnetic shield especially designed to operate in very high external magnetic fields. The effect of the magnetic shield on the internal cyclotron beam has been compensated by pole shims. The deflector yields a total meson flux of approximately 500 mesons per minute.

THE artificial production of mesons by means of high energy α-particles in the 184-inch cyclotron at Berkeley[1] indicated the desirability of making mesons available outside the cyclotron tank in order to make investigations possible by means other than photographic plates inside the tank. A magnetic deflector to draw mesons out into a re-entrant chamber in the cyclotron wall was therefore constructed.

The circulating α-particle beam strikes a target at a radius of 80½ inches from the center of the cyclotron. The magnetic field at the target position is close to 14,000 gauss, so that low energy mesons are unable to leave the cyclotron. The magnetic deflector consists simply of a magnetic shield placed in such a manner that it shields the meson beam and permits it to enter a re-entrant chamber in the cyclotron wall (Fig. 1).

A magnetic shield for this purpose has to meet four requirements: 1. The field in the channel must be sufficiently low to permit exit of the mesons from the field. 2. It must have a sufficiently high geometrical aperture. 3. The shield must not disturb the field at a radius less than target radius. 4. The shield must not interfere with the electrostatically deflected beam[2] in the cyclotron.

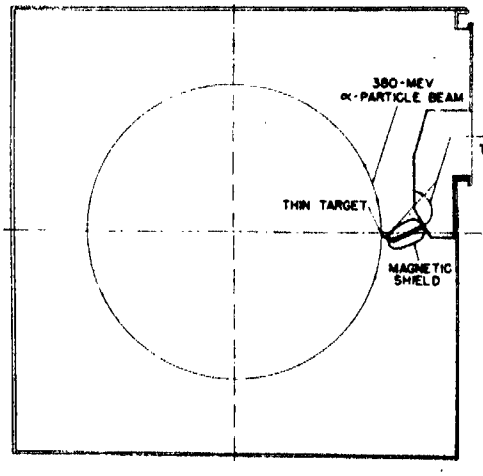

FIG. 1. Geometrical distribution of meson deflector and target in the magnet of the 184-inch cyclotron. Note the trajectory of the alpha-particle beam and the mesons produced in the target.

The problem of shielding magnetically to a sufficient extent in an external field of 14,000 gauss is made difficult by the saturation of iron. Saturation effects are reduced if the shield is not circular but has its large dimension perpendicular to the field; this will only give a small increase in flux density in the iron relative to the external field. These considerations lead to the choice of a shield approximately an ellipsoid whose smallest axis is parallel to the field. The ellipsoidal shape is superior to any rectangular geometry since corners would saturate and thus not contribute to the shielding while still contributing to the disturbing field.

The ellipsoidal shape can be easily analyzed

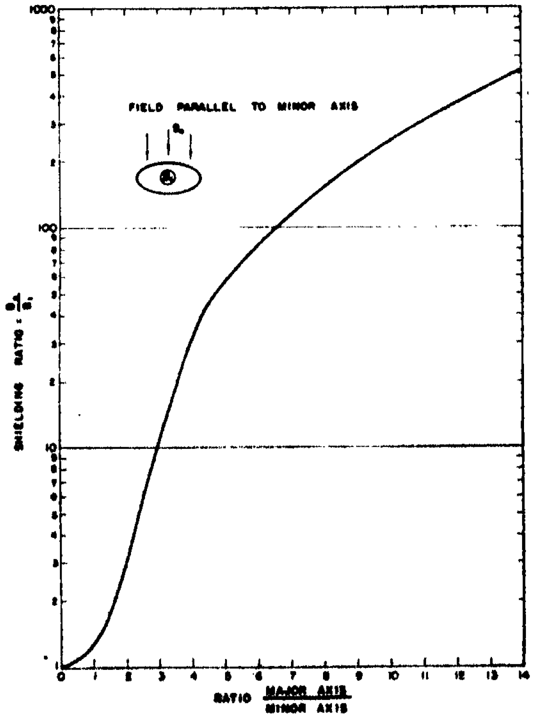

FIG. 2. Theoretical shielding ratio of an oblate-spheroidal shield with cylindrical hole as a function of axial ratio of the spheroid in an external field of 14,000 gauss.

---

[1] E. Gardner and C. M. G. Lattes, Science 107, 270 (1948).

[2] Powell, Henrich, Kerns, Sewell, and Thornton, Rev. Sci. Inst. 19, 506 (1948).

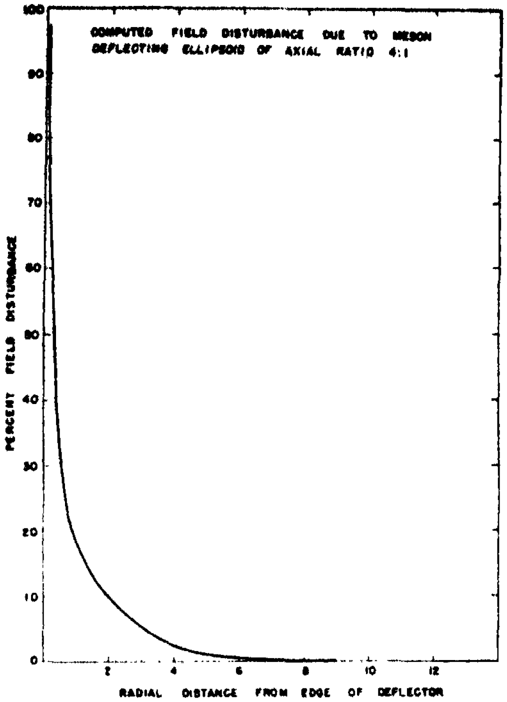

FIG. 3. Percent field disturbance due to spheroidal shield of axial ratio 1 to 4 on the magnetic field in the cyclotron.

mathematically for a given magnetization curve of the iron used. Figure 2 shows a theoretical plot of the shielding ratio attainable with an oblate spheroidal[8] shield with a small cylindrical hole inside the spheroid. The curve is computed for cold rolled steel in an external field of 14,000 gauss. Note the rapid improvement of the attainable shielding ratio with increase in axial ratio of the ellipsoid. An axial ratio of 4:1 was chosen here.

The theoretical disturbance in the field resulting from the ellipsoid is shown in Fig. 3 for an ellipsoid of 12-in.×3-in. axis. The shield was placed 3½ inches from the target radius, thus disturbing the field by approximately 3½ percent. This disturbance is compensated by shims supported on the cylcotron poles, in accordance with the method of Powell *et al.*[2] A radial experimental field plot and the field corrected by the shims is shown in Fig. 4. The position and geometry are also shown in Fig. 4.

Owing to the fact that the shielding action of the iron cannot be computed accurately, it was necessary to estimate the meson trajectory first, construct a deflector, compute the trajectory, and then build a new deflector to conform to the computed trajectory. The final shape of the shield and the position of the meson trajectory is shown in Fig. 5. Figure 6 shows the magnetic field in the channel with and without the shield. Owing to the curvature of the trajectory and the ellipsoidal cross section of the shield, the shield is constructed of 12 layers of hot rolled steel plate, flame-cut to proper shape and bolted together. The hole for the trajectory tapers from an initial hole of 1½-in. vertical ×1-in. horizontal to 2½-in.× ½-in. square at the exit end. Figure 7 shows the assembled deflector.

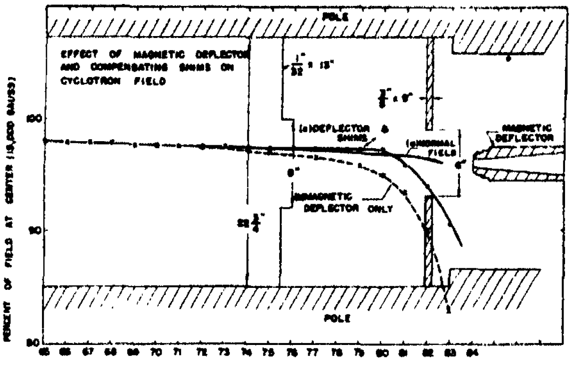

FIG. 4. Radial magnetic field in the cyclotron under the following conditions: (a) Before introduction of meson deflector. (b) After introduction of meson deflector, but uncompensated. (c) Meson deflector in place and compensated with shims as shown.

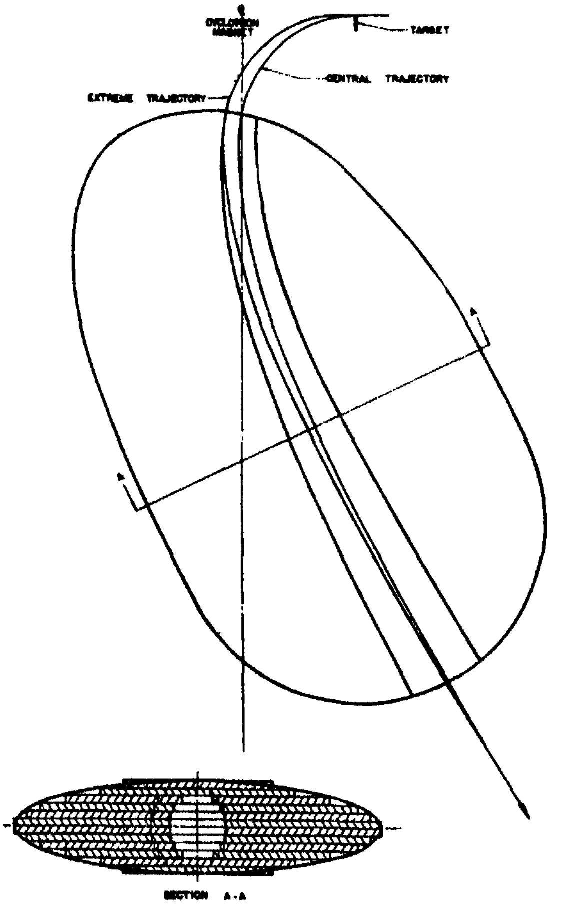

FIG. 5. Meson trajectories from target through meson deflector, as plotted from field measurements.

---

[8] For solution of potential problem, see e.g., H. Smythe, *Static and Dynamic Electricity* (McGraw-Hill Book Company, Inc., New York, 1939), pp. 156ff.

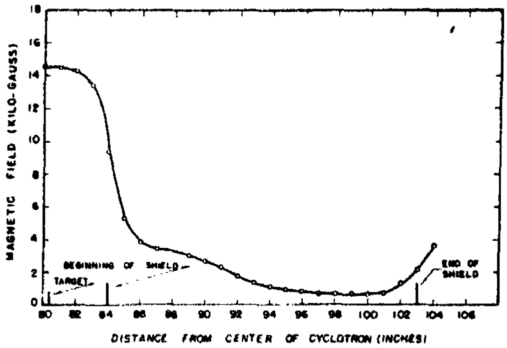

FIG. 6. Experimental magnetic field as a function of position along meson trajectory through meson deflector.

FIG. 7. Photograph of meson deflector in retracted position.

The deflector is designed for a central trajectory corresponding to $B\times\rho=147{,}000$ gauss-cm, corresponding to an 8.5-Mev μ-meson (taking the mass of the μ-meson as $215m_e$) or a 6.0-Mev π-meson (taking the mass of the π-meson as $286m_e$). The deflector will accept beams of vertical divergences of ±6°, horizontal divergences of ±7.2° (at central value of energy); the range of momenta accepted is ±12 percent about the central value.

At this date the deflector has been used only in conjunction with the photographic means of detection. With a cyclotron bombardment of 3×10^{-7} amp. of α-particles for 30 minutes the meson yield is about 30π-mesons in the edge of a 100-micron emulsion; this corresponds to a total flux of about 500 mesons/minute out of the aperture of the deflector.

The problem of deflecting mesons by means of a magnetic shield was suggested by Professor L. W. Alvarez. We are greatly indebted to the magnetic measurements group of the laboratory, notably D. C. Sewell and A. J. Hulse for making magnetic measurements and to Professor Wilson Powell for valuable discussion. This work was performed under the auspices of the AEC.

(Received January 13, 1949)

The use of very thin Zapon or Formvar windows for G-M counter tubes in beta-spectroscopy is limited by the fact that the filling mixture of the counter diffuses or leaks through the window, which forbids the use of very thin windows. A pressure regulator is described which will permit the maintenance of a constant pressure of filling mixture even if the window of the counter allows the slow escape of the gas. A thin window G-M counter presenting some improvements is also described.

PRESSURE REGULATOR

THE window separating a G-M counter from the vacuum system of a beta-ray spectrograph should be as thin as possible in order that low energy electrons may be observed. Zapon and Formvar films, prepared according to well-known techniques,[1,2] have been used in this laboratory. Multiple layers were usually used to decrease the probability of holes occurring. Satisfactory films having electron cut-off energies of higher than 5 kev are easy to prepare. However, it has been found that thinner films (~2 kev), even those which do not leak when first used, develop slow leaks after a period of days. This is attributed to the occurrence of very small holes or cracks accompanying the observed stretching of the film caused by the gas pressure in the counter.

A counter in this condition is difficult to use, since the plateau shifts continuously as the pressure decreases. The use of lower pressures of filling mixture in the counter is helpful in preventing window leakage, but a lower limit of 3 to 5 cm Hg is set by the fact that at lower pressures the efficiency of the counter becomes appreciably less than 100 percent, and changes with electron energy.

The connection of a large ballast volume of filling mixture to the counter affords some improvement but is not entirely satisfactory. A system in which there is a continuous flow of gas into the counter, with the excess flowing out through a mercury bubbler, was also tried. It was found that this system was not capable of maintaining the pressure sufficiently constant.

The following scheme was found to be satisfactory. A filling mixture of the proper composition is prepared and stored in a container at approximately atmospheric pressure. This container is connected to the inlet of the device shown in Fig. 1. The outlet is connected to the counter. If the pressure in the counter falls below the preset level, the tungsten contacts sealed into the mercury manometer close and actuate a relay which powers the coil. The iron plunger rises, lowering the mercury level to a point where more filling mixture can flow through the porous glass plug. The device operates smoothly over a wide range of flow rates, and the manometer is observed to vary not more than $\frac{1}{2}$ millimeter.

Care should be taken that sparking does not occur at the manometer contact, as this has a tendency to decompose the quenching vapor in the mixture. The use of a d.c. relay operating on a few milliamperes of current, together with a resistance and capacitance connected in series across the manometer contacts will prevent sparking.

THIN WINDOW GEIGER-MUELLER COUNTER

The conventional G-M counter as used in most laboratories is usually constructed in a semipermanent manner with heat-treated seals of glass, Kovar, or solder. A counter so constructed renders itself quite awkward for experimentation, since a change in design requires either the construction of an entirely new counter or the careful breaking of the heat-treated seals. The counter herein described

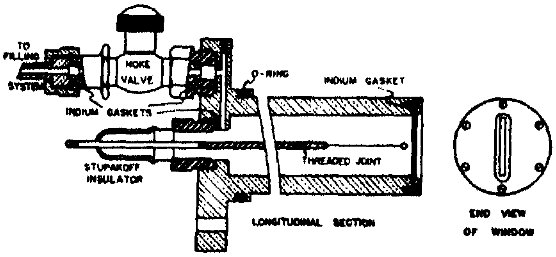

FIG. 2. Thin window G-M tube designed for easy assembly.

eliminates these difficulties by providing gasket seals which may be broken easily and quickly without damage to any portion of the counter mechanism.

The body of the present counter is bored in a piece of brass cylinder, highly polished inside, and chromium plated. The purpose of plating the inside is to obtain a stainless, hard surface, easy to clean when the counter is taken apart.

The filling mixture from the pressure regulator is fed into the counter through a bellows-type Hoke valve (type No. 431). This type of valve has been tried on several counters and has always been found to be gas tight. The Hoke valve is screwed into a stainless steel plug and soft soldered to assure a perfect tightness. This plug is screwed into the flange of the counter. A 0.010″-thick indium gasket assures the tightness of all joints. Three of these gaskets are used in the present counter. A flexible brass tubing connects the counter to the pressure regulator.

In the counter constructed here, which has a cathode diameter of 1″, the anode used is a tungsten wire 0.006″ in diameter and 1¼″ long, the end of which is insulated by a glass bead. It is hard-soldered into a brass threaded plug which is screwed into the central lead. This arrangement permits the easy replacement of the wire. No dimensions except those quoted above will be given, since other dimensions are not critical and can be readily adjusted to the purpose of the counter.

The central lead is a stainless steel rod, hard-soldered to a Stupakoff glass Kovar seal, which is itself soft soldered to a threaded plug similar to the one used with the Hoke valve. An indium gasket makes the joint tight. The window of the counter is a thin film of Zapon cemented with Formvar to the end plate which is attached to the body of the counter by six screws. In this case again an indium gasket assures the tightness of the system. All of the surfaces inside the counter have been carefully polished and all the sharp edges broken. The plateau of this counter is flat between 1400 and 1600 volts when filled to 8 cm Hg of an argon (80 percent)-ethylene (20 percent) mixture.

No rubber has been used in the system described above.[3] All the tubings are sylphons and the joints are similar to the one shown in Fig. 2, the tightness being obtained by the use of indium gaskets. This counter can be taken apart, cleaned with alcohol or ether, and, when mounted, will not show any variation either in the threshold or in the efficiency.

The pressure regulator and G-M counter described have been added to a 180° beta-ray spectrometer[4] in this laboratory and have given satisfactory service during the course of investigations.[5]

ACKNOWLEDGMENTS

The authors wish to thank Mr. O. Retzloff for his excellent machine work in the construction of the Geiger counter.

THE REVIEW OF SCIENTIFIC INSTRUMENTS VOLUME 20, NUMBER 4 APRIL, 1949

Electronic Apparatus for the Determination of the Physical Properties of Freely Falling Raindrops

ROSS GUNN
Physical Research Division, U. S. Weather Bureau, Washington, D. C.

(Received January 13, 1949)

An apparatus is described for measuring the mass, velocity of fall, sign, and free electric charge of individual falling raindrops. Two vertically separated rings are so arranged that naturally charged raindrops fall through them and induce pulses on the grid of a vacuum tube amplifier which in turn operates a tape oscillograph. From the characteristic double pulses produced, the charges and transit times may be determined. The mass of the droplet is simultaneously determined by measuring the size of the spot produced when the drop falls on blueprint paper tape traversing the oscillograph. Short cuts for the reduction of data on drop sizes are given.

SURPRISINGLY little information is available in the literature on the physical and electrical properties of natural precipitation, particularly in relation to the characteristics of single elements. It is the purpose of this paper to outline briefly the principles, design, and calibration of a new electronic instrument that has made possible a detailed study of natural raindrops in relation to their mass, velocity of fall, rate of evaporation, and transported electrical charge. It is believed that the instrument will be generally useful in further studies of the precipitation processes and the physical phenomena associated therewith. Improved methods for the rapid determination of approximate raindrop masses by the use of blueprint paper are outlined, since this method forms a valuable adjunct to the strictly electronic equipment. Perhaps the greatest value of the apparatus resides in the fact that it easily collects information on a large number of individual events, and these appear to be more descriptive of weather processes than statistical results.

BASIC PRINCIPLES

It is an observed fact that a large fraction of all naturally falling raindrops or snowflakes carry appreciable electric charges. Moreover, it has been found practicable to indicate the proximity of such charged precipitation by suitable electronic amplifying equipment appropriately connected to an oscillograph.[1] For example, if a carefully shielded and highly insulated induction ring is so positioned that a charged water droplet falls through it, the charge on the droplet by inducing an opposite charge on the ring, can be arranged to produce a pulse on the grid of a vacuum tube, which in turn can operate an amplifier and associated oscillograph. The magnitude and sign of the electrical charge on the droplet is measured by the direction and magnitude of the pulse recorded on a moving tape oscillograph. It is further easy to see that by positioning two similar inducing rings, separated by a known distance, and making provisions for the rain droplet to pass successively through both inducing rings, a double pulse will be recorded. Now, since the time between the two pulses may be measured by their relative displacements on a moving tape oscillograph, and this is the time it took the droplet to travel the distance between the fixed electrodes, it is clear that the velocity of the droplet may be easily and quickly determined.

Because of the mechanical forces caused by turbulence and the electric fields occurring in the atmosphere, the velocity of fall of natural raindrops of a given size is variable. For this reason, it was necessary to measure the mass of the falling raindrops by an independent means. Earlier work[2] has demonstrated that the mass of natural raindrops can be quickly and conveniently determined by allowing them to fall on blueprint paper. The rain droplets produce spots on the coated paper which can be made semipermanent by developing the paper with light. The method is an adaptation of one widely employed by early German experimenters who used ordinary absorbent paper, and dusted a water soluble dye over the spots to preserve the record.[3] To a first approximation the area of the spot is proportional to the mass of the impinging droplet, and, therefore, the size of the spot is readily calibrated in terms of its mass.

The new apparatus combines the above elements in such a way that the signature traced by a droplet and the spot size are presented as simultaneous events on a moving paper tape. Thus, for each event the mass, velocity of fall, and sign and magnitude of the electric charge on each droplet may be determined. Obviously, such an apparatus is important in any study of the precipitation processes.

THE APPARATUS

The general arrangement and design of the first successful instrument is shown in Fig. 1. The outer

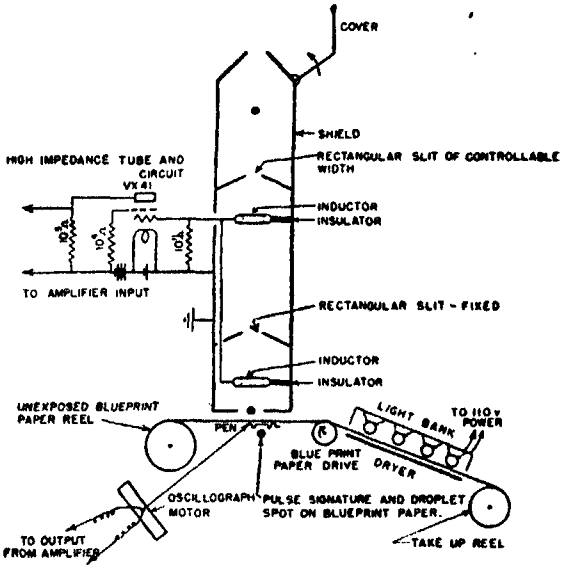

FIG. 1. Arrangement of the apparatus and electrical circuits.

shield of the instrument was an aluminum tube 18 inches in diameter and about 10 feet high. The top of this tube was a cone having an angle of about 45 degrees and arranged with a 6-inch hole at the top. A cover was provided as shown that could be turned back and be entirely clear of the hole. About 4 feet below the top, another cone with a hole about 4 inches in diameter was arranged as shown. A slit was mounted over this hole in such a way that its surfaces were about 45 degrees to the horizontal. It was found convenient to make this slit 4″ long and variable in width from about ¼ inch to ¾ inch. Eight inches below the first slit, a highly insulated brass cylinder 6 inches in diameter and 6 inches long was mounted, concentric with the supporting tube and centered immediately below the first slit. Four feet directly below the first slit a second slit was mounted on another internal cone. This second slit was 4″×¾″ and was so aligned as to be immediately under the first slit. Below the second slit another highly insulated inductor electrode identical with the top one, was mounted and these two were joined electrically by an air insulated wire running down the large tube near its wall.

Mounted in a dry compartment inside the large supporting tube was an electrometer tube having a high input impedance (such as the Victoreen VX-41). Its control grid was connected directly to both inducing electrodes as shown in Fig. 1. The screen and plate voltages on this tube were adjusted by experiment so that the tube would modulate either upward or downward by the same amount for opposite potentials of the same magnitude on the grid. The magnitude of the input resistance placed across the grid and filament of the electrometer tube plays an important part in determining the characteristic response of the apparatus to the electric charge. For example, when the product of the input resistance, *R*, and the input capacity, *C*, or the electrical relaxation time is appreciably greater than the transit time of the charged particle through the electrode, the amplitude of the output pulse measures the total quantity of the electricity on the droplet. On the other hand, if the relaxation time is notably less than the transit time, the magnitude of the pulse is determined by the current flowing and is proportional to the electric charge on the droplet and to the velocity with which it traverses the electrode. Thus, when it is desired to use the apparatus to measure free electrical charge, the resistance-capacity product should be made large, and the charge magnitude may then be immediately scaled from the oscillograph trace. It has been found, on the other hand, that if the device is to be used to measure accurately the velocity of a particle traversing the inducing electrodes, then it is desirable to reduce the input resistance to make the relaxation time smaller than the transit time. The signature given by a traversal of the latter type may be more accurately measured in terms of velocity than the signature normally produced when the relaxation time is large. Characteristic signatures for the two conditions outlined are shown in Figs. 2a and 2b.

Immediately below the tube containing the slit and inductor system, a shelf is provided to carry the oscillograph. The oscillograph was a Brush Laboratory double channel Type BL-202 fed by one of their Type BL-905 amplifiers. The standard recorder paper provided by the manufacturer was replaced by a roll of unexposed blueprint paper about 4″ wide that was pulled through the feed by the small synchronous motor built into the oscillograph. The oscillograph is arranged to be movable on the shelf and is positioned in relation to the projected area of the slits in such a way that a droplet falling with a mean velocity of 400 cm/sec., arrives at the blueprint paper just at the position where the pulses produced by the same droplet are traced by the moving oscillograph pen. Thereafter, the blueprint paper with its spot of water and continuously inked trace is pulled through the oscillograph drive and thence down a trough about five feet long lined with 50-watt electric light bulbs, where the wet spots are dried and the blueprint paper exposed to make a semipermanent record. The paper finally proceeds to a take-up reel driven by a weak friction clutch onto a final process roll. At the paper speeds usually employed, namely 2.5 cm/sec., the blueprint paper was adequately exposed to the light and sufficiently dried to wind up on the final spool. It has been found economical and convenient to buy the blueprint paper in wide rolls and cut them up into rolls of width to fit the oscillograph.

In practice the apparatus operates as follows: the top door of the instrument is opened, and a drop falls through the top cone and succeeds in passing the first slit. If it is not making a large angle with the vertical, it will pass the inducing ring at some distance from its wall, and thence proceed to the second slit about a meter below. If the droplet is not well lined up, it does not get through the second slit and only a single pulse will be recorded. However, if the drop is moving in a substantially vertical direction, it will pass through the second slit and traverse the second inductor, landing finally on the moving blueprint paper immediately below. A pulse will be produced on the grid of the electrometer tube by the droplet as it traverses both the first and second inductors. Thus, characteristic double pulses are traced on the oscillograph paper for droplets so lined up as to traverse both slits. The direction and amplitude of these pulses determine the sign and free electric charge actually resident on the drop. Having traversed the slit and inductor system, the droplet falls on moving blueprint paper adjacent to the trace of its own double pulse, and the size of the spot it produces permits one to determine its mass by an independent measurement. A little experience enables one to associate the double pulses of the oscillograph with the proper spot on the blueprint paper. However, a certain small fraction of the incoming raindrops are electrically neutral or discharge themselves by touching the edge of the slit, and these frequently confuse the interpretation.

A number of typical signatures and rain spots produced by natural raindrops are reproduced in Fig. 2 both for positively charged droplets giving an upward pulse, and for negative ones producing a downward pulse. It may be noticed that the passage of an electrical charge through the highly insulated inductor system modifies the charge on the grid of the electrometer tube when high input resistances are employed, and thus, shifts the zero position of the oscillograph. For this reason, the second pulse is slightly displaced, although its magnitude in relation to the new zero is the same as the original one. It may be noted, further, in Fig. 2a that the width of the second pulse is somewhat less than for the first one. This difference in width results from the different geometry of the lower inductor in relation to its surroundings. At first this difference was considered a misfortune, but actually it has been most useful in defining the signature for an actual passage of a single drop. For example, two droplets occasionally traverse the first inductor only, in about the right sequence to produce a nearly typical signature, but by careful examination it is possible by the above characteristic to separate out these occasionally recurring pulses from the typical signature for a single droplet.

It should be evident from Fig. 2 that the velocity of fall of the droplets may be easily measured by determining the time interval between two succeeding pulses of a given signature. Further, since the average terminal velocity for large numbers of naturally falling raindrops are now available as a result of investigations with this apparatus, it becomes practicable to determine the mass of a falling raindrop which has not been touched or contaminated in any manner simply by knowing this measured time interval. It is clear that such a "weighing process" is most convenient in a number of measurements of the physical properties of raindrops.

The reduction of the data displayed on the blueprint paper tape has been considerably simplified by the adoption of a convenient classification of raindrop sizes together with the use of a transparent mask upon which is reproduced the various spot sizes equivalent to various droplet masses. The added convenience of these short cuts suggests that the method will be generally used in further experiments. The magnitude of the electric charge on naturally falling raindrops is readily scaled from the oscillographic trace when the electrical circuits are calibrated with the standard to be described in a later paragraph.

THE BLUEPRINT PAPER METHOD FOR THE MEASUREMENT OF THE MASS OF RAINDROPS

Early German experimenters[3,4] made extensive use of the absorbent paper method for measuring drop size because of its convenience. Originally the droplets were collected on a suitable absorbent paper and the droplets developed by dusting the paper with a soluble dye. The size of the spot for uniform absorption by the paper may be calculated by equating the area of the spot multiplied by its effective thickness of absorbed water, to the volume of the incident raindrop. It is well known that this is only an approximation under most conditions and the effective thickness, determined by calibrating

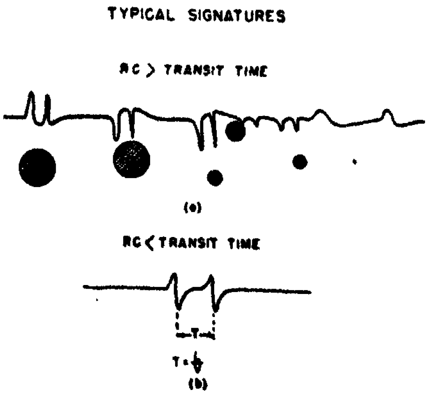

FIG. 2. Characteristic signatures produced by natural rain.

---

[4] E. Niederdorfer, Meteorol. Zeits. 49, 1 (1932).

measurements, varies slightly from the larger drops to the smallest ones. Niederdorfer[4] has estimated the various sources of errors and states that the average error for the above method ranges from 6 percent for the large drops up to 15 percent for droplets as small as 40 micrograms.

The convenience of the original spot method encouraged one to see if the method could not be appreciably improved. It was found that a good quality standard blueprint paper is practical for the determination of the mass of falling raindrops. Such paper, prior to its coating, is carefully freed of all grease and the sensitive coating is uniformly applied. This sensitized coating, being easily wetted, promotes the spread of the impinging droplet in such a way that the produced spots are nearly circular and, therefore, easy to measure with fair accuracy. However, the over-all accuracy that may be achieved by the use of blueprint paper is about that obtained with ordinary absorbent paper sprinkled with dye unless unusual care is taken in the calibration of the paper, the control of its original moisture content, and in the reduction of the data.

It has been found that the determination of the actual masses from the size of the spot produced on the blueprint paper may be greatly facilitated by a classification scheme and by the adoption of a transparent photographic film provided with a large number of circles of graded size that may be slid over the various spots to determine their area. It is pointed out that because of the continuous deformation and vibration of the freely falling raindrops, their diameter has little meaning, whereas the mass of the droplet is specific. Moreover, because the masses of natural raindrops vary from 10 to more than 100,000 micrograms, it seems necessary to adopt some method to collapse the scale. Critical examination of the problem suggests that the best and most convenient scale of raindrop masses will result if one adopts as a classification standard the Briggsian logarithm of the mass expressed in micrograms. On such a scale, raindrops from the finest mist to the largest droplets fall in the range 0.00 to 5.00, while fog and cloud droplets are to be found in the range from 0.00 to -5.00. With such an adopted scale of masses, as many significant figures may be retained as the accuracy of the data suggest.

In developing means for rapidly classifying raindrops from the size of spot produced on blueprint paper, it has been sufficiently accurate to divide the most common range of measurable droplets into 65 intervals of 0.05 unit each. Such an arbitrary subdivision yields a scale in which each interval represents a 12.2 percent increase in mass over the preceding interval, but this represents only a 3.9 percent increase in the effective diameter of the droplet. It should be clear that by the adoption of a uniform fractional increase in the mass for each interval, the area of the droplet spot produced on blueprint paper is similarly increased fractionally by the same amount. Thus, if broken circles are drawn on a large chart in such a way that their areas form a geometric progression of common ratio $R=1.122$ ($\log R=0.05$), and if the assumption is made that the paper absorption or the mass of water per unit area of the spot is a constant, then it follows that the logarithm of the mass for each circle increases by uniform steps and appropriate mass values can be assigned to each circle. The above selection was made because a photographic reduction of such a chart preserves the relative sizes and any selected mass per unit area may be exactly produced by adopting the proper photographic reduction. Thus, a carefully prepared master chart in which the relative diameters are accurately drawn permits one, through easy photographic techniques, to produce a transparent mask that accurately fits any selected blueprint paper. By this means, the masses and radii of the original droplets may be directly read off of the mask when the appropriate circle is fitted to an actual spot on the blueprint paper. A reproduction of such a mask is given in Fig. 3.

In order to determine the effective thickness of the water film absorbed by the paper, it is necessary to make calibration measurements. This was accomplished by letting a number of droplets of known mass fall upon the blueprint paper at their terminal velocity. The size of the spots produced thereby was measured to determine the area corresponding to the known mass. From these data the photographic reduction factor to be applied to the original chart of circles was determined. In general, 4 or 5 masks, all having slightly different reduction factors grouped about the calculated reduction were produced, and by the selection of one of these, the size of circle corresponding to a given droplet mass could be adjusted for a perfect fit. On the assumption that the effective thickness of the water film was constant, all other circles were automatically fitted, and the actual masses could, therefore, be read directly off the transparent mask. Slight departures from the basic assumption occasionally led to corrections for the smaller droplets. In practice, it has been found that the ordinary variations in the behavior of the paper, errors of judgment, and absence of a perfectly sharp edge to the various spots are as great as the departures from the basic assumptions. In general, one attempts only to find the circle on the mask that best fits the spot to be measured. By carrying on the matching processes under a low power binocular microscope, it is found that different observers easily agree to within 0.05 classification unit or to about 12 percent of the mass. Careful and experienced observers can successfully interpolate, but the spot method is not a very pre-

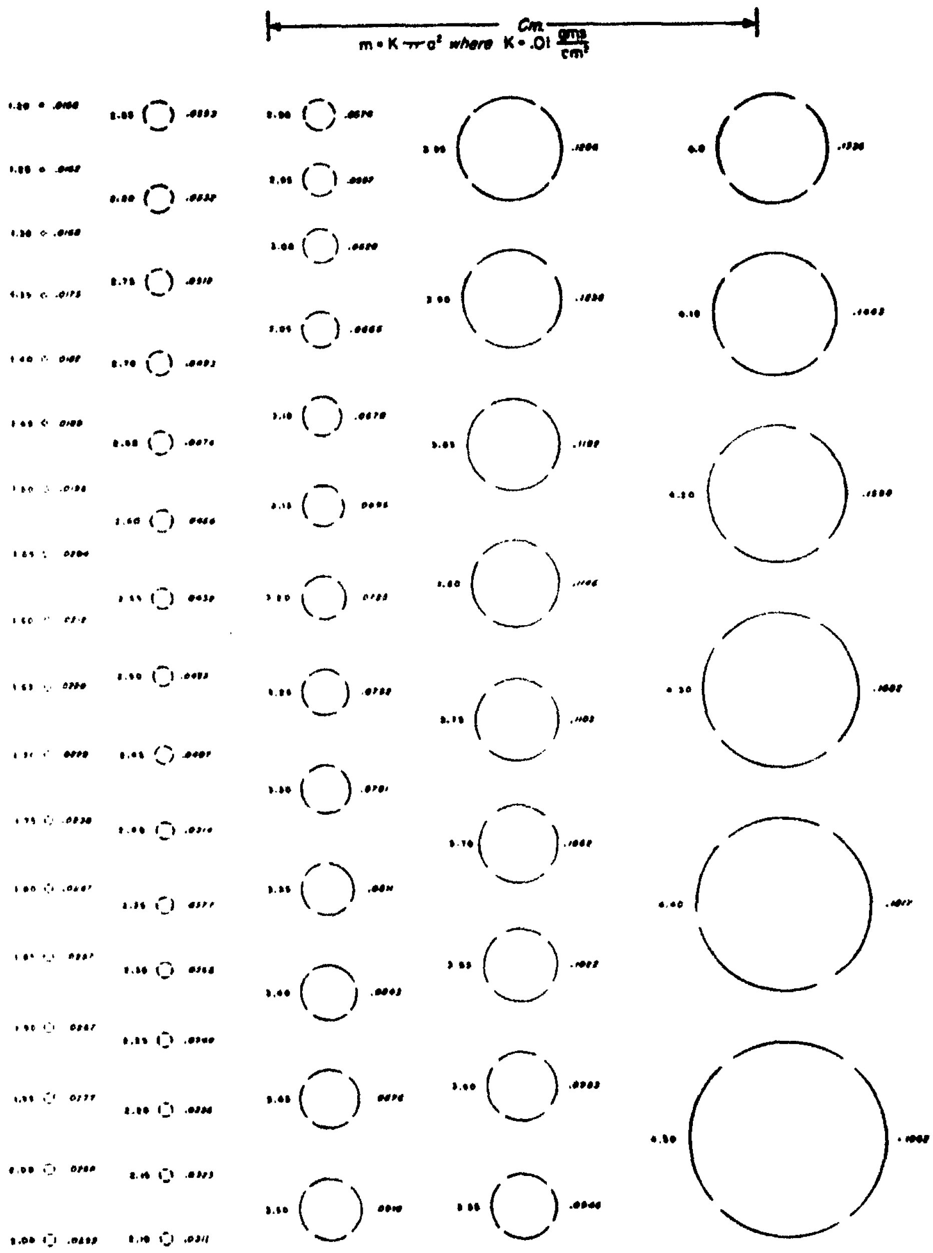

FIG. 3. Cut of transparent film mask for the determination of droplet masses. Logarithm of the mass in micrograms to the left of the circle, equivalent radius in centimeters to the right.

cise one, and it is valuable principally because of its convenience.

In the calibration of the blueprint paper, two methods for measuring the mass of the water droplets were employed. These two methods overlapped for droplets of medium size and gave identical results. For the large droplets the masses were determined by catching one to several drops in a covered aluminum can with a layer of cotton lying on its bottom, covering the can immediately to stop evaporation and carefully weighing on a precision chemical balance. The mass of the smaller drops are most easily determined by catching the droplets in a shallow glass pan filled with vacuum pump oil, covering the droplets as soon as caught by the oil, and measuring their diameter with a calibrated low power microscope. If this method is used for the larger drops, the vertical diameter, measured conveniently by the use of a small, total reflecting prism immersed in the oil, must be determined along with the horizontal diameter. A small camels' hair brush is employed when the droplets are first caught to cover them with oil. If the measurement of the diameter is made within a few minutes of capture, the absorption of the water in the droplet by the dry oil is negligible.

value of the electrical charge on falling raindrops may be accurately determined, it is important to produce a standard impulse in the apparatus for its calibration. This has led to the development of a standardizing dropper that simultaneously produces consecutive drops of nearly uniform mass and places a free electrical charge of predetermined amount on each. It is theoretically possible to calibrate the apparatus by an absolute method employing ball bearings half submerged in a metallic plate and exposed to a charged parallel plate some distance away in such a way that when the ball is dropped, it carries a known and easily calculable charge. The method was tried with some success, but difficulty was encountered in getting the falling ball to detach itself from the supporting mechanism in a reproducible manner. A more practical solution is to construct a water dropper and arrange an inducing electrode so that each droplet carries an induced electrical charge of selected sign upon it. The design of the calibrating dropper is shown in Fig. 4 and is seen to consist of a bottle to supply the water, a hypodermic needle, and an insulated cylinder concentric therewith. Water slowly dropping from the end of the needle, which has been carefully cleaned and ground to be at right angles to the axis of the needle, is exposed to an electric field produced between the needle and the cylinder by a battery of known and constantly measured potential. With appropriate care and keeping the drop rate close to one drop per second, it is found that the probable variation in the mass of each droplet is less than 2 percent, and the charge induced on each droplet by the surrounding cylinder is constant to better than 1 percent. The mass of each droplet may be determined by the methods outlined elsewhere in this paper, and the average electrical charge on the droplets may be determined by catching a hundred (for example) droplets in an insulated cup directly connected to a calibrated electrometer and condenser system whose voltage sensitivity and capacity are accurately known. This calibration can be carried out with little difficulty and the constant for the calibrating dropper determined once and for all. It is found over a limited range, that the charge induced on each droplet is proportional to the radius of the droplet and to the voltage difference applied between the water droplet and the surrounding cylinder, appropriately corrected for contact electromotive force. Thus, if Q is the charge on each droplet in e.s.u.,

$$Q = KR(\varphi + \Delta), \tag{1}$$

where K is the constant of proportionality and R is the radius of the droplet in centimeters. φ is the battery potential applied to the cylinder, and Δ is the contact potential, each expressed in e.s.u. With the particular dimensions shown in Fig. 4 and employing droplets having a mass of about 10,000 micrograms, the constant of proportionality K as determined by calibration measurements is 1.03. The contact potential between the brass cylinder and water in our experiments amounted to about 0.25 volt and was in such a direction as to put a small negative charge on each droplet. Thus, if an inducing voltage of 30 volts is applied to the inducing electrode, the corrections for contact e.m.f. may be kept to less than 1 percent.

In practice, it has been found convenient to construct an assembly consisting of a supporting metallic plate, the water reservoir, and inductor assembly, together with necessary batteries and a reversing switch, all arranged in such a way that the whole calibrating unit can be conveniently placed in position on top of the electronic analyzer so that the calibrating droplets fall through the apparatus. It has been practical to use this standard unit before every run in order to check the behavior of the apparatus since it is calibrated in terms of absolute electrical values, and the known mass of the droplets from the standard, can be used to calibrate the blueprint paper employed for recording purposes.

THE REVIEW OF SCIENTIFIC INSTRUMENTS VOLUME 20, NUMBER 4 APRIL, 1949

A Large Mass Spectrometer Employing Crossed Electric and Magnetic Fields

THOMAS MARINER* AND WALKER BLEAKNEY
Palmer Physical Laboratory, Princeton University, Princeton, New Jersey

(Received January 17, 1949)

Because of continued general interest in this type of instrument and because of relationship with previously published work it has seemed desirable to report here the progress made, up to cessation of work in 1940, on a large crossed field mass spectrometer, the basic design features of which were directed toward a resolution of about 25,000 in order to permit its use for mass measurement. Although the instrument was necessarily diverted to less exacting applications before development was sufficiently complete to permit attainment of this high resolution, nothing in experience with the instrument indicated that the goal could not substantially have been reached.

INTRODUCTION

EARLY in 1937 the experiments of Bleakney and Hipple[1] had proceeded far enough to give promise of realizing in practice the advantages of perfect focus, linear mass scale, high intensity, and high resolution which they had predicted theoretically for an m/e analyzer consisting of electric and magnetic fields at right angles to each other. Owing to the advantages which this type of analyzer appeared to have over the "double-focus" mass spectrometers,[2-6] we were encouraged to undertake immediately the development of a high resolution instrument employing the new arrangement of fields. With the hope of attaining a precision at least equal to that of existing mass spectrometers[6] we planned for a resolution of about 25,000 using a slit-to-image separation of about 250 mm and an entrance slit width of about 0.01 mm. This would lead to a dispersion of 2.5 mm for 1 percent mass difference, and it was expected that a precision of mass measurement of about 2 to 4 in 10^6 would be achieved.

Our plans were so disrupted by the circumstances concomitant to the recent war that the instrument was not developed to a state suitable for mass measurement. It was, however, put in operable condition and applied to other problems,[7] which fact in itself makes it desirable that the instrument be described in the literature. Further stimulus for presenting a description arises from the hope that some of the findings may be helpful in connection with other instruments of this type which have been or are being constructed. It will be of primary interest that we encountered in our work no phenomena which indicated that the ultimate goal could not have been attained. In particular, we found no evidence for radical departure from theoretical resolution such as has recently been reported for a similar analyzer.[8]

If the description of the progress on the large mass spectrometer could have been presented when development work was stopped in 1940, the details of design might have been of sufficient general interest to justify protracted treatment. Now, however, since the intervening years have brought many of the particulars of design and technique into the realm of general practice (and some into the state of obsolescence), an attempt will be made to present the description as briefly as possible. A considerably more detailed treatment, including extensive drawings and photographs, can be made available to anyone desiring further information.[9]

CONSIDERATION OF THE ORBITS

The first detailed step in design was the selection of suitable orbits for the ions, in the discussion of which we shall use the notation of Bleakney and Hipple, except that in place of β (defined by their Eq. (13)) we shall use a parameter β_1 defined as V_0/E, the ratio of accelerating potential in the ion gun to the analyzing field. This simply postpones consideration of mechanical details of design.

Since it was proposed that the relative advantages of the curtate and prolate orbits be investigated in the new mass spectrometer, a number of trochoids of each type were drawn using the trochoid drawer described by Bleakney and Hipple.[1] More or less intuitively a well-shaped trochoid of each type was then selected for trial as a mean orbit. The first criterion of a good orbit, obviously, was that it remain within the boundaries of a conveniently shaped vacuum chamber. In selecting the prolate trochoid a further consideration was that when adjusted for normal incidence on the focal plane it should have a wide enough cusp to permit the use of a photographic plate or slit carriage of reasonable size. For the curtate trochoid special precautions were taken to avoid a sharp cusp, since failure to do so might lead to undesirable space-charge effects. Preliminary consideration of the mechanics of design indicated that a 3″ magnet gap would be used and that a 20″ pole diameter would accommodate the prolate trochoid enlarged to the size required for a resolution $m/\Delta m$ of 25,000 without placing any part of the orbit outside the probable uniform part of the magnetic field, which was taken to have a radius equal to the pole radius less the gap width. Actually, under this limitation, it was possible to enlarge the chosen prolate trochoid to a total span of 340 mm, with a slit separation $b=262$ mm, so that a resolution of 26,200 would be anticipated with an entrance slit 0.01 mm wide. The curtate trochoid was then enlarged to make use of the total available span in the focal plane, so that for this orbit $b=340$ mm and the theoretical resolution is 34,000 for the slit width considered. One of the selected mean orbits is shown in Fig. 1.

[9] T. Mariner, Ph.D. thesis, Princeton, January 1947.

After the chosen orbits had been enlarged to the proper size, the parameters b, $y_{\max}$, and $y_{\min}$ were measured for each. Then a, ρ, and ψ_0 were computed using Eqs. (9), (17), and (18) of reference 1. Since a, θ, and β_1 seemed to be the most convenient orbit parameters to use in connection with later mechanical and electrical considerations, θ and β_1 were also computed. The expression for $\tan\theta$ in terms of known parameters was readily obtained by taking the ratio of Eqs. (13) and (14) of reference 1, and β_1 was computed from the relationship

$$\beta_1=(\rho^2\cdot\sin^2\psi_0/2a\cdot\sin^2\theta),$$

which, in turn, was obtained by using Eq. (13) of reference 1 in the expression for the initial kinetic energy: $V_0e=mv^2/2$. Finally, the ratio of the minimum energy of the ions to their initial energy was computed from the relationship:

$$V_{\min}/V_0=1+y_{\min}/\beta_1.$$

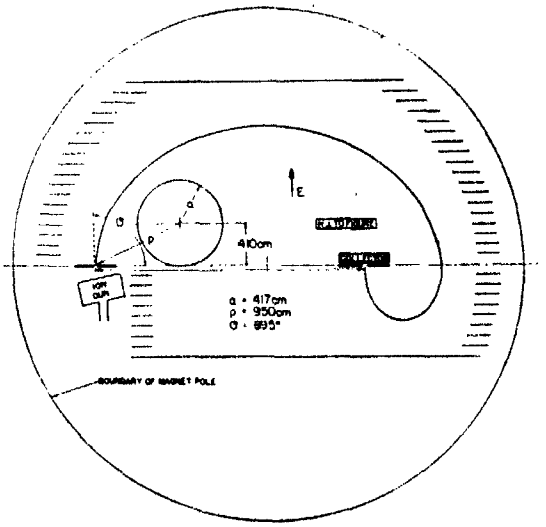

FIG. 1. Schematic drawing of the arrangement of the electrodes in the crossed-field mass spectrograph.

The values of the orbit parameters thus computed for the two selected orbits are listed in Table I.

The parameters thus far considered are associated only with orbit shape and position with respect to the focal plane. They involve relationships between V_0, E, and H without specifying their order of magnitude, so that operating conditions are not fully defined until one of these has been selected for ions of a particular mass-to-charge ratio. A value $E=200$ v/cm was chosen after canvassing the power supplies already at hand. With this value of E, the initial and final energy of the ions would be 1760 volts for the prolate orbit and 820 volts for the curtate orbit. These values are sufficient to give photographic traces in exposures of a few minutes.[10] With $E=200$ v/cm the minimum ion energy would be 685 volts for the prolate orbit and 45 volts for the curtate orbit. Since it would be possible to nearly triple E and $V_{\min}$ for the curtate orbit employing the power supply under consideration, and since it would be possible to build higher voltage equipment if required, the selected orbits seemed satisfactory from the standpoint of convenient shape, adequate final energy of ions, and adequate energy to minimize space charge effects. They were therefore adopted and the instrument designed around them.

THE ANALYZING CHAMBER

The Enclosure

The vacuum chamber is a short cylinder 4¾″ high outside and about 21″ O. D. A 1″-thick Armco iron cover rests on a recessed ridge cut into the top of the ¾″-thick sidewall (which was made of 18-8 stainless steel on account of the low magnetic permeability of this material) and a 1″-thick Armco iron bottom is arc-welded to the sidewall. 18-8 SS tubes of large diameter are welded into the sidewall at appropriate places to accommodate ion guns, slit mechanisms, pumping lines, and cold traps; and thirty smaller side tubes permit attachment of demountable Kovar glass seals through which electrical connections are made from an external voltage divider to the electrodes for the analyzing electric field, E. (Use of an internal voltage divider[8] would be more desirable from the point of view of structural simplicity, but less convenient for carrying out proposed tests on the effect of non-uniform electric fields.)

---

[10] K. T. Bainbridge, J. Franklin Inst. 212, 498 (1931).

The Electrodes for the Analyzing Electric Field

In principle the electrode arrangement for providing the analyzing electric field is a condenser with end plates spaced 27 cm apart and with guard rings or "picture frames**" every centimeter to reduce edge effects. The assembly fills most of the vacuum chamber, shown in Fig. 2 with the cover removed. The end plates are made of fine mesh 18-8 SS screen, and the guard rings are made of 0.006″ Nichrome *V* sheet. Each guard ring has a rigid retaining frame of $\frac{5}{32}''\times\frac{3}{8}''$ Nichrome *V* on each side of it to keep it planar, and these unit assemblies are spaced from one another by mica washers. Six grounded tie rods of Nichrome *V*, insulated from the unit assemblies by Pyrex tubing and from the end plates by Pyrex blocks, are used to compress the whole array into a rigid unit.

The guard rings project into the analyzing region past their retaining frames for a distance about equal to their separation, and the $\frac{3}{4}''$ high ion beam clears all but two of the guard rings by a distance equal to about half their separation.

There is no guard ring in the plane that passes through the axis of the analyzing chamber since the frame in this position holds the slit carriages. The adjacent guard rings therefore project into the analyzing region farther than the others and clear the ion beam by only $\frac{1}{32}''$.

The Slit Assemblies

For mass measurement investigations it was proposed that an entrance slit of fixed width would be used and that a camera, operated through the exit slit port, would handle the plates on which the mass spectra would be recorded. For preliminary survey work greater flexibility seemed desirable, and the slit mechanisms constructed for this purpose were the only ones built.

Three independent adjustments of the entrance slit are possible. These are effected through extensible bellows so that all adjustments may be made while the instrument is in operation. One adjustment permits locating the entrance slit in the optimum position in the incident ion beam, another permits adjustment of slit width, and the third permits alignment of the slit with the magnetic field to secure maximum resolution. Parallelism of exit slit and magnetic field is first secured by tilting the whole vacuum chamber.

Two independent adjustments are possible on the exit slit while the instrument is operating. One external control adjusts the slit width and another turns a lead screw to which the exit slit carriage is attached, so that it is possible to scan mechanically a mass range with extreme values of m/e in the ratio of about 2:1. The ion collector is mounted on the exit slit carriage, and the collector lead and its associated shield are arranged to telescope so that they are effective at all positions of the exit slit.

TABLE I. Characteristics of the selected mean orbits.

Orbit \ Parameter	b cm	$y_{\max}$ cm	$y_{\min}$ cm	a cm	ρ cm	ψ_0	θ	β_1 cm	$V_{\min}/V_0$
Prolate	26.2	13.6	−5.4	4.17	9.5	64.4°	89.5°	8.8	0.39
Curtate	34.0	3.78	−3.88	5.42	3.83	90.75°	35.0°	4.1	0.055

The slit carriages and the central frame in which they are tracked were all made of Nichrome *V* since preliminary tests indicated that this alloy could be run satisfactorily against itself in a vacuum. At infrequent intervals, however, the exit slit was locked by a ball of Nichrome *V* torn either from the central frame or the slit carriage by the other. This effect was eliminated by wiping both parts very lightly with a clean cloth slightly dampened with Lytton molecular lubricant *C*.

In addition to the slit carriages, the central frame also retains a thin sheet of Nichrome *V* to cut off "*N*th order" ion beams. If there are no obstacles in the analyzing region, ions of mass to charge ratio m/Ne, where N is an integer greater than 1, will be detected under the same conditions which permit detection of ions of mass to charge ratio m/e. Where prolate orbits are involved, the general condition for eliminating this possibility is somewhat more critical than that stated by Bleakney and Hipple[1] for curtate orbits, and requires that a length somewhat greater than $b/2$ be blocked off in the focal plane in one piece either beginning at the entrance slit or ending at the exit slit.

THE VACUUM SYSTEM

All of the demountable joints in the vacuum system are sealed with rubber gaskets, neoprene being used where there is exposure to oil vapors.

FIG. 2. Photograph of the vacuum chamber with top cover removed. The size may be estimated from the 30-cm scale at the top of the photograph.

** An apt descriptive phrase borrowed from reference 8.

Permanent joints in the vacuum chamber itself are arc-welded, except that the stainless steel bellows associated with the slit controls are attached with solder. Solder was also used in the pumping lines. Electrical connections are brought into the vacuum through tungsten pinches in the Kovar glass seals, which are themselves mounted on rubber gaskets.

The seam welds of the stainless steel bellows were the only troublesome source of leaks until they were sealed with clear glyptal, which proved sufficiently flexible not to fail in use. Only one or two leaks were found in the other welded and soldered joints, and none in the metal-glass seals. Of all the rubber gasketed joints only the cover seal leaked, and this only when the magnetic field was on. Wedges between the top pole piece and the cover rectified this trouble.

A temporary vacuum system consisted of a four-stage Leybold Hg diffusion pump backed by a Hypervac. In addition to the liquid air trap on the vacuum chamber proper, there was also one on top of the diffusion pump. The small throat of the diffusion pump (1″ diameter) limited the pumping speed at low pressures, and the small forevacuum lead (¼″ diameter), which is an integral part of the Leybold pump, prolonged evacuation time; thus the system was not satisfactory.

The final vacuum system consists of a metal fractionating oil diffusion pump (employing Octoil-*S*), which evacuates the mass spectrometer through a 4½″-diameter line, and a Kinney model CVD556 mechanical pump operating through a 1″-forevacuum line. A large manifold above the oil pump contains a copper liquid air trap. Although the speed of the diffusion pump was not measured, it is commonly accepted to be 80 litres/sec. Valves are provided to isolate the diffusion pump, a backing volume, and the manifold, so that the diffusion pump can be kept operative while the vacuum chamber is at atmospheric pressure. "Roughing" of the vacuum chamber can then be effected through a 1″-diameter bypass tube.

The performance of the vacuum system proved entirely satisfactory. One test was made to get rough data on the speed of evacuation. The mass spectrometer was initially at atmospheric pressure while the manifold was being continuously evacuated by the oil diffusion pump working into the backing volume. After the Kinney pump was started, the bypass valve was opened for 2½ minutes and then closed, immediately after which the gate valve between the diffusion pump and the mass spectrometer was opened. One-half minute later the pressure in the manifold above the diffusion pump was only forty percent greater than normal ultimate pressure. After a total elapsed time of ten minutes the filament of the ion gun was safely lit.

No attempt was made to measure absolutely the ultimate vacuum attained since the performance of the mass spectrometer itself was the final test. However, Pirani gauges and ionization gauges were used in leak hunting and the latter provide a reasonable basis for estimating the ultimate vacuum. The Western Electric D-79510 and D-79512 gauges are operated from a modified Ridenour Lampson[11] circuit which maintains 10-ma grid current at 300-v grid voltage under running conditions and has convenient arrangements for outgassing the gauges. One gauge is inserted at the top of the manifold above the diffusion pump and the other is mounted on the mass spectrometer shell among the leads to the analyzing field electrodes. With liquid air on the manifold and vacuum chamber traps, plate currents of the order of 0.7 microampere were customarily obtained on both gauges. Extrapolation of the data of Jaycox and Weinhart[12] to a grid voltage of 300 volts gives an estimated pressure of 1×10^{-6} mm Hg under the operating conditions.

Before the temporary pumping system was discarded, a test was made to compare the efficacy of the old and new arrangements. With the Hg pump working, the plate current of the vacuum chamber ionization gauge was read and the intensities of the background ion beams in the low mass range were measured. The stopcock to the Hg pump was then closed, the gate valve to the oil diffusion pump opened, and similar measurements taken again. The results given in Table II indicate the superiority of the oil diffusion pump and the larger pumping lines.

It was hoped that tests could be made to determine the degree of necessity for the liquid air trap above the oil pump, but time did not permit. Data bearing on this point have subsequently been obtained by others.[13]

THE MAGNET

General Remarks

The pole radius was selected by consideration of the probable minimum slit widths and the maximum resolving power desired, allowances being made for probable loss in usable radius due to edge effects. The loss was taken to be equal to the effective gap width; and this was justified by subsequent measurements of the field distribution both parallel and perpendicular to the pole pieces. The other dimensions of the magnet were made compatible with the cross section of the pole, with work space requirements, and with space needed for windings. Room was left for more windings than required for the immediately proposed application in order that the magnet should not be too restricted in usefulness. Rough calculations indicated that the shape of the magnet would have little effect on the cost within the limits of practical design; therefore, convenience was given first consideration. Of great assistance*** in designing the magnet were the data on the model magnet for the cyclotron.[14]

The Coils

In order to be able to utilize as nearly as conveniently possible the maximum power output of any one of three different generators which might be assigned to the mass spectrometer, it was necessary that the total winding for which room was provided be split into twelve separate coils wound with No. 6 copper wire. Square wire was selected to minimize winding losses and to aid in cooling; and asbestos plus single cotton insulation was selected for durability and heat resistance.

Each coil is a 330-pound "pancake" (44⅜" O. D. ×1⅜" thick) of 373 turns, with a resistance of 1.1 ohms. After being wound, each coil was baked and impregnated with transformer varnish, not only to exclude vapors, but also to make the coils rigid and to aid in cooling. Twelve such coils could utilize a maximum of 17.4 kilowatts from a 20-kilowatt 120-v d.c. generator, or 39.3 kilowatts from a 40-kilowatt 120-v or 240-v d.c. generator. The corresponding current densities are 222 amp./cm^2 and 334 amp./cm^2. With twelve coils these upper limits of current density correspond to 21,300 and 32,100 ampere-turns/cm of gap, and the model magnet data indicate that about 14 kilogauss may be obtained at the lower power using cylindrical poles, whereas about 18 kilogauss may be obtained at the higher power using complex poles.

Although original plans called for twelve coils with water-cooled separators, only eight were installed. These were air-cooled, since the need for very high fields was not in view. Moreover, development work on the mass spectrometer had to be terminated while tests were in progress on electronic control of the synchronous motor generator set assigned to the mass spectrometer. Storage batteries were therefore used in the application of the instrument already reported.[7]

The Core

The core**** of the magnet looks somewhat like a cyclotron magnet core 62" long, 55" high, and 20" wide in outside dimensions. It was made as a one piece 6.5 ton casting of Armco electromagnet iron so proportioned as to present to the flux approximately the same total cross section throughout. After the casting was made, part of the center section was cut out and the pole tips machined. In order to provide for the possibility that contoured poles might be desirable in future applications of the magnet, a six-inch length of each pole tip was made removable. With the pole tips in place, the gap is 5", but this is reduced to an effective 3" by the cover and bottom of the vacuum chamber. The pole tips vary in diameter from 20" to 20¼" and are out of vertical congruence by $\frac{3}{32}$" in the worst place. The 5" gap is uniform to within 0.002" in the worst place, and there is no evidence of voids in the casting.

VOLTAGE SUPPLY, STABILIZER, AND CONTROL FOR THE ANALYZING ELECTRIC FIELD

To be consistent with the initial goal with regard to resolution, the analyzing field should have a stability of about one part in 250,000, at least for periods of a few minutes, and for convenience should generally be coupled to the ion accelerating voltage in such a way as to maintain a constant ratio of the two. Only preliminary progress was made toward the first objective, and consideration of practical schemes for realizing the second was not undertaken.

In the previously reported application of the mass spectrometer[7] the analyzing field was supplied from a 27-segment voltage divider with a total resistance of 2.7 megohms. This was attached to the output of a degenerative stabilizer based on the circuit of

*** We are indebted to Dr. M. G. White for the use of these data prior to publication.

[14] M. C. Henderson and M. G. White, Rev. Sci. Inst. 9, 19 (1938).

**** Made by the American Rolling Mill Company, Middletown, Ohio.

Fig. 9 in the paper of Hunt and Hickman.[15] A full wave voltage doubler rectifier supplied the input to the stabilizer. The output voltage of the stabilizer was adjustable over the range 1100 to 5400 volts by variation of a resistance constituting part of a bleeder in parallel with the voltage divider. Conveniently, the output voltage of a degenerative stabilizer of this type varies nearly in inverse proportion with the control resistance, with the obvious consequence that the control resistance is nearly proportional to the *m/e* of the ions being observed.

A basic feature in the design of the analyzing chamber was that the slit plane be at ground potential, which, in turn, required that the voltage divider supplying the analyzing electric field be grounded at a point not common to either side of the rectifier or stabilizer. Since all leakage currents from the power supply to ground must complete their circuits through the voltage divider in such an arrangement, it is desirable, first, to minimize such currents by using specially selected or specially constructed power supply components, and, second, to minimize the importance of the currents by using a large divider current. The decision to use an existing power supply for the work of reference 7 limited the extent of possible compliance with the second consideration. However, in keeping with the first consideration, it was found possible to substantially improve the stability of the analyzing field by rebuilding several critically located circuit components. Since greater refinement was not required for the purposes at hand, work was terminated when the d.c. fluctuations in the voltage divider had been reduced to about one part in 30,000 and ripple had been reduced to amplitudes of 3.7 and 1.5 parts in 10,000 in the negative and positive branches of the load, respectively. The ripple probably arose mostly from leakage between the primary and secondary of the high voltage transformer, there being only 10^{10}-ohm resistance between them.

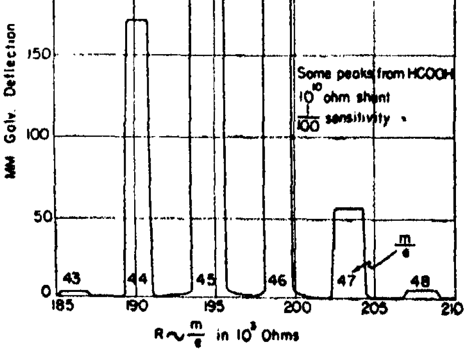

FIG. 3. Spectrum of formic acid in the mass range 43 to 48.

THE ION GUN

No development work was done on ion guns designed to take advantage of the permitted large angular spread in the ion beam. For survey work and for application to the investigation already mentioned[7] a conventional type of ion gun was built. Storage batteries were used to heat the conveniently replaceable tungsten filament whose emitted electrons were accelerated downward in two independently adjustable steps. After passage through the ionization chamber the electrons impinged upon a collector held positive with respect to the ionization chamber in order to suppress secondary emission. A vacuum tube microammeter patterned after that of Shepard Roberts[16] was used to measure the collector current. The sample gas was led through a reentrant tube and introduced directly into the ionization chamber in a stream (directed counter-current to the electron beam) in order to gain a factor of about two in ion intensity.[17]

Before encountering the entrance slit to the analyzing chamber the ion beam passed through three slits in the ion gun. The first of these was generally only a few volts negative with respect to the ionization chamber. Between the second slit and the ionization chamber only 10 percent of the total ion accelerating voltage was applied in order to minimize penetration of the ionization chamber by the accelerating field. The final slit was at ground potential so that no electric field was present between it and the entrance slit to the analyzer. Since the ion gun had to be tilted with respect to the entrance slit plane in order to fulfill conditions for the selected orbit, a non-uniform field would otherwise have prevailed, making it difficult to compute the ion orbit between the ion gun and the slit plane.

The relative positions of the slits in the ion gun were selected after the orbits of the electrons and ions had been calculated under several sets of conditions. (The orbits can be treated by the same equations which apply to the orbits within the analyzing chamber if the electric fields within the ion gun are assumed to be uniform.)

---

[15] F. V. Hunt and R. W Hickman, Rev. Sci. Inst. 10, 6 (1939).

[16] Shepard Roberts, Rev. Sci. Inst. 10, 181 (1939).

[17] Leonard B. Loeb, *Kinetic Theory of Gases*, 2nd Edition (McGraw-Hill Book Company, Inc., New York, 1934), p. 309.

The position of the ion gun was adjusted to be consistent with the requirements for securing the selected prolate orbit in the analyzing region. Energy for accelerating the ions was provided by a stabilized power supply basically the same as that used for the analyzing field, but operating at lower voltage. For convenience, the output meters of the two stabilizers were made to read the same when $\beta = 8.8$ as required for the orbit selected.

THE ELECTROMETER TUBE AMPLIFIER

The ion currents were measured on a Barth type amplifier[18, 19] using a Western Electric D-96475 tube and a Leeds and Northrup galvanometer with a maximum current sensitivity of 9×10^{-11} amp./mm at 1 meter, which can be reduced by an Ayrton shunt. The sensitivity of the amplifier is 108,000 mm/volt on highest galvanometer sensitivity. Random fluctuations were generally of the order of 0.75 mm on 10^{10}-ohm shunt, full sensitivity. Both electrostatic and magnetic shielding were provided for the electrometer tube, and its enclosure was evacuated.

Conclusion

As mentioned at the beginning of the paper, the original purpose in building the mass spectrograph was to obtain an instrument of high resolving power, high intensity, and great utility. Circumstances permitted only a few studies of ionization processes, in which the high resolving power was not required and hence not exploited. The operating parameters used for our research were $b = 262$ mm, $H = 2200$ gauss, exit slit width 3.17 mm, and entrance slit width 0.05 mm. The slit widths represent nominal values inasmuch as no attempt was made to secure accurate alignment with the magnetic field. The theoretical resolution was thus about 81, and the observed resolution differed from this by less than 5 percent.

Although the above result means little with regard to ultimate resolving power, one can see from the slope of the sides of the peaks in Fig. 3† that this must be quite high, probably greater than 1000, even with slits not carefully aligned. Certain preliminary runs made under somewhat different conditions than those quoted above implied considerably higher values of ultimate resolving power, and nothing in our experience with the instrument indicated that the goal of 25,000 could not substantially be reached.

In other respects the device measured up to expectations. The peak shapes were uniformly symmetrical and the tops were really flat. Intensity was excellent, and stability was very good except in a few instances when the effects of improvisations in some of the circuits became apparent. Although vacuum conditions were about as expected, reduction of background would have been undertaken prior to more exacting applications of the instrument.

ACKNOWLEDGMENTS

The greater part of the machine work on the mass spectrometer was executed in the Palmer Laboratory machine shop, to the personnel of which the authors are indebted for their contributions.

The assistance of C. S. Cummings, Robert Matheson, and George Reynolds in constructing and testing some of the electrical circuits is greatly appreciated, as is the aid of Roger Sutton in leak-hunting.

[18] G. Barth, Zeits. f. Physik. 87, 399 (1934).

[19] D. B. Penick, Rev. Sci. Inst. 6, 115 (1935).

† The peaks at $m/e = 44$ and 46 are narrower than the other peaks because of a slight lack of precision in the elements of the control resistor, R, of the analyzing field stabilizer. Each of the two peaks in question encompasses a range on the resistance scale within which the combination of resistance elements was changed, a large one replacing the sum of ten smaller ones.

A Novel Recording Accelerometer

ARTHUR S. IBERALL
National Bureau of Standards, Washington, D. C.

(Received January 3, 1949)

The novel features of a small recording accelerometer of slow chart speed are described. Principally, these are its compactness—the recorder, less power supply, fits into a panel type aircraft instrument case—and the use of spark recording to obtain a visible record on a paper chart. Components selected to achieve compactness are a timing type synchronous motor to drive the chart; a 35 mm film cartridge to store the chart, and a model airplane spark coil to provide a high voltage repetitive spark. A simple preliminary chemical treatment for ordinary paper was developed to obtain an intensified trace on the record chart. Small or panel type recorders of other physical quantities can be similarly built, applying the main features of this design.

INTRODUCTION

At the request of, and with the financial support of the Aero Medical Laboratory of the U. S. Air Force, the National Bureau of Standards undertook the development of a recording accelerometer to be used in testing personnel in flight. It was essential that the size be small. Other requirements were a range of 12 g, accuracy within 4 percent of full scale, a natural frequency of 10 c.p.s., a permanent record visible while recording, a paper speed between 4 to 12 inches per minute uniform to within 5 percent, and, if electrically operated, operation from 28 volts d.c.

The method of design, illustrated in an experimental model, may be followed in constructing other small or panel type slow speed recording instruments using certain existing sensitive elements without seriously modifying them.

An exploded isometric drawing of the recorder is shown in Fig. 1, and a schematic diagram of the power supply is shown in Fig. 2. The description of the recorder can best be followed by reference to the figure.

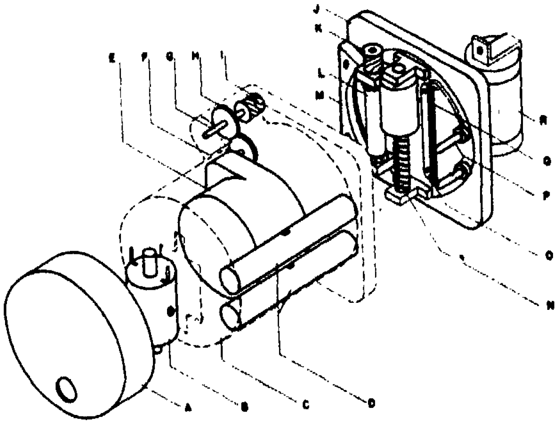

FIG. 1. Schematic layout of component parts of the accelerometer recorder. (A—false bottom, B—spark coil, C—case, D—high voltage receptors, E—motor, F—motor spur, G—shaft, H—shaft spur, I—shaft spiral gear, J—cover, K—driven spiral gear, L—sprocketed roller shaft, M—slotted guide bar, N—accelerometer element, O—plate electrode, P—banana plugs, Q—cartridge slot, R—cartridge.)

CASE

A small recording instrument desirably should be designed to fit into a case of moderate depth, with a small, round or square dial. The preference for a conventional aircraft installation for this instrument led to the choice of a standard aircraft panel type case. The case of a rate-of-climb indicator, C, Fig. 1, is particularly suitable because of a setting shaft, G (part of the zero setting mechanism) built into one square corner. The setting shaft is utilized to transmit power from a motor (placed in the back of the case) to the front of the case without encumbering the inside of the case.

MOTOR

Small synchronous timing motors are suitable for a chart drive because of their small size, their uniform speed, their operation at the common supply frequency of 60 c.p.s., and their availability in a wide range of shaft speeds (integral gear trains provide shaft speeds from 10 r.p.m. to 1 r.p.d.) with a torque output up to 30 in.-oz at 1 r.p.m. Their application depends upon being able to design a chart drive sufficiently free of friction. It is estimated that these motors cannot be used to obtain linear chart speeds in excess of 100 inches per minute. However, they are satisfactory for chart speeds of about 10 inches per minute.

A 2-r.p.m., 3-watt, 24-volt, 60-c.p.s. motor, E, was chosen for the recorder. It is mounted back in the case on tubular shims and fastened from the back of the case with screws. Its location in the case is chosen so that its shaft overlapped the setting shaft to permit gear coupling.

GEARING

A set of spur gears, F and H, of approximately one to one ratio connects the motor to the setting shaft. The only limitations on the gear sizes are that the shaft spur must be large enough to permit its teeth to project from the setting shaft pocket, but small enough to fit in the pocket, and the motor spur gear diameter must be large enough to clear the motor and engage the shaft spur gear. In the experimental model, the shaft and motor spurs had 40 and 60 teeth respectively.

Rotary motion is transformed from perpendicular to parallel to the plane of the cover by means of a set of like-rotation spiral gears, I and K, one of which is mounted on the setting shaft. The spiral gears have the advantage of establishing the axis of rotation as far over to one side of the case as possible, leaving the front end of the case still relatively free.

RECORD DRIVE

The proximity of the spiral gear axis to the side suggested that the record chart could be pushed through the case for the short remaining distance. Considerations of loading and storing the record chart pointed to the desirability of mounting, driving and storing the chart on the cover (see J). The favorable mating characteristics of spiral gears made them the logical breaking point of the driving connection.

The cover glass of the conventional case was therefore removed and replaced by a thick transparent plastic disk. The second spiral gear, K, was pressed on a shaft retained by two bearings mounted on the inside of the cover. Since 35 mm appeared to be approximately the widest record width practicable, and made possible the use of replacement parts from cameras, this size was adopted. A sprocket drive from a 35 mm camera was therefore adapted to drive the record chart by pressing it on the same shaft as the driven spiral gear. The chart thus passes underneath the sprocketed roller shaft, L, in the inside plane at the cover. The cover is undercut in narrow slots underneath the sprocket teeth.

The record chart is stored in a 35 mm film cartridge. The cartridge, R, is mounted from the outside of the cover in a semi-cylindrical hole (not visible in the figure), formed as far over to the side of the cover opposite the sprocketed roller as possible. A slot, Q, cut in the bottom of the hole permits the tangent lip of the film cartridge to project into the case. The record chart is thus drawn from the cartridge with minimum number of contacts by the sprocketed roller.

In order to pass the chart out of the case, a U-shaped slot (not visible in the figure) was cut in the case and a slotted guide bar, M, attached to the cover, was put in this space. With the gearing and motor used, a chart speed of 6½ inches per minute was obtained.

ACCELEROMETER ELEMENT

A range of about 12 g-units and a natural frequency of about 10 c.p.s. were required for the accelerometer element. Coupled with small-size for the recorder and the consequent use of a recording paper 35 mm wide, this led to the use of a simple mass and spring element, without mechanical multiplication of the mass displacement. A scale sensitivity of about one g-unit per 1/16 inch was obtained.

A fixed shaft, on which a bob slides, was mounted in two bearings attached to the inside of the cover plate between the film cartridge and the sprocketed drive roller (see N). The bob size was chosen to be as large as could safely fit in the available space (limited by the motor, the cover plate, the cartridge, and the roller). The shaft size was chosen to have high rigidity. A spring of appropriate diameter (0.02-inch wire) was wound to slide freely on the shaft. In order to restrain the bob from rotating (so that an electrode might be mounted on it), a V-groove was cut in the shaft, and a steel ball was inserted in a snug radial hole which passes through the bob. The ball was retained in the groove by a set screw. The spring was attached at one end of the shaft to an externally threaded sleeve, keyed to the shaft, and at the other end, to a similar sleeve threaded into the bob.

The use of a porous oil-impregnated metal for the sleeve inside of the bob provided some damping.

RECORDING MEANS

The repetitive puncture of a paper chart by a high voltage spark was used to obtain a record trace. This system has the advantages of permitting recording at the back of the paper, securing a record visible immediately at either front or back

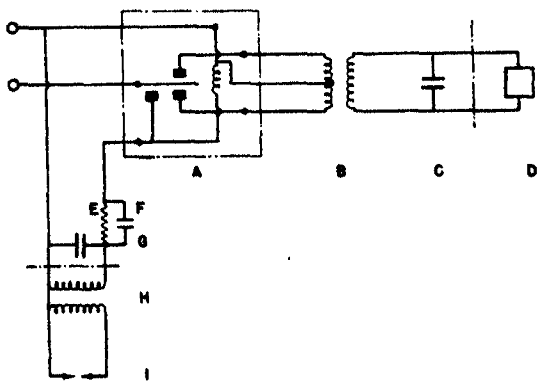

FIG. 2. Schematic layout of the power supply for the accelerometer recorder. (A—vibrator (5 terminal, 28 v, 50 w, 60 c.p.s.), B—coupling transformer, C—filter condenser (16 m.f.d.), D—motor (25 v, 60 c.p.s., 2 r.p.m., 3 w), E—limiting resistor (15 ohm, 25 w), F—bypass condenser (100 μf), G—tuning condenser (4 μf), H—spark coil (model airplane coil), I—spark gap.)

without the need of subsequent development, and of having no writing friction.

The recording electrodes consist of a nickel tip screwed into the bob (a point electrode) and the edge of a plate, O, mounted directly under this tip on the inside of the cover (a line electrode). The electrode spacing is approximately 0.008 inch. The electrode plate is countersunk in the cover and is slightly wedge-shaped so that the edge, underneath the point electrode, projects slightly above the plane of the cover. The paper rides over this edge and is punctured along this line as the bob deflects.

In order to minimize the risk of shock to personnel and to permit free removal of the cover, the plate electrode is made the high voltage electrode, leaving the bob at low potential. The supply voltage to both electrodes is brought in by conducting strips from banana plugs, P, screwed into the cover plate. Mating receptors, D, are fastened to the inside of the case. A small spark coil, B, furnishing the high voltage, is mounted in a slot cut in the back of the case. The slot is covered over by a false bottom, A, added to the case.

POWER SUPPLY

The electrical requirements of the recorder are a 24 volt, 60-c.p.s. sine wave for the synchronous motor, and a high voltage for the sparking electrodes, preferably in the form of a repetitive voltage "pip." The supply voltage available in aircraft is 28 volts d.c. The requirements were successfully met through the use of a 60 c.p.s. vibrator. The vibrator used, A, Fig. 2, has a main driving reed contact and an additional set of single-pole double-throw contacts. The description of the power supply may be followed by reference to Fig. 2.

Two half waves from the double throw contacts are coupled together in the center tapped primary of a small transformer, B. The transformer and a shunt condenser, C, form a filter circuit for the 60 c.p.s. wave. This furnishes the motor supply voltage (see D).

The main reed contact passes a voltage consisting of 28 volts d.c., while the reed contact is closed, and a "pip" of opposite polarity while the reed contact "breaks," due to the inductive delay of the vibrator coil. The only spark coil of minute size available is a model airplane coil, H, operating on 3 volts, so that a matching circuit had to be devised to permit using the vibrator output.

The d.c. component from the reed contact is reduced by a dropping resistor, E, shunted by a large capacitance, F, which passes the "pip." This supply is then fed to the spark coil. The spark is intensified by the use of a shunt capacitance, G, across the primary of the spark coil. The two shunt capacitances have the additional function of quenching the reed contact spark.

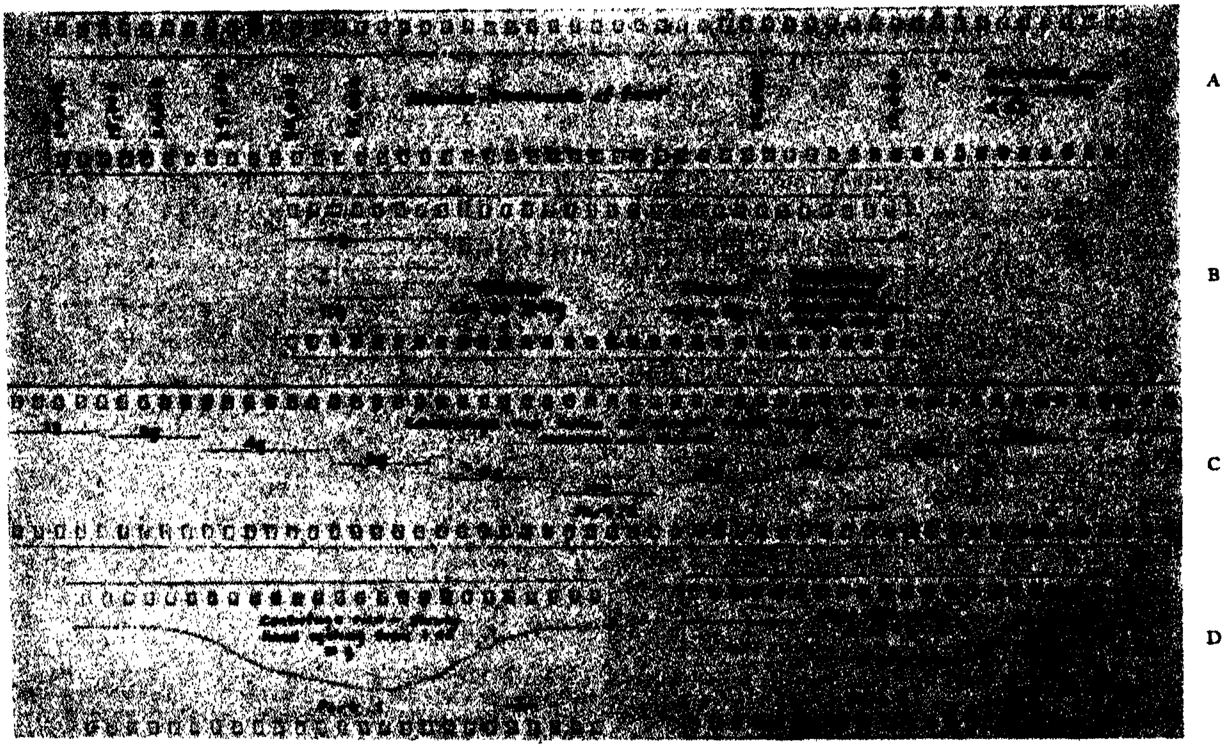

FIG. 3. Typical calibration and performance records obtained with the accelerometer recorder. (A—trace at simulated altitude, B—trace with rapidly oscillating accelerations, C—static calibration trace, D—trace under cyclic accelerations).

In order to avoid external lines for the high voltage, the spark coil is built into the instrument case, for which the only available space is behind the motor.

The remainder of the power supply elements—vibrator, transformer, resistors, capacitances—are housed in a small radio chassis. The operation of a switch simultaneously starts or stops the motor and spark.

PAPER

A 35-mm single weight perforated photographic paper from which the emulsion had been removed was chosen for the record chart. It was found that a higher energy level than available from the small spark coil was necessary to form a trace easily visible at ordinary reading distances. A chemical treatment was developed for the paper that would intensify the trace as it formed. Among the various chemical solutions tried, the following was found to be quite satisfactory. The function of each chemical is given in parenthesis.

In one liter of distilled water dissolve

100 g potassium nitrate (oxidizing agent)
50 g gum acacia (binder)
5 g potassium chloride (catalyst)
5 g ammonium nitrate (oxidizing agent)
0.3 g potassium hydroxide (alkali)
0.5 ml formaldehyde (hardening agent)
6 drops of 5 percent Aerosol OT (wetting agent).

The paper was immersed in this solution for one minute and then passed over a heated dryer. The belt tension of the dryer was adjusted to produce as little distortion as possible in the paper.

PERFORMANCE

The experimental accelerometer was given some laboratory tests to determine its performance before being delivered to the Aero Medical Laboratory. Figure 3 shows some representative data. The first strip, A, Fig. 3, shows the effect of reduced pressure (simulated high altitudes) on the dispersion of the trace; the second strip, B, shows the adequacy of the trace under oscillatory conditions; the third strip, C, shows the static calibration of the accelerometer in a centrifuge, and the fourth and fifth strips show, D, the performance of the accelerometer in a centrifuge under cyclic accelerations chosen to simulate flight turns.

ACKNOWLEDGMENTS

The author wishes to acknowledge the invaluable help and advice given him by the following Bureau of Standards personnel: Jack Sargent, electrical circuit; Leo Schubert, chemical record intensification; Russell Baum, construction.

Book Reviews

The General Properties of Matter

Fourth edition. BY F. H. NEWMAN AND V. H. L. SEARLE. Pp. 431+xi, Figs. 103. Longmans Green and Company, New York, and Edward Arnold & Company, London, 1948. Price $5.25.

This textbook, originally published in 1929 and now in its fourth edition, is clearly intended for students of physics, chemistry, and engineering with special emphasis on the first-named group. It is written with the special aim, however, of including material of interest and application to all three groups which shall be so thoroughly correlated as to emphasize the essential unity of the entire body of information. Readers from each group are thus encouraged to study more closely the related subjects in fields adjacent to their own. The broadening effect on students in these days of extreme specialization should be most beneficial and welcome.

The title is so inclusive that almost any material whatever in physics, chemistry, or engineering *could* be covered by it. The preface gives no clue to the choice of material, but a careful examination shows that the authors have restricted themselves almost exclusively to topics which can be roughly designated as *classical* or *nineteenth century physics*. Only slightly more than two pages are devoted to the statement of a few consequences of the restricted theory of relativity (at the end of Chapter III which bears the title *Gravitation*). The huge body of experimental and theoretical information which has grown up almost entirely in the present century and which, in this country, usually goes by the name of physics of the solid state (cf. Frederick Seitz, *Modern Theory of Solids*, for example) is almost completely ignored. Nothing whatever that could be termed either atomic or nuclear physics is included in the book. Nothing is said of the Uncertainty Principle. The fundamental particles of matter are not discussed. Electricity and magnetism, light (optics, spectroscopy, etc.) per se, even in the classical aspects of these subjects are omitted. Since, however, this reviewer knows of no traditional limits for a book or a course bearing the title *General Properties of Matter*, the above statements are intended as information to the prospective purchaser rather than as strictures. It is quite possible that this text is specifically designed to cover material traditionally offered in certain courses in this country or in England of which this reviewer is ignorant.

The material covered by the text might be roughly outlined as follows: Chapters I to IV inclusive: Elementary mechanics of particles and rigid bodies, gravitation and gravitational potential, gyroscopic problems. Chapter V: Theory and applications of elasticity. Chapter VI: Surface tension. Chapter VII: Viscosity. Chapter VIII: Kinetic theory. Chapter IX: Fourier series. Chapter X: Osmosis, diffusion, and Brownian motion. Chapter XI: Production and measurement of low pressures. Chapter XII: Elementary dynamical problems (such as simple and damped harmonic motion, motion under inverse square law of attraction, motion of projectile in viscous medium). Chapter XIII: Equations of fluid motion. Chapter XIV: Equations of wave motion. Chapter XV: Units and dimensions. Some of the chapters bear rather curious titles. Chapter XII for instance, is called simply "Dynamical Basis—Including Vibrations" and Chapter XIII on fluid dynamics is called simply "Equations of Motion."

The text is written on an elementary or intermediate level so that it can be used by any student who has mastered elementary calculus. It would be suitable for majors in physics in their junior or senior years. Although it contains a great deal on the subject of dynamics, the treatment is entirely on an elementary level—the methods of advanced dynamics, generalized coordinates, LaGrange's and Hamilton's equations etc., are not touched upon.

Within the above roughly outlined framework of its content, *the book is excellently constructed.* It is exceptionally thorough in its treatment. The exposition is lucid and leaves little for the reader to supply from other sources. It is outstandingly well furnished with footnote references to the original papers (extending as far back as the beginning of the nineteenth century and as far forward as the present day), a rare virtue indeed in texts at this level. The problems at the end of each chapter are well selected and interesting. The answer to each problem is given. Each topic is brought up to date with commendable thoroughness. Thus, for example, in the discussion of the numerical value of the universal constant of gravitation, the latest (1942) results of Heyle are given, and in the discussion of the determinations of Avogadro's number, Birge's 1941 results are cited.

The enormous impetus that the "new physics" has received from the tremendous discoveries of twentieth century research has drawn the attention of physicists away from many of the solid and useful achievements of the earlier "classical" period. This book serves a very useful purpose, therefore, in recalling in compact form this earlier store of fundamental information which the beginning student, bewildered with the glamour of betatrons, cosmic rays, and chain reactors might otherwise overlook or ignore. This reviewer prizes it as a valuable addition to his library.

Physico Chemical Experiments

BY ROBERT LIVINGSTON. Pp. 267, Figs. 72, Macmillan Company, New York, 1948. Price $3.30.

This is the second edition of the well-known laboratory manual prepared as a companion book to F. H. MacDougall's text, *Physical Chemistry*. There have been very few changes: One experiment has been dropped and two added; the text has been revised in some places.

Forty-two experiments are discussed. These are designed to give the student laboratory experience in the fields which are usually included in the elementary physical chemistry course and should be useful in connection with any textbook or course of lectures on the subject. The specific subjects covered are: Measurements, errors, and computations; the gaseous state; the liquid state; the solid state; the structure of atoms; physical properties and molecular constitution; solutions; thermochemistry; equilibrium; heterogeneous equilibrium; chemical kinetics; electrical conductance; equilibria involving ions; electromotive force; electrolysis and polarization; photochemistry; and the colloidal state.

Discussions of the theory related to the individual experiments are not given in the manual except in a few cases. This seems highly desirable since there is not space for a thorough exposition, and reference to a standard theoretical text is certainly preferable to the inclusion of a sketchy account which the student may accept in preference to looking for a more adequate one elsewhere.

Each experimental discussion includes a preliminary brief outline of the experiment and techniques; a list of apparatus and materials required; a description of procedure that is sufficiently detailed to permit the student to proceed without too much assistance from the laboratory instructor; and a list of computations to be made on the basis of the data obtained in the laboratory. In addition, there are a number of special sections on the use of various pieces of apparatus such as the barometer, the Lind electroscope, the differential thermometer, the polarimeter, the Westphal balance, the Abbe refractometer, etc.

Especially praiseworthy is the introductory section on "Measurements, Errors, and Computations," to which 52 of the 255 pages of the text are devoted. The exposition of the theory in this section is admirable because of its completeness, suitability for its purpose, and the abundance of illustrative examples. In this section the subjects, physical laws and measurements, dimensions, significant figures, exponential notation, distribution of errors, best values, application of error theory to experimental data, evaluation of constants of empirical equations, and graphical methods of computation are discussed.

Notable omissions from the manual are experiments concerning the heat capacities or thermal conductivities of gases; the diffraction of x-rays by solids; the dielectric properties of chemical substances; the magnetic properties of chemical substances; and the distribution of solutes between solvents. It would seem that such experiments would be quite valuable accompaniments of the usual course of lectures in elementary physical chemistry.

The experiments are quite generally designed to require relatively simple equipment which is, in general, desirable at this level. However, there are no experiments included which give the student familiarity with high vacuum techniques, use of electronic equipment, use of modern recording meters of various types, etc.

The printing and binding are excellent.

Velocity-Modulated Thermionic Tubes

By A. H. W. Beck. Pp. 180, Cambridge University Press, The Macmillan Company, New York, 1948. Price $3.75.

This volume of the series on *Modern Radio Technique* edited by J. A. Ratcliffe is intended to acquaint the reader, who is familiar with prewar radio technique, with the principles of operation of velocity-modulation tubes and their limitations. The author's intention was not to write a formal textbook with full documentation but rather a personal account of a division of research which is still progressing rapidly. He has attempted to build up the theory from simple postulates by successive refinements so that physical facts dominate mathematical considerations, and has stuck mainly to the theoretical side, only occasionally remarking that the results are (or are not!) in satisfactory agreement with experiment. Mr. Beck was a Senior Scientific Officer in the Admiralty Signal Establishment at Bristol and was personally responsible for much of the research reported. Naturally most of his applications are drawn from British practice, but the liaison between British and American laboratories during the war was sufficiently good that all our contributions of importance are covered. The book abounds in references to the European literature and especially the work of Warnecke in France.

Following a brief historical introduction, the first chapter deals with the elementary principles of velocity-modulation tubes and describes the principal types. Next is a chapter giving the essential minimum of information on cavity resonators, including some discussion of relaxation methods for approximating the resonant frequencies. The major part of the work is Chapter 3 in which the theory of velocity modulation is developed. Following a chapter on focusing of high current electron beams, which is most important for an understanding of the limitations of velocity-modulation tubes, the various types of v.-m. tubes of practical importance are treated in four chapters.

Chapter 5 covers amplifiers and frequency multipliers including some discussion of multiresonator (cascade) amplifiers. The klystron oscillators are considered next, including a brief treatment of the Heil and Samuel tubes. Reflex klystrons are covered in Chapter 7, and miscellaneous types in Chapter 8. Here we find discussion of the v.-m. mixer, the monotron, v.-m. reactance tubes, and the multireflection tube.

The next chapter deals (all too briefly, I fear) with the limitations and defects of v.-m. tubes, considering maximum frequencies at which klystrons will operate, hysteresis, and problems of modulation. Chapter 10 is devoted to design requirements and manufacturing techniques applicable to v.-m. tubes, and the book is completed with two appendices and a collection of tables useful in calculating v.-m. tube performance. The first appendix gives an example of the application of the results obtained to the design of a moderately high powered C. W. klystron, and the second treats the traveling wave tube.

The author is to be congratulated on a well-rounded and clear presentation of the basic principles of v.-m. tube operation. Most all topics of interest have been covered at least briefly, and this reviewer's principal comment is that in spots the treatment could have been improved by a little expansion. I should like to have seen somewhat more comparison of the theoretical results with experiment and discussion of those cases where agreement is poor, but this may be only a personal preference. As it stands the book is written mainly for tube designers, while incorporation of a little more material of value to the circuit designer would broaden its audience considerably. Specifically the treatment of hysteresis effects, and of noise output could have been expanded, and some mention of phase aberrations due to mechanical defects in the reflector (such as tilt) might have been worth while. Since the book is largely concerned with theory, the material on construction techniques in Chapter 10 seems a bit incongruous, but it should prove valuable to anyone contemplating the construction of experimental tubes. The author's optimism concerning the future importance of v.-m. tubes as microwave mixers may well be unwarranted in view of further studies of space charge suppression of shot noise.

The typography is excellent and the proofreading was done with great care; therefore, it is a piece of really bad luck that Eq. 43 of Chapter 2, said to give correct results for the Q of a cavity in all cases, lacks a factor 2π. But these are minor points and the book can be recommended to engineers and physicists interested in microwaves or to students at the graduate level who wish a general account of the velocity-modulation field.

Brookhaven National Laboratory

Radioactive Tracers in Biology

By Martin D. Kamen. Pp. 281, Figs. 38. Academic Press, Inc., New York, 1947. Price $5.80.

This book is an answer to the demand for collected information on the biological applications of radioactive tracers. Although many detailed chemical procedures and experimental techniques are given, this is far from a scientific cook book or a laboratory manual. Three chapters, constituting almost 19 percent of the book are devoted to the fundamentals of nuclear structure, nuclear reactions, and the properties of nuclear radiations. A fourth chapter discusses the principles of instrumentation and the corrections and statistics involved in making assays with radioactive isotopes. In this chapter the emphasis is placed primarily on G-M counters with relatively little space devoted to electrometers. These useful instruments should not be sold short. The Lindemann electrometer, which has proved quite useful in the assay of C^{14} is not even mentioned. The average non-physicist is apt to be more familiar with G-M counters than with electrometers and, consequently, may need more information about them.

About one-half of the book is devoted to the discussion of the uses of specific radioactive elements of biological importance. Typical syntheses and methods of assay are given and illustrative examples and typical protocols help to steer the biologists through the necessary mathematics. The value of the illustrative calculations would have been enhanced if they had been set apart from the text.

For many readers the most-used part of the book will be the chapters devoted to the general aspects of tracer methodology and their applications to specific problems and isotopes. One hesitates to disagree with the choice of material by an author with a well-established reputation in the field. However, several rather important radioactive elements are not mentioned in the text. For example, there is no discussion of the tracing of lead, bismuth, and other elements of some interest. It is also regretted that a complete isotope table was not included. Isotope tables are available in several places but it is a convenience to have the data in the same volume with the text.

The discussion of radiation hazards is very sketchy, taking up less than two pages and giving only scanty references to the literature. The readers of this book are precisely the ones who must understand the hazards of radiation and methods of protection against them. It is unfortunate that an opportunity for a thorough indoctrination was missed.

Given identical material, no two authors would write identical books and the criticisms given should be considered as differences in viewpoint and interest. This book contains a wealth of information badly needed by many workers who are invading a new field of research, and will serve as a valuable reference book to those who are more familiar with the use of radioactive isotopes.

National Institute of Health

The Measurement of Stress and Strain in Solids

By London Institute of Physics, Pp. 114+xvi, Figs. 33, Plates 8. London Institute of Physics, London, 1948. Price $4.00.

There are twelve papers in this very readable and worth while survey of the subject of stress and strain measurements. The papers can be divided by subject matter into about three groups: First, there are a set of three papers on the wire-resistance strain gauge; second, there are a set of three papers on photoelasticity; and finally, there are two papers on the measurement of strain by x-rays. There are several papers which do not fall into this classification, notably one which deals mainly with mechanical and optical devices for measuring strains.

The papers on wire strain gauges are interesting and informative. In the first of these, E. Jones discusses "Some Physical Characteristics of the Wire-Resistance Strain Gauge." Jones states that without special precautions strains can be measured with an accuracy of ±2 percent. He then goes on to describe the various types of wire-resistance gauge. He discusses the proper selection of the three elements, i.e., the wire, the plastic in which the wire is imbedded, and the adhesive. The article gives details on the effects produced by high humidity, temperature changes, high gauge current, imperfect sticking, and high frequency. Zero drift, fatigue, and the range of the instrument are discussed. The rather complete numerical bits of data given are very useful. Only a few references are quoted. In another article, F. Aughtie treats "The Use of Resistance Strain Gauges in Combination—With Particular Reference to Component Loads." In this article the problem of how n gauges, each having an indication which depends on n factors, shall be connected so that the resulting indication depends only on one of the n factors. A theoretical analysis of the problem is given. Applications to temperature compensation, to the measurement of tensile strain in a bar also undergoing bending, and to more complicated situations are given. E. P. George discusses "High Frequency Strain Gauges." In this article the author points out that the change in the resistance of a strain gauge made, using ferromagnetic wire, is as much as forty times as great at a frequency of 20 megacycles as it is if direct current is used. The change in resistance is not proportional to the strain over any appreciable strain range.

W. A. P. Fisher gives "A Review of Some Recent Developments in Photoelasticity." This article is a review of the progress which has been made in this field in the past eight years. The newer more sensitive resins are described, as are the use of polaroid and the changes which these improvements cause in the optical arrangement. Since as many as 12 fringes may pass a given point on the specimen during loading, monochromatic light must now be used. The accurate observation of boundary stresses is discussed. Three methods of investigating stresses in three-dimensional models are described. The "freezing" method which is most widely used depends upon the fact that glyptal and certain resins, if loaded at high temperature and cooled under load, will lose only a very small proportion of their strain and birefringence upon removal of the load. A plane slice is then cut out of the model and the "frozen" birefringence is examined. Pictures are given. In plane photoelasticity the separation of the principal stresses is discussed. Applications to special problems are mentioned. The references given seem quite complete. H. Mc. G. Ross describes methods used in "The Photography of Photoelastic Stress Patterns."

C. E. Phillips gives "A Review of Some Strain Measuring Devices." This article deals chiefly with optical and mechanical devices. The problem's accuracy and sensitivity are discussed in general, and then a number of instruments in current use are briefly described. In some cases the sensitivities are given. A rather complete set of references are given.

D. E. Thomas describes "The Measurement of Strain in Metals by X-Rays." The author describes how, by making measurements on the Debye rings, a quantitative value for the strains in the surface of a metal specimen can be obtained. In industrial steels, the accuracy obtainable for the lattice constant is one part in 20,000. In some cases five times this accuracy can be obtained. Practical details and examples from the author's experience are given. References to other work are incomplete.

In general the summary given of the progress made during the war years in the application of physical methods to the measurement of stress and strain is a most valuable contribution to our literature.

Carnegie Institute of Technology

Technique of Organic Chemistry Vol. II

By V. I. Komarewsky and C. H. Riesz, W. A. Noyes, Jr. and V. Boekelheide, and S. Swann, Jr. Pp. 229, Figs. 66, Tables 10. Interscience Publishers, Inc., New York, 1948. Price $5.00.

Catalytic Reactions (V. I. Komarewsky and C. H. Riesz)—The chief contribution of this portion of the book is the material found in Part III on "Laboratory Techniques in Catalysis." This part includes discussions of batch and continuous flow systems at atmospheric pressure, low and high temperature flow systems, batch and flow systems at reduced pressures, and batch and flow systems at elevated pressures. Emphasis is placed on basic procedures and equipment used in carrying out catalytic reactions under the conditions noted above. The survey of equipment in general use is well presented and is accompanied by a large number of excellent illustrations. General availability of the various types of equipment is considered, and leading references to the literature on catalysis are included. Expansion of the material on basic procedures used in catalytic reactions, as well as the inclusion of a larger number of specific examples of catalytic reactions, would increase the value of Part III for the average reader.

The section on "General Principles" (Part I)is too brief to be of any practical value. Its brevity may actually lead to erroneous conclusions on the part of the chemist who is not already well versed in the principles of catalysis.

"Catalysts and Their Preparation" is also presented in too brief a manner in Part II. The methods for preparing, activating, and storing of catalysts are so essential to the practice of catalysis that this section can scarcely be considered to be adequate. The brief and general nature of this section is further weakened by the lack of a sufficient number of examples.

Photochemical Reactions (W. A. Noyes, Jr., and V. Boekelheide)—The authors of this article have done an excellent job in condensing a large mass of material and have succeeded in giving an accurate and relatively broad picture of the techniques employed and results obtained in this field. The reader quickly becomes aware of the continuity of the presentation and of the orderly and logical manner in which he is led through the general principles to the practical applications. The usefulness as well as the limitations of photochemical reactions are considered.

The study of photochemical reactions is divided into two main parts: (1) the primary process or the immediate effect of light on the absorbing molecules; and (2) secondary reactions or reactions produced by the primary process. This section (Part II), which also includes a discussion of light absorption of monatomic gases, diatomic and polyatomic molecules, is clearly presented. The treatment of light sources, selection according to the nature of the reactants and the intensities needed (Part III), is quite adequate.

The discussion of the "Concept of Quantum Yield," although brief, is sufficient for the obvious purposes of *Photochemical Reactions*. This section also considers radiation standards and methods for the measurement of light intensity. Part V "Factors Influencing Design of Photochemical Apparatus," includes effect of absorption coefficient and of type of absorption, flow and static systems, temperature regulation and effects of intensity, vessel dimensions and effects of impurities. These two sections contain very useful information and the presentation is of the same high quality as noted for the previous sections.

In Part VI a variety of photochemical reactions are discussed. A sufficient number of types are included to give a good, general idea of photochemical applications to organic chemistry.

Electrolytic Reactions (S. Swann, Jr.)—The section on "General Theory" (Part II) includes definitions, mechanism of electrolysis, and calculation of the theoretical amount of current necessary for a given reaction. The discussion of the mechanism of electrolysis covers conductance, reactions at electrodes, polarization and overvoltage, depolarization and catalysis. Part II is quite brief, considering the number of topics covered. Most courses in undergraduate physical chemistry discuss this subject matter in greater detail. Presumably the reader will have had such a course and so the brief resume of general theory may be sufficient. Other than that, the material is well chosen and presented.

The discussion of "Apparatus and General Procedure" includes general equipment, electrodes, electrolytes, diaphragms, and general procedures which are used in carrying out electrolytic reactions. This section (Part III), although brief, is compact and contains much useful information.

Parts V and VI consider "Reactions at the Cathode" and "Reactions at the Anode," respectively. A large number of reduction reactions are included in Part V. A critical examination of the controlling factors in electrolytic reduction reactions, such as composition of the catholyte, cathode material, current density, temperature, etc., is presented in this section. Part VI deals with reactions at the anode in a similar manner. In general, the subject material in Parts V and VI has been carefully selected and the general procedures have not been neglected. *Electrolytic Reactions* serves a useful purpose in pointing out the applications of electrolytic techniques to organic reactions.

It is difficult to predict just how useful this book will prove to be. It will undoubtedly serve to stimulate interest in the three fields which are surveyed. Because of the brevity of the book, however, it can scarcely compete with more comprehensive works. In general, the book is well written and is relatively free of the minor errors which are sometimes found in first editions.

ALLAN R. DAY
University of Pennsylvania

Cathode Ray Tube Displays

EDITED BY THEODORE SOLLER, MERLE A. STARR, AND GEORGE E. VALLEY, JR. Pp. 746+xvii. McGraw-Hill Book Company, Inc., New York, 1948. Price $10.00.

This is Vol. 22 of the now well-known M.I.T. Radiation Laboratory Series devoted to radar and allied techniques. Three editors and twenty-one authors have cooperated to summarize within the confines of a single volume the information accumulated by the Radiation Laboratory, during the war, on cathode ray tubes and the associated circuitry required for the production of visual displays for radar applications. An idea of the extent of utility of cathode ray tubes for display and measurement purposes may be had from the fact that nearly three million tubes were manufactured during the war.

This book is extremely informative not only to persons in the field of radar, but also to those interested in oscilloscopes and their less familiar applications. Since some of the radar display techniques described are similar to those used in television, the television engineer will find in the book considerably helpful information, although there are only a few pages that deal directly with television.

The title *CRT Displays* is somewhat misleading since the reader might expect the discussion to be limited to the displays on the face of *CRT*s. Essentially, the book deals with cathode ray tubes and with the technique of radar display production.

The general lack of references in the book not only detracts from its value, but may leave the reader with the impression that little work was done in the field prior to the war. Certainly it must be admitted that television techniques developed prior to the war form the basis for the techniques used in producing radar displays.

The more basic work on cathode ray tubes was done prior to the war at a relatively leisurely rate in this country and abroad. The task during the war was to adopt and extend this basic work to radar application as quickly as possible. The rapid progress demanded by the war necessarily placed greater emphasis on results than on understanding.

The book consists of 18 chapters and 5 appendices. The introductory chapter gives a general survey of cathode-ray tubes, radar displays and signal discernibility, and resolution. This chapter should be of considerable value to the novice and a good refresher to those who have already forgotten.

Eight chapters (2, 3, 8, 9, 12, 16, 17, 18), for some reason scattered throughout the book, deal with the cathode ray tube and its accessories. The chapter entitled "Cathode Ray Tubes" gives some theory of electron guns and condenses a great deal of functional information on cathode ray tubes used during the war. Many users of electrostatically deflected cathode ray tubes will find very useful the section which deals with the adjustment of the mean potential of the deflection plates in order to obtain optimum spot size. It might have been well to point out more clearly why magnetically deflected tubes are the logical choice for intensity modulation and electrostatically deflected tubes for deflection modulation. A chapter devoted to spot size gives the most extensive discussion on spot size measurement at present available in published form. Four chapters are concerned with focus coils and magnets, deflection coils, pattern distortion in magnetic cathode ray tubes, and special deflection coils and magnets for off-centering. The chapter dealing with mechanical and optical devices describes such practically important accessories as shields, optical filters, optical superposition devices, video mapping, direct projection by means of reflective optical systems, and photographic projection. The longest chapter in the book (97 pages) is concerned with luminescent and dark-trace screens for cathode ray tubes. Unlike the rest of the book, luminescent screens are not treated from the functional point of view. The treatment of dark-trace screens is quite detailed and is the most complete available in published form.

The remaining chapters cover circuit techniques, displays, and technique of display production. One chapter describes in considerable detail a number of deflection-modulated displays including the J-scope generally recommended for the accurate measurements of time intervals, and a high speed oscilloscope. Four chapters deal with general circuit techniques including high voltage power supplies, the fundamental problems and means of transmitting position data, electronic markers and indices, and driving circuits for deflection yokes. Four more chapters describe in considerable detail particular methods for obtaining rectangular-coordinate displays, radial-time-base displays, sector displays, and range-height displays.

Last but not least, five appendices supply data on construction of focusing coils and magnets, construction and characteristics of deflection coils, impregnation of deflection and focus coil, characteristics of 40 types of cathode ray tubes including some of the presently used television tubes, and characteristics and circuit diagrams of eight video amplifiers.

Although, because of the magnitude of the task, the treatment of many topics is necessarily superficial and the arrangement of the material not the best, the editors and authors are to be congratulated for so ably presenting so much useful information within the covers of one volume.

Cathode Ray Tube Displays will undoubtedly serve as a fitting memorial to the hundreds of scientific workers and engineers whose work this book describes.

RCA Laboratories

Radio at Ultra-High Frequencies, Vol. II, 1940-1947

Edited by RCA Review. Pp. 485, Figs. 260, Summaries 22, Appendices 2. Radio Corporation of America, Princeton, New Jersey, 1948.

Reviewing *Radio at Ultra-High Frequencies, 1940–1947* may be likened to reviewing an issue of the Proceedings of the I.R.E. Subjects of the various papers here reprinted include antennas, transmission lines, propagation, reception and receivers, microwaves (a not-elsewhere-classified category), measurements, radio relay systems, and aids to navigation. The unifying ties are that the papers are all from RCA sources (geographically from Rocky Point, New York, Harrison, Princeton, and Camden laboratories), and the title, which serves to distinguish this collection from other RCA volumes on television, facsimile, etc.

The book tends to show (presumably its purpose) that RCA has had an active research interest in problems in many aspects of the field specified by the title. That the reprinted papers happen to cover an interval in which there was great development in the field occasionally yields a touch of antiquity to the reading—1940 is a long time ago in ultra-high frequency work—but on the whole the group is relatively up-to-date and many of the papers are excellent.

Brown and Woodward in the leading paper, on the measurements of impedance characteristics of cylindrical antennas, fail to confirm a conclusion of Brillouin, and point to the need of more experimental work in an area in which there has been theory. Iams describes a phase-front plotter of considerable interest. The development of some antennas for producing circularly polarized waves (for ground-to-airplane communication) is described, as well as some work on slot antennas. Noise studies and a discussion of receiver sensitivity and signal-to-noise ratio in u-h-f receivers follow.

A 110-page group of articles "Aspects of Reception at Ultra-High Frequency" is an excerpt from lecture notes for a u-h-f course of the 1941–42 variety. Judged by the material, however, the course must have been a good one and possibly superior to the standard course of the time.

Radio relay systems are now in operation and in certain fields—telegraphy, for example—are supplanting previous methods of transmission. An interesting incidental from one of the papers on such systems points out that RCA had one in operation in 1923 (at 182 kc/sec.).

The aids to navigation section gives only summaries of papers, including some on shoran and teleran. Topics of other papers in the book range from the high frequency spectrum of ignition noise to the absorption of microwaves by gases. A bibliography of about 300 RCA papers in or touching on the u-h-f field is given.

All the papers in the book including those given only in summary form and the excerpts from the u-h-f course have appeared in print previously.

Principles of Mathematical Physics

Second edition. By William V. Houston. Pp. 363+xii, Figs. 43. McGraw-Hill Book Company, Inc., New York, 1948. Price $5.00.

This is the second edition of an excellent and deservedly popular text intended as an intermediate course for juniors, seniors, and first-year graduate students in those branches of physics requiring mathematical analysis. There is little new material in the second edition, but rather the emphasis has been on increasing the clarity of the explanation by rewriting the difficult passages with more drawings and illustrative examples.

The student is expected to have had a course in elementary physics, analytic geometry, and calculus. Without having to wait until the student has also had differential equations, vector analysis, and the calculus of variations these subjects are supplied in sufficient detail for the analysis of physical phenomena. The treatment does not take the place of a thorough sequence in mathematics, but enables the student to get on with the physics without having to wait until graduate school before being able to tackle some of the more theoretical aspects.

The physics treated is mechanics, thermodynamics and statistical mechanics, and electricity and magnetism: the usual intermediate sequence with the exception of optics. The book hits the high spots of the courses in these subjects not shrinking in doing so from a point of view sufficiently sophisticated to enable the student to cope with the more advanced courses. There is no quantum mechanics, but the classical analysis and methods included will aid the student in quantum mechanics. No use is made of the Laplace transform or of the analogy between mechanical vibrations and electrical circuits, methods which seem to be gaining favor in some quarters today.

The treatment admittedly leaves some scope for the ability of the instructor which tends to give it a categorical flavor. The problems are an integral part of the development of the theory. Equations are derived in some problems and applications illustrated in others. This has the advantage that the student gets a grasp of the subject as he must work it out for himself. Even if he cannot work all the problems he will at least be able to understand the development when it is explained to him. In a few places, on the other hand, as for example in the discussion of moving axes, the principle of leaving it to the instructor to explain could be relaxed just a little with considerable gain in clarity for the student. The physical significance of what is happening is kept continually in mind, and physical arguments are employed as in the case where the smallness of forced oscillation of the frequency is high enough. The author has a happy facility for anticipating just what is going to bother the student and answering his question in the next phrase. He states clearly what he is going to do, what he is not going to do, and what the assumptions are. If something is left out it is stated or put in a problem and the student is not left to wonder whether he should be able to prove it or not.

The m.k.s. units are used throughout, but the Gaussian system is also explained and conversion tables given. This is in line with the growing popularity of these units. It might help to overcome the objections of some of the most violent opponents of m.k.s. units if peculiar properties were not assigned to empty space. A constant of proportionality in a physical equation which depends only on the units used should be treated merely as such and not as a characteristic of space. This outburst is prompted by the author's care in pointing out that the "apparent role of κ_0 as the 'permittivity of a vacuum' is not taken as suggesting the possibility of polarization in a vacuum." Let us lay the ghost of κ_0 as a property of space in the first place.

Electricity and magnetism are treated following Maxwell with just a paragraph on Lorentz in conclusion. These chapters have clearly been written from the experience gained by watching students flounder around in the electromagnetic field. The author has a knack of foreseeing the block on which the student is about to stumble and of pushing it out of his path. This well written intermediate text ends with some properties of the Lorentz transformation and the equivalence of mass and energy.

University of Pennsylvania

Electrical Measurements in Theory and Application

Fourth Edition. By Arthur Whitmore Smith. Pp. 371, +xix, Figs. 250. McGraw-Hill Book Company, Inc., New York, 1948. Price $4.25.

This is the fourth edition of Professor Smith's book on electrical measurements. The previous editions appeared in 1914, 1924, and 1934 (Rev. Sci. Inst. 5, 381 (1934)). This book may be used as both a text and a laboratory guide. The explanations of experiments are not set apart from the other material, but are indicated in the Table of Contents by a star.

The author writes, as he states in the Preface, for "students who have had one year of college physics and desire further knowledge of electrical and magnetic matters." However, little previous knowledge is presumed, and the elementary ideas of electron flow and the fundamental definitions of mechanical and electrical units are given in the Introduction. The first chapter contains simple experiments for the instruction of "students with little laboratory experience." "Those with college laboratory training can pass on to the advanced subjects and more complicated methods." "The simple and more fundamental ideas are treated in the first chapters, and in the first part of each chapter, more difficult measurements and methods requiring more extended knowledge are reserved until the student has attained greater proficiency."

This is a book on electrical measurements and its scope is well outlined in the Table of Contents. The first eight chapters deal with the study and use of the ammeter, voltmeter, ballistic and current galvanometers, Wheatstone bridge, potentiometer, and the fundamental measurements of current and power. Electron tubes are introduced in Chapter Nine and a few important electronic instruments are pictured later. The magnetic circuit, measurements of magnetic flux and magnetomotive force, and magnetic tests of iron and steel are given in three chapters. Simple a.c. circuits are clearly treated in terms of vector diagrams and the fundamental differential equations. Measurements of capacitance and inductance particularly by bridge methods are treated quite extensively. The text concludes with a brief chapter on the calibration of alternating current instruments.

The book is illustrated with clear diagrams and useful pictures of modern apparatus. The meter-kilogram-second system has been employed throughout. A few examples and problems, some with answers, are given, mainly for d.c. and a.c. circuits. Calculus is used, but with each step clearly indicated so that it may be easily followed by a student not too familiar with such mathematics.

This text is restricted to the field of electrical measurements, and, as the title indicates, the principle ideas presented are the theory and application of methods for measuring fundamental quantities such as current and power, charge, resistance, voltage, inductance, capacitance, magnetic flux and intensity, magnetomotive force; and some of their complexities such as temperature variations, electron emission, and hysteresis. The whole field of electricity and magnetism is not covered to the extent that might be needed by an undergraduate student of today in the physical or biological sciences. Perhaps no one text can cover such a broad field.

There are a few short additions that might have been made, however, such as: the mention in the opening paragraph of neutrons in the atom, a brief explanation of diamagnetism, and a diagram of a cathode-ray tube.

In the field for which it is intended, this book, with the material clearly and simply presented, should be a welcome help to the students for whom it was written.

Margaret N. Lewis
Boston University

Vacuum Tube Amplifiers

Edited by George E. Valley, Jr. and Henry Wallman. Pp. 743+xvii, Figs. 391, 22½×15 cm. McGraw-Hill Book Company, Inc., New York, 1948. Price $10.00.

Vacuum Tube Amplifiers is Vol. 18 in the Massachusetts Institute of Technology Radiation Laboratory Series and, like other volumes in the series, represents the combined efforts of a group of specialists to set down the knowledge, experimental and theoretical, which they found useful during the active days of the Radiation Laboratory. Although most of the material in the volume is of importance in radar, much of it will have a continued interest to physicists and engineers who have occasion to design electronic circuits. This is because the various authors have endeavored to emphasize principles of design and have assigned a secondary role to the discussion of specific radar circuits.

It is evident that an effort was made by the editors and by the contributing authors to achieve a unified volume. Nevertheless each chapter, or group of related chapters, bears the stamp of the individual authors, and for the most part forms a self-contained account of a particular aspect of amplifier design that can be read independently of the remainder of the book. This is perhaps an advantage in a volume that will find its greatest usefulness as a reference work. In view of the joint authorship and the variety of topics considered, it appears advisable to mention each chapter in turn.

Chapter 1, "Linear-Circuit Analysis and Transient Response," by Richard Q. Twiss (70 pages) is a concise, formal account of network analysis based on the Laplace transform. The chapter should appeal to the reader who has some prior knowledge of its contents and wishes to improve his understanding of the modern method of computing the transient response of linear networks.

Chapter 2, "High-Fidelity Pulse Amplifiers," by Robert M. Walker and Henry Wallman (42 pages) contains a valuable discussion of the theoretical aspects of the high-fidelity amplification of pulses, together with a number of practical circuits for use with pulses. The number of complete amplifiers is unfortunately limited.

Chapter 3, "Pulse Amplifiers of Large Dynamic Range," by Harry J. Lipkin (53 pages) is concerned with a problem that is peculiar to radar in which a high gain, low pass amplifier is called on to amplify signals from a few microvolts to several volts without blocking for an appreciable time. One gathers that the chapter summarizes a development that required considerable time, effort, and ingenuity on the part of the group working on this problem. It appears unlikely that the design procedures described here will have a very general application in other branches of electronics.

Chapter 4, "Synchronous and Staggered Single-Tuned High-Frequency Bandpass Amplifiers," by Henry Wallman (35 pages) contains a clear mathematical analysis of these types of wide-band amplifiers, illustrated by several practical examples. Emphasis is placed on design considerations. This is the first of four chapters devoted to wide-band bandpass amplifiers.

Chapter 5, "Double-Tuned Circuits," by Richard Q. Twiss (31 pages) constitutes an extension of the usual theory of the double-tuned interstage coupling to the wide-band case. The treatment is mathematical and is illustrated by three examples.

Chapter 6, "High-Frequency Feedback Amplifiers," by Harry J. Lipkin (42 pages) considers the improvement in the gain-band width product and other properties of bandpass amplifiers incorporating inverse feedback.

Chapter 7, "Bandpass Amplifiers: Pulse Response and General Considerations," by Henry Wallman (37 pages) discusses the transient response of bandpass amplifiers to a carrier-frequency pulse, as well as problems arising in the large scale production of bandpass amplifiers. This, and the preceding three chapters constitute an exhaustive account of the design of bandpass amplifiers for radar applications.

Chapter 8, "Amplifier Measurement and Testing," by Yardley Beers and Eric Durand (32 pages) considers methods of measuring the frequency response and the transient response of low pass and bandpass amplifiers used in radar.

Chapter 9, "Low-Frequency Amplifiers with Stabilized Gain," by Duncan MacRae, Jr. (51 pages) deals with the design of very stable amplifiers used in electronic computers. The material in this chapter is capable of rather wide application in the design of electronic circuits. It should appeal to a greater class of readers than the material in the preceding chapters devoted to bandpass amplifiers.

Chapter 10, "Low-Frequency Feedback Amplifiers," by Harold Fleischer (25 pages) is concerned with the theory and design of low-frequency selective amplifiers based on the use of a twin-T or bridged-T network in the feedback loop of the amplifier. The material here should be of considerable general interest.

Chapter 11, "Direct-Coupled Amplifiers," by John W. Gray (87 pages) contains a wealth of practical data pertaining to the design of circuits for amplifying d.c. signals. This chapter should be extremely useful to the circuit designer.

Chapter 12, "Amplifier Sensitivity," by E. J. Schremp (108 pages) is essentially a monograph analyzing the origin and the properties of thermal and shot noise. The treatment is rigorous and requires considerable background in mathematics and physics on the part of the reader. The chapter constitutes a definite contribution to the theory of fluctuation noise.

Chapter 13, "Minimal Noise Circuits," by Richard Q. Twiss and Yardley Beers (80 pages) is concerned with the design of practical circuits for achieving the highest possible signal-to-noise ratio in the case of bandpass amplifiers used in detecting radar signals. The chapter contains considerable information that can be applied in the design of other types of amplifiers, e.g., the pulse amplifiers of nuclear physics.

Chapter 14, "Measurement of Noise Figure," by Yardley Beers (26 pages) describes methods of measuring the performance of amplifiers in detecting weak signals. The methods described are intended to be used with the types of amplifiers described in early chapters and in Chapter 13.

Swarthmore College

Electromechanical Transducers and Wave Filters

By Warren P. Mason. Pp. 419+xii, Figs. 147. 16×23½ cm. D. Van Nostrand Company, Inc., New York, 1948. Price $6.00.

This is a second edition of a scholarly and thorough book on the theory of electrical networks and vibration of coupled acoustical, mechanical, and electrical systems employing electrical, mechanical, and acoustical analogies. The author is an outstanding authority in the field of network and vibration theory and the book follows, for the most part, the field in which he has made outstanding contributions. The new material in the second edition is an outgrowth of the work on filters and transducers made during the war. Eighty-six pages and twenty-seven figures have been added. All the new material is placed at the end of the book. For those who are not familiar with the first edition, a brief review will be given of this portion of the book. This will be followed by a review of the new material.

The treatment throughout the book is almost self-sufficient. However, a considerable knowledge of network theory is required to obtain a working knowledge of the material in the text. The illustrations are adequate and well done.

The electrical network theory in this book shows how the characteristics of the ladder and T sections can be derived from the lattice. A table of filters useful in the design of acoustical and mechanical systems is included. The application of network theory or analogies to the solution of mechanical and acoustical systems, together with both the direct and indirect analogies, is treated in considerable detail. Another subject is the propagation of sound in systems with distributed constants such as pipes and horns. The theory of the vibration of plates and membranes and the use in telephone receivers and as elements in an acoustical filter is also treated in this section of the book.

In the field of electromechanical converting systems, the following transducers are considered: electrostatic, piezoelectric, magnetic, dynamic, and magnetostrictive types. A horn loudspeaker and a crystal-driven ultrasonic radiator are used to illustrate the application of the theory.

Another valuable chapter deals with electromechanical impedance elements in electrical filters. The consideration of mechanical elements for filters includes a very complete treatment of piezoelectric as well as magnetostriction systems. In this field, Mason has been the principle contributor in the literature.

The addition to the book in the new edition includes wave guides and wave guide filters. One very interesting subject and a new concept is the application of a gyroscope as an impedance element. The propagation of sound in air- and liquid-filled ducts as well as the subject of ducts lined with absorbing materials is covered. In the field of underwater sound, consideration is given to the construction and design of directional underwater transducers and the description of a water tank with absorbing walls. Another new subject is torsional vibrating crystals. Altogether, the revision contains an excellent addition to the first edition, which was a valuable and outstanding contribution.

HARRY F. OLSON
RCA *Laboratories*

Practical Spectroscopy

BY HARRISON, LORD, AND LOOFBOUROW. Pp. 605, illustrated. Prentice-Hall, Inc., New York. Price $6.65.

The appearance of *Practical Spectroscopy* by Harrison, Lord, and Loofbourow is very opportune in view of the recent history of that branch of physics. The science of spectroscopy had a long slow growth in which the development of instruments and techniques far outdistanced their use. The consequence was that the sudden outburst of activity on the part of the physicists which took place after the first World War was able to solve in principle in a few years' time most of the fundamental problems of the external structure of atoms and molecules. A great mass of detailed analysis remains to be done by the few remaining physicists interested in such problems. On the other hand, to the astrophysicist, spectroscopy has become his most powerful tool and he already feels the failure to complete the job. The chemists and biologists also are now large "users" of the spectroscope and of spectroscopic data in purely scientific fields; but probably the largest group of "users" is the great number of industrial scientists who find in spectroscopy one of their most powerful analytical tools. These facts, coupled with the scarcity of competent trained spectroscopists in university laboratories, make it increasingly necessary that books such as that under review should be written.

Practical Spectroscopy is addressed to the "users" of spectroscopy whose chief concern is with the results that it will furnish to them. Consequently, it is not a compendium of present day knowledge of the art as was "Kayser" in 1901 or "Baly," the English counterpart of Kayser. It is, rather, a well considered selective condensation of our present knowledge of techniques in all the branches of the subject. Very wisely, the authors have not hesitated to give their judgments on the choice of instruments instead of facing the inexperienced user with unweighted alternatives.

As with all books, there are bound to be details with which any particular reviewer will disagree. Some points of this sort are the following. In Chapter 4, where various mountings of the concave grating are discussed, there is no general formula for the dispersion given. In fact, on page 85 a serious error of statement occurs because such a formula was not used. The statement is that the dispersion of the fourth order of the red end of the spectrum by a 15,000-line per inch grating in a 3-meter Eagle mounting is 1.3A per mm, whereas it should be about 0.4A per mm. I missed also any reference to the very useful fact that Rowland ghosts are displaced from the parent line by a definite fraction of its wave-length, usually 1/1000 or 1/750. The discussion of the concave grating in the Wadsworth mounting is, I think, insufficient, considering the usefulness of that mounting for analytical work. It should be mentioned that the focal curve, over its usable length, can scarcely be distinguished from a circle of radius $r = R/2 + 3\cos i$), which is the actual radius of curvature at the normal. For some uses, it may also be important to know that due to the off-axis position of the mirror and grating, there is a slight astigmatism.

I particularly appreciated the discussion in Chapter 6 on the illumination of the slit. It is a subject usually treated in a very cursory manner in spite of its essential importance. It is natural that Chapters 12 and 13 on the measurement of intensities should be excellent since this is a field in which Professor Harrison is an expert. The recent work on the use of photoelectric cells for the measurement of intensities may have a considerable effect, but it seems fairly certain that photographic techniques will hold their own for some time. The chapter on quantitative analysis, although it draws largely on previous chapters, seems to me too short. On the other hand, the chapters on the vacuum ultraviolet and on interferometry are correctly kept within small compass, since they are unlikely to be of interest to most present users of spectroscopy. It should, however, be noted that in Chapter 20 the authors have transformed Professor R. W. Wood into a superman who can observe the green line of mercury in the seventh order of a 15,000-line grating!

At the present low ebb of spectroscopic training in the universities, those who need spectroscopic techniques for the solution of their problems will have to rely more and more on such books as this. Especially in the industrial laboratories will it be indispensable.

A. G. SHENSTONE
Princeton University

Principles of Servomechanisms

BY GORDON S. BROWN AND DONALD P. CAMPBELL. Pages 400, Illustrations 207, Tables 21. John Wiley and Sons, Inc., New York, 1948. Price $5.00.

The development of the theory of servomechanisms has been rapid over the past ten years, in fact, so rapid that not until the publication of *Principles of Servomechanisms* has there appeared a correlated work suitable for use as a textbook in engineering schools.

The book is confined to linear closed-loop servomechanisms, and attention is centered on their frequency response, the use of which has proved itself a powerful tool not only in the analysis but in the synthesis of servomechanisms.

After an introduction to the elements of automatic control and the problems of synthesis, the differential equations of several simple systems are examined to provide the student with a "feel" of the subject. The transient response of an elementary positional servomechanism is worked out in detail along classical lines and criteria of good performance based on experience are stated.

The theory of the Laplace transform is summarized in Chapter 3 to furnish a systematic means of solving differential equations and to lay the groundwork for the definition of the transfer function which is an important concept in synthesis when systems become at all complex.

Chapter 4 introduces the student to the frequency response of servomechanisms and its correlation with transient response. Chapter 5 is a well prepared discussion of equivalent circuits, transfer functions, and block diagrams. By means of several examples, it is shown how the transfer functions of devices like motors, electron tube amplifiers, and hydraulic transmissions can be formulated.

The bulk of frequency response theory is covered in Chapters 6 through 8. Several techniques of plotting frequency response data are given: Nyquist diagrams, inverse plane diagrams, log magnitude and angle *versus* frequency diagrams, and log magnitude *versus* angle diagrams. Each of these techniques is important for the light it sheds on the performance of servomechanisms and for the familiarity it gives the student with presentations current in the literature.

Chapters 9 and 10 are concerned, respectively, with systems subject to output as well as input disturbances and with experimental procedures. The experimental procedure chosen is limited to servomechanisms with synchro data systems, and it seems that the value of the chapter could be measurably increased by presenting the matter of testing in a more general way. For instance, in closed-loop servomechanisms with electrical data systems, the servomechanism can be left intact and a signal inserted in series with the controller input across a low impedance. This makes it possible to test servomechanisms such as those using bridges or potentiometers where the input cannot be rotated continuously at reduced amplitude to obtain the desired signal. The signal required for testing a so-called d.c. servomechanism is sinusoidal and that for a carrier frequency servo is a double-sideband suppressed carrier signal produced by sinusoidal modulation. Several ways of generating such signals suggest themselves.

Especially valuable is the last chapter on approximating the transient response from the frequency response. The reviewer feels that the method of trapezoidal approximation given is the simplest yet devised. Computations are facilitated by a four place table of sin x/x which appears in the chapter. However, the use of the contour integral to obtain the inverse Laplace transform in the proof of the method is somewhat confusing after having been introduced to partial fractions in Chapter 3. It might have been better, though somewhat harder on the student, if the inverse transform had been performed by evaluating the contour integral to begin with.

In general, the book is well organized and understandably written. Illustrations are freely used to amplify the text and the tabulations of equations and pertinent data are extremely helpful. The back of the book contains a complete bibliography to which references are made throughout the text and an adequate set of problems arranged by chapters. The book should be very helpful to engineers interested in servomechanisms and should find widespread acceptance among instructors as a textbook.

W. J. Brackmann
Norden Laboratories Corporation

Distillation and Rectification

By Emil Kirschbaum. Translated by M. Wulfinghoff. Pp. 426, Figs. 236. Chemical Publishing Company. Inc., Brooklyn, 1948. Price $10.00.

This is not the complete up-to-date book on distillation for which so many of us have been waiting. However, it does present a fairly good coverage of material in this field except for developments which have occurred during the past twelve or thirteen years. It is the translation of a book first published in German in 1940 and covers in a comprehensive manner only information up to about five years before that time.

The treatment of the fundamental principles involved in distillation is thorough and good discussions of the various types of partial pressure-composition, temperature-composition, and equilibrium diagrams are included. These descriptions show the applications to miscible, immiscible, binary, multicomponent, and azeotropic systems. The effect of pressure is discussed at some length. Information regarding the design, construction and the various methods of operating distillation equipment is presented. A long section is devoted to the details of construction and behavior of bubble caps in operation. There are many useful illustrations interspersed with the text, the total number of figures being 236 within the 426 pages.

Methods for determining the size of column required for a given separation for both batch and continuous distillation are illustrated with a few numerical examples. Where possible, graphical methods have been employed in preference to those which require involved calculations. Ample consideration is given to the use of the enthalpy-concentration diagram as applied to binary mixtures. Other subjects considered include the use of sieve plates and packed columns, details of heat exchangers and control equipment, and the fundamentals of molecular distillation.

Interesting features not included in previous books on the subject are: the presentation of empirical graphs for estimating the permissible vapor velocity in plate columns; photographs showing fluid motion and distribution on bubble cap trays; tables of vapor-liquid equilibrium data and 8″×8″ graphs on loose sheets depicting these for 63 systems. The translator has included a rather inadequate review of progress made since the original publication. This takes the form of a series of short abstracts of some articles which have appeared in technical journals in this country from 1940 to 1946.

The book is written more in the fashion of a dissertation or thesis rather than an American technical book as it contains no chapters but merely headings and sub-headings throughout. It will be difficult for those in this country to read chiefly because of the use of symbols entirely different from those to which we are accustomed. In addition, the diagrams, graphs and illustrations are lettered in German but do have captions in English and translations beneath the figures. The index and bibliography are decidedly incomplete.

This translation will prove interesting to those well versed in the art of distillation due to its different approach to many of the topics but it will not fill the need for those who wish to learn of recent developments. Libraries will find it useful as a reference for the subjects, such as bubble cap operation, which have been treated thoroughly.

Laboratory and Shop Notes

Electron Trajectories in a Gamma-Ray Spectrometer

H. Hurwitz, Jr.
Knolls Atomic Power Laboratory, General Electric Company, Schenectady, New York*

February 9, 1949

IN designing a gamma-ray spectrometer of the type recently described by Lawson,[1] it is necessary to compute the trajectories of electrons emitted radially inward from a target near the edge of a cylindrically symmetrical magnetic field. The deflection, φ, of the electrons when they have returned to the radius, r_0, of the target is given by the formula

$$\varphi=2\epsilon\int_{r_m}^{r_0}\frac{Hdr}{(1-\epsilon^2u^2)^{\frac{1}{2}}}=\pi-2\epsilon\int_{r_m}^{r_0}\frac{udr/r}{(1-\epsilon^2u^2)^{\frac{1}{2}}}, \tag{1}$$

where

$$ru(r)=\int_r^{r_0}rHdr,\quad \epsilon=e/cp.$$

Here p is the momentum of the electron, and r_m is the radius at which ϵu is unity. For large p or a uniform field φ is given by

$$\varphi=2\arctan\left[\epsilon\int_0^{r_0}Hdr\right]. \tag{2}$$

This formula is surprisingly accurate even when p is comparatively small and the field is not uniform. For electrons of small energy, the numerical computation of φ can be done most conveniently by use of the following alternate form of Eq. (1):

$$\pi-\varphi=\frac{2}{\epsilon}\int_0^1\frac{dy}{u+rH},\quad u=\frac{(1-y^2)^{\frac{1}{2}}}{\epsilon}. \tag{3}$$

To integrate Eq. (3), u is first computed numerically as a function of r. Then $u+rH$ can be obtained as a function of u, and hence of y.

After the deflection, φ, of an electron at r_0 has been computed by Eq. (2) or (3), the additional deflection $\Delta\varphi$ corresponding to the path from r_0 to a larger radius r_e is given by

$$\Delta\varphi=\epsilon\int_{r_0}^{r_e}\frac{udr/r}{(1-\epsilon^2u^2)^{\frac{1}{2}}}. \tag{4}$$

---

A Timer for Short Intervals*

R. Stuart Mackay
Department of Physics, University of California, Berkeley, California

January 25, 1949

IN a forthcoming study of the stoppage of centricular fibrillation by electrical impulses, it was desired to pass pulses of current of variable duration through a heart. Because the currents involved would be one or more amperes, it was necessary either to use rather large thyratrons in some form of inverse parallel connection, or to construct a device activating a fairly rugged relay. The latter was thought preferable from a standpoint of simplicity if a satisfactory unit could be designed. Interval times involving the gradual charging of a condenser through a resistor to some predetermined voltage are well known, but few have been specifically designed to act for times less than the period of the a.c. supply line frequency. In fact, most such timers have made use of the passage of the voltage into negative values to deionize a thyratron. The present circuit was built to cover the range of times from 0.01 second to 10 seconds, but with small changes in the circuit time constants it gave satisfactory results from about 0.002 second to several minutes. These short time intervals were accurately calibrated by counting with a scaling circuit the number of cycles passed by the relay from a 10-kilocycle oscillator. The oscillator used was the horizontal sweep circuit of a standard oscilloscope. A single RC differentiating circuit sharpened the pulses sufficiently to work a standard scaling circuit. The scaling circuit was also used to calibrate the oscillator frequency by counting the number of cycles produced in a five-minute interval.

The relatively large plate currents drawn by relays of substantial enough design can most efficiently be handled by a small thyratron. Because of the short time intervals involved one cannot depend on an alternating plate voltage to deionize the tube and thus release the relay. Also, a relay to be used on the plate current pulses of an a.c. fed thyratron must be made extra slow in acting so that it will not chatter. For these reasons the thyratron in the present circuit is fed with filtered direct current. The thyratron is normally on and the current it passes holds the relay open. The relay is allowed to fall closed by breaking the plate current for a time less than the timing interval, but greater than the deionization time of the tube. This momentary current interruption is produced by a single pole double throw snap-switch arranged to complete the circuit in both of its positions. However, during the transit time of the moving member neither pole is connected for a suitable instant, thus allowing the grid to regain control. The relay, after it has fallen closed, completes the external circuit through one set of contacts, and starts the charging of condenser C (Fig. 1) through resistance R by means of the other set. After a time roughly equal to RC, the condenser will charge to a voltage high enough to ionize the gas in the neon bulb, whereupon the condenser starts to discharge through the bulb and the 15,000-ohm resistor. The positive pulse so produced is applied to the thyratron grid to reionize it and pull in the relay, thus again opening the external circuit. At the same time the other set of contacts shorts the condenser through the 10,000-ohm resistor, thereby discharging the condenser ready for another cycle.

The relay used, because of ready availability, had a 300-ohm coil resistance. An extra 1000-ohm current-limiting resistor then had to be placed somewhere in the circuit, and it was used so as to act as part of a voltage divider to supply cut-off bias once the tube is extinguished. It is to be noticed that it is shown shunted by a one-microfarad condenser. Without this, though the timing interval was always correct, the tube wouldn't deionize with every flip of the switch. This condenser then maintains the falling cathode potential quite positive for the time required for deionization. The positions of relay coil and resistor could be interchanged if a higher resistance relay was to be used.

In the present version of this circuit, C was a one-microfarad paper condenser in all cases, while R was made the variable

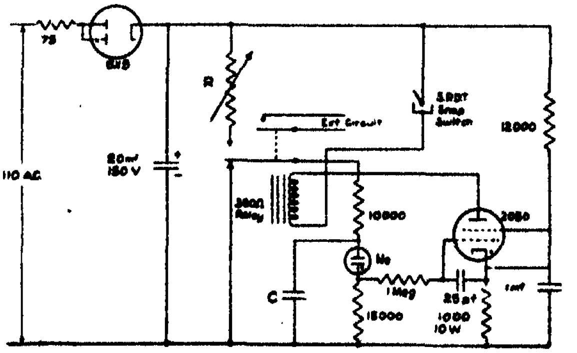

Fig. 1. A timing circuit in which the relay is deenergized for a time of approximately RC. Especially at the short intervals, a power supply with better regulation will give greater reproducibility.

element. It is preferable in the low ranges to use a linear wire wound potentiometer of say 100,000 ohms for R and a series of fixed resistors and a step switch in the higher ranges. For an increased range one should also allow C to vary. The shortest time interval was produced with an R of zeró ohms because then the charging current was limited only by the 10,000-ohm resistor. This resistor was so placed that it not only determined the shortest time, but also, at the end of an interval, it discharged the condenser gradually rather than abruptly, as would be the case if the condenser were shorted directly by the contacts. There seems to be some evidence that this is advantageous to the condenser as well as to the relay contacts.

The neon bulb, before installation, was placed in series with a suitable resistor across the a.c. line for a week of aging in order to reduce any tendency towards a change in characteristics. Since the life of such a bulb depends on the time integral of the current passed, and since this bulb is only required to pass one small pulse for each timing cycle, it should provide long and stable operation. Variations in the characteristics of the thyratron, of course, do not matter since it is merely pulsed at the proper time by the neon bulb. If left unregulated, variations in the line voltage will still somewhat affect the interval by changing the condenser charging rate, but at least the firing point will not also be variable. Since the neon bulb breaks down at a time when the condenser is only about half-charged, the derivative of the charging curve is still high at the operating point, thus making for positive reproducible action. The size of the resistor delivering the pulse isn't critical since, though it does control the neon bulb current, in any case the size of the pulse will be the difference in the neon bulb firing and operating potentials (the latter, though approximately constant, taken at the stated current). The 25-$\mu\mu$f condenser was introduced to minimize the possibility of a positive plate transient ending the timing interval too soon (by raising the grid potential).

We might now consider the main feature contributing to the high speed of response of this circuit. It is only after the relay has completely fallen closed that the external circuit is completed and the condenser starts to charge. Thus it does not matter how sluggish the relay is in dropping out, as only its pull-in time limits the speed of operation. This latter time can be rather small even for relays usually considered big and slow in action. Furthermore, it is reduced from its normal value by the large initial current surge from the one-microfarad condenser upon ionization of the thyratron. This discharge current is limited only by the relay impedance since the condenser is effectively placed across the relay coil and thyratron by the low impedance of the power supply. If the relay impedance is small then these initial currents will be high and will cause a fast snap in action. The thyratron is quite capable of carrying momentary high current surges, and since it turns the relay on, there is no danger of welding the contacts of even a small switch.

In conclusion, the application of this system to the activation of various other mechanical elements might be mentioned. For example, at present it is being used in conjunction with a high speed magnetic shutter activated by a light integrating photo-cell on an automatic enlarger. It was found impossible to turn the light off quickly enough when the proper exposure was reached so a shutter had to be used. Its magnet is placed in a circuit similar to the magnet of the relay except that R is replaced by a multiplier photo-tube aimed at the light reflected from the emulsion. When the proper quantity of light has impinged on the paper the exposure is terminated by pulling the shutter closed. Here also the opening time does not matter as any light passed during this phase is monitored by the photo-cell and counted toward the total desired.

A New Discharge Tube for the Hydrogen Atom Spectrum

W. P. van Oort and A. C. S. van Heel
N. V. de Bataafsche Petroleum Maatschappij, Laboratorium, Amsterdam, Holland

January 6, 1949

A DISCHARGE tube emitting strong Balmer lines is of great importance for refractometry. The Balmer lines are very sharp and extend over the whole visible range of wave-lengths. The source of light which has been generally used until now is a Geissler tube, which gives good Balmer lines, though of a very low intensity A Geissler tube consumes about 1 watt. This is inconveniently small especially when handling colored solutions.

A new tube will be described which emits Balmer lines of high intensity and has a long lifetime. The power consumption is 400 watts and the lifetime reaches at least 500 hours. The tube is shown in Fig. 1.

The material of the tube is Thuringer glass. The electrodes are of aluminum sheets of 2 mm thickness and are mounted in such a way that the discharge has to turn once through 180° and once through 90° before reaching the capillary tube, in which we do not want metal particles. The avoidance of metal in the capillary tube is necessary to obtain a pure hydrogen atom spectrum. Aluminum has been chosen for the electrodes because of its very low sputtering caused by ion bombardment.

As the ends containing the electrodes are placed sideways the radiation of the capillary tube in the longitudinal direction can be utilized ("end-on"). In this way a small but very strong source of light is obtained. The diameter of the capillary tube is 3 mm, its length 80 mm.

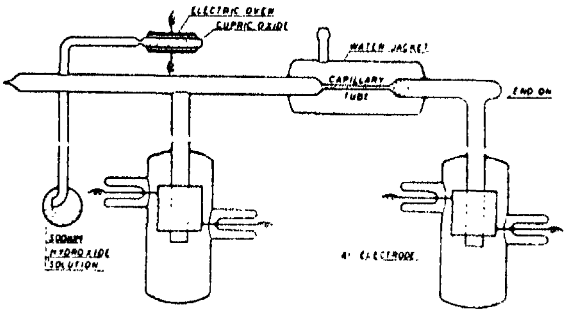

FIG. 1.

The tube is filled with water vapor. During the discharge water is dissociated and hydrogen ions and atoms are obtained. As long as an adequate amount of oxygen is present no H_2 molecules can exist and the H atom spectrum is emitted. However, the oxygen will be taken up by the Al of the electrodes and H_2 molecules will appear in the tube. As a result the blue H_2 molecule spectrum will be emitted. This spectrum is undesirable because of its many lines in the visual range of wave-lengths.

In the new tube all H_2 molecules which may be formed are removed by the following device. A tube filled with CuO rods is sealed to the discharge tube and is heated by a small electric oven to 270°C. At this temperature the H_2 molecules reduce the CuO to Cu and H_2O is formed. If no H_2 molecules are present, nothing happens and the tube is in the right condition. The CuO rods are cylinders with a diameter of 0.5 mm and a length of 5 mm.

A very strong solution of NaOH in H_2O ensures the right vapor tension of H_2O in the tube. At room temperature the vapor pressure will be about 1 mm.

The diffusion of H_2 to the CuO and the combustion to H_2O take place at a rapid rate, thus enabling operations to go on continuously for hours on end.

The total life of the tube is restricted by the amount of oxygen present in the CuO. With an amount of CuO of 10 grams more than 500 working hours may be counted on. An increase of this amount of CuO immediately results in a longer lifetime.

The tube is fed by means of a transformer on the mains. The power taken up is 400 watts at a terminal voltage of 1360. The current amounts to 300 mamp. For a short period a current of 500 mamp. is allowable, in which case the energy taken up is 700 watts.

The power consumption of the small electric oven is 35 watts.

A new type of gas discharge tube emitting Balmer lines of high intensity is described. The tube is useful in refractometric work. The power consumption of the tube amounts to 400 watts. The tube can be used continuously for at least 500 hours.

Improving the Response Characteristic of Graphic Recorders

P. G. Sulzer and A. H. Waynick
Electrical Engineering Department, The Pennsylvania State College, State College, Pennsylvania

January 25, 1949

It is frequently desirable to record fluctuating, variable voltages with a sensitive graphic recorder such as the Esterline-Angus Model AW. When continuous and long-term recordings are to be made, such as the recording of radio wave field strengths, it is further desirable to utilize a sensitive movement so that the power requirements for the meter amplifier will be small.

Experience with a recording system utilizing an Esterline-Angus 0.001-ampere, full-scale recorder driven by a 6SN7 amplifier has indicated that fluctuations of less than about five percent of the total deflection are not recorded. The frictional forces between the pen and the paper prevent response to the small torque involved when the pen pressure is adequate for trouble-free, long-term recording. Consequently, the recording could only be accurate to within ten percent of full scale which is quite inadequate for the above and many other purposes.

A solution of this problem which permits recording to within the accuracy of the meter movement alone was obtained by means of the circuit shown in Fig. 1. The circuit is a conventional bridge comprised of the plate loads and plate resistances of V_1 and V_2 and the two 10-K resistors in series with the relevant portions of R_1. It is unbalanced by an amount which is a function of the magnitude of the input signal, when the latter is applied, with consequent proportional meter deflection.

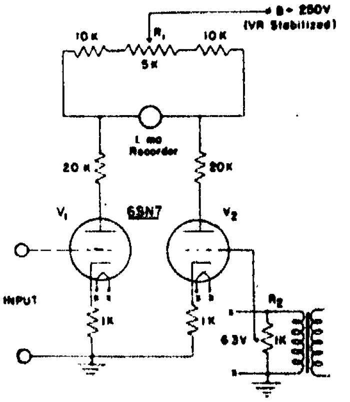

Fig. 1. Schematic diagram.

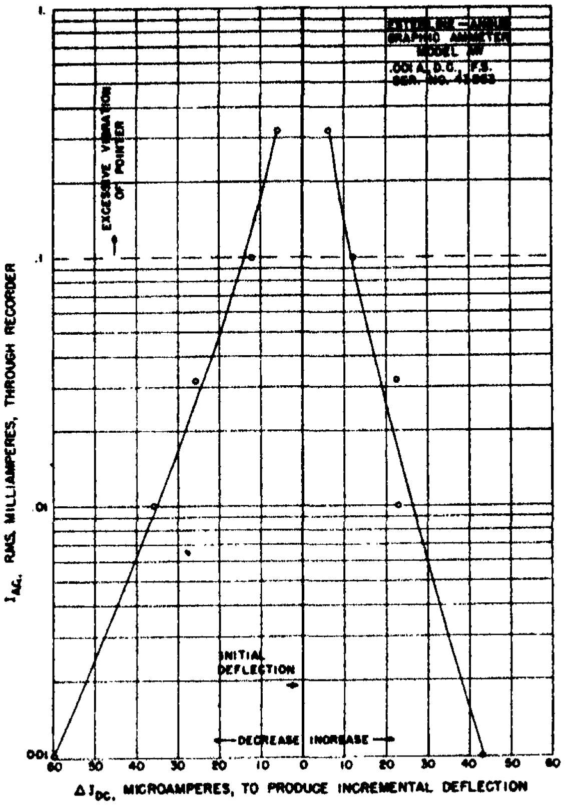

Fig. 2.*

The unusual feature of the circuit is the injection of a 60-cycle voltage into the grid circuit of the "sleeper" tube, V_2 The magnitude of this "jitter" voltage is controlled by the adjustment of R_2. Since the recorder frequency response drops off very rapidly above a few cycles per second, the recorder cannot follow the "jitter" current fluctuations. However, the vibratory forces set up in the meter movement are found to greatly reduce the friction of the meter pen with the recording paper, with consequent improvement in the accuracy of the recording.

A simple experiment, whose results appear in Fig. 2, illustrates the improvement that may be obtained by this method of operation. Referring to the figure it will be noted that the abscissa indicates the increment in d.c. signal current required to produce an increment in recording pen deflection. The ordinate is in r.m.s. a.c. "jitter" current through the recorder. It was found that "jitter" currents of less than one microampere had negligible effect on the recorder operation. As indicated on the figure, $I_{a.c.}$ greater than 0.1 milliampere resulted in excessive vibration of the recorder pointer with consequent broadening of the recorder trace. By utilizing an $I_{a.c.}$ of slightly less than 0.1 milliampere a.c., the increment in $I_{d.c.}$, required to produce an increment in the deflection was reduced by a factor of four in comparison with the value required for zero $I_{a.c.}$. It was determined that the magnitude of the initial deflection and the recording paper speed, for values less than about 6 inches per hour, had no significant effect on the above results.

Three Esterline-Angus 0.001-ampere recorders have been in continuous operation for one year using the above technique with excellent results.

A Vacuum Tube Relay for Thermostat Control

I. Sucher and H. S. Anker*
Department of Biochemistry, Columbia University, New York 32, New York
January 25, 1949

The determination of the density of water by the "falling drop" method is simple and accurate and has proven valuable for the measurement of the abundances of the hydrogen and oxygen isotopes in experiments using the tracer technique.[1] The apparatus required for the application of the falling drop method has been described in detail.[1,2] It includes a thermostat controlled to better than ±0.001°C by a thyratron relay.[2]

However, the high cost and limited life of the thyratrons as well as the bias battery necessary prompted the development of a self-contained high vacuum tube relay. Such a relay has operated for several years without trouble in this laboratory. Its circuit is given in Fig. 1. The relay operates in the following manner: If the temperature increases, the contacts of the toluene regulator close so that zero bias is applied to V_2. This tube consequently passes current through R_3, thereby biasing the V_1's negatively. The V_1's do not conduct in this condition. The impedance of the primary of T_1 is therefore high so that very little current is drawn through the heating element (H). At the same time a blower (F) connected in parallel with the primary of T_1 is energized blowing on the surface of the thermostat and cooling it by increasing the rate of evaporation of the water. On opening of the toluene regulator contacts, the actions of V_2 and V_1 are reversed, lowering the impedance of the primary of T_1 which permits a large current to flow through the heater and cutting the fan off. In using this device it should be remembered that in contrast to a mechanical relay the heater is not completely shut off and that the wave form of the heater current is seriously distorted. A differential output of about 200 w is obtained for the heating element. In operation the toluene regulator is shaken mechanically due to vibration of the stirrer resulting in very rapid switching. Thus very smooth control of the thermostat is obtained.

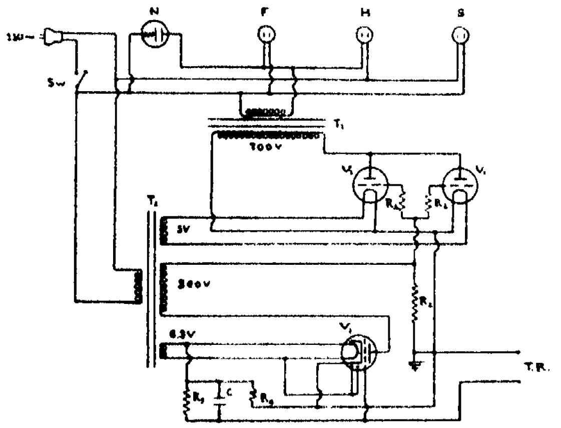

Fig. 1.

N: Neon lamp; NE 30
F: Fan outlet; (25-w motor)
H: Knife heater outlet; (500 w)
S: Stirrer (Cenco No. 18850)
T_1: Stancor P-6314
T_2: Stancor P-6119
R_1: 10,000 ohms; carbon; ½ w

R_2: 100,000 ohms; carbon; 2 w
R_3: 5 megohms; carbon; ½ w
R_4: 20,000 ohms; carbon; 1 w
C: 0.1 μf; paper; 400 v
V_1: 2 $A3$
V_2: 6 $SQ7$
T.R.: Toluene regulator

Note: Since all tubes are operated by unrectified alternating current, the secondary voltages of T_1 and T_2 must be connected in phase. This is achieved as follows: The filament windings of T_2 are connected permanently and V_2 is inserted into its socket. The high voltage winding of T_2 is now connected in such a manner, that on shorting the terminals T.R. a large bias voltage appears across R_3. Then after insertion of the V_1's and of a 200-w lamp into the outlet H, T_1 is connected in such a way that on shorting the terminals T.R. the lamp extinguishes nearly completely. For safety the relay is ground to a water pipe.

---

Accurate, Simple Recording Microphotometer

P. Rosenblum and A. deBretteville, Jr.
Signal Corps Engineering Laboratories, Fort Monmouth, New Jersey
January 25, 1949

A MICROPHOTOMETER, suitable for the study of x-ray diffraction film, was designed in the Squier Signal Laboratory. This instrument may be of general interest since it is applicable for recording a wide range of film and glass plate photographs. The results of tests made with this microphotometer proved to be satisfactory. The instrument was designed with only essential components in order to facilitate manufacture in the laboratory shop. It was also possible to use a simple optical system of low resolving power because of the large grain size of the film used in x-ray diffraction work in contrast to fine grain spectroscopic plate. Perrine has described a microphotometer using an optical system which is somewhat similar.[1] Brentano also describes a microphotometer for x-ray diffraction work.[2] Most laboratory microphotometers use photographic type recorders. However, to facilitate the rapid analysis of results, electrical type recording was chosen. A standard electronic recorder was found applicable for this purpose.

Figure 1 shows a general picture of the microphotometer. A light beam emerges from the right and left of the large horizontal tube which contains the light source in the middle. The left beam passes into a compensating photo-cell, while the right beam after passing through the x-ray film enters an appropriate slit in front of the scanning photo-cell. The compensating and scanning photo-cell are in a Wheatstone Bridge circuit with the recorder across the bridge, registering the unbalance.

A 6–8-volt light bulb wired as a light source for the photometer is mounted on a rod which can slide in and out of an opening in the tube. A set screw locks the rod in the correct position on the optical axis. The optimum focusing adjustment for the scanning lens is by a rack and pinion. The lens for the compensating system can be adjusted and the amount of light altered by an iris diaphram.

The film holder consists of two highly polished chromium bars which are held on the film carriage by four thumb screws. Several spring clips fit into holes on these bars which

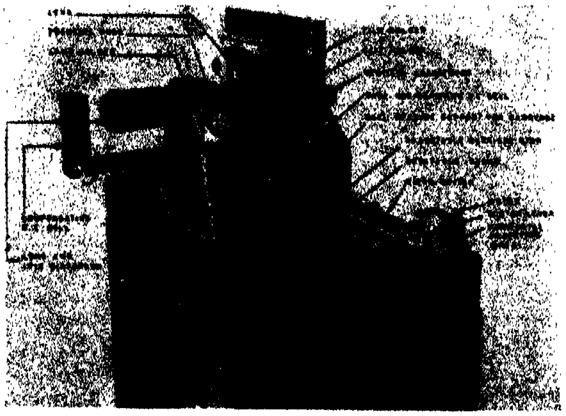

Fig. 1. Microphotometer showing component parts as indicated.

hold the film securely in place. By spacing the bars apart, a large range of film and glass plate photographs is easily accommodated An adjusting knob (Fig. 1) on the side of the film holder positions the film vertically. The small hand wheel on the right is used for quick horizontal alignment.

The movable film carriage track uses rollers which are of the ball bearing type fixed on the inner race to the film carriage while the outer race is free to rotate on the heavy round chromium plated bar Extreme accuracy is possible using this method of construction since there are so few moving parts.

The drive for transporting the film carriage across the light beam uses a lead screw mounted on the base which rotates in a split nut enabling the film to move back and forth. A 1-r.p.m. reversible motor with a simple lever-operated clutch drives the lead screw through two spur gears. It is possible to easily change film speeds by interchanging the spur gears between the clutch and the lead screw.

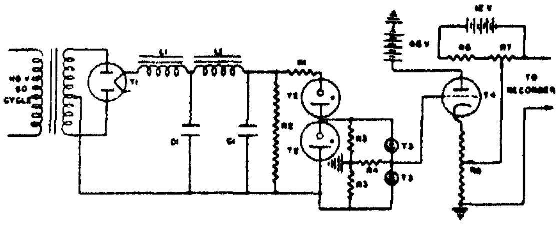

FIG. 2. Wiring diagram of power supply for photo-cells and impedance matching cathode follower for voltage recorder.

$T1$ = 5U4-G
$T2$ = 150-VR
$T3$ = 918 P.E. cell
$T4$ = 5692
$C1$ = 4 μf
$L1$ = 20H

$R1$ = 2K
$R2$ = 1M
$R3$ = 25K
$R4$ = 20M
$R5$ = 1K
$R6$ = 3K
$R7$ = 1K

The main base is constructed of heavy steel plate bent and welded at the corners. It is reinforced by steel channels for rigidity.

The electrical system as mentioned above should be so designed as to minimize the fluctuation of the light source and the power source. A Superior Electric Company "Stabiline" No. 1 E 5101 which is an electronic voltage regulator circuit, was used to obtain constant input voltage for the entire electrical system. To minimize the fluctuation of the light source, the two photo-cells are mounted in a bridge circuit as shown in Fig. 2.

The lamp is operated through the voltage regulator circuit using a "Variac" to change the lamp intensity.

Since the recorder has a low impedance transformer input and the photo-cells have a high output resistance, a cathode follower was used to match impedances. A 5692 tube was used successfully for this purpose. To overcome drift in the output, the plate of the 5692 was reduced to 45 volts and the filament voltage was supplied by a 6-volt storage cell instead of an a.c. transformer.

The optimum fixed slit is selected for the type of film one desires to measure. The film is then adjusted on the carriage for scanning. A trial setting is made using the sensitivity adjustment (or cathode follower potentiometer, R-5). The starting point of the pen is then set by means of the biasing potentiometer (R-7). It takes a few minutes to find the optimum sensitivity setting that will cover the chart.

In order to obtain maximum integrated area from the chart curve, the greatest possible expansion ratio is used. A planimeter then can be used to measure the line areas and thus determine the integrated intensity with the minimum error. This expansion is accomplished by reducing the film carriage speed to the minimum of 1¼ inches per hour and increasing the chart speed to a maximum of 120 inches per hour, giving a 96:1 expansion.

In order to insure stability, the background should always be checked to obtain a straight line output without scanning, i.e., for a fixed position of the film.

This adjustment can be obtained by lowering the sensitivity of which there is more than an adequate amount, and increasing the lamp voltage if need be. In order to check the stability, a Debye x-ray pattern was recorded by scanning the same portion of the film in opposite directions. The record obtained is shown in Fig. 3. The area of the peaks for the left and right traverses should be equal. However, the human element enters in selecting the background so the authors each measured the areas for their own chosen background. Both ob-

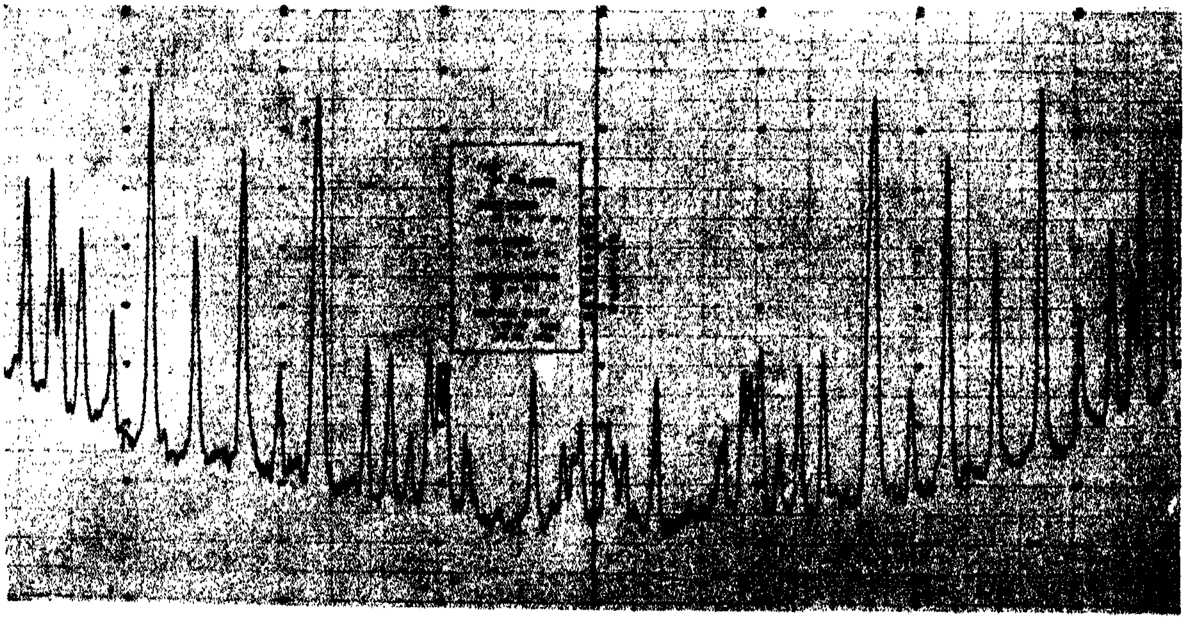

FIG. 3. Record obtained on a 10-inch chart by electronic recorder (Brown Model No. 153X12V-X-30Y10 range 0–50 M.V.) of a Debye x-ray diffraction picture of $AlPO_4$ powder.

servers found the area on each side of the reversing point to differ by less than one percent, and the mean area for each observer differed by 1 percent which was due to the different backgrounds chosen.

The authors wish to thank Dr. R. Brill for his suggestions in the building and testing of the instrument; also Mr. F. Priebe for assistance in the electrical circuit design. The authors wish especially to thank Mr. E. Limpier and Mr. F. F. Cruell of the Squier Signal Laboratory for their excellent craftsmanship in the construction, and without whose ability the photometer would not have been possible.

A Vacuum-Tube Current Integrator of Improved Design

L. H. v. d. Twerl
Wetenschappelijke Adviezen, bouw Wetenschapp. Apparaten, Lijnbaansgracht 284b., Amsterdam, Nederlands

February 1, 1949

VARIOUS types of current integrators have been used employing a gas-discharge tube and a condenser charged to the breakdown voltage of the glow tube. It is obvious that some disadvantage is inherent in these methods. The currents to be measured by these methods were limited at the low side to 10^{-10} ampere. Recently,[1] a method has been described lowering this limit, but many precautions have to be taken and special construction of the discharge tube is essential. Another drawback is the variation of the breakdown voltage of gas tubes.

Using neither relay nor gas tube, the circuit diagram is given in Fig. 1 and is essentially a normal one-shot multivibrator. At the beginning of the cycle the control-grid voltage of tube *V1* is well below cut-off and increases steadily when the grid capacitance is charged through *R1* (which may be a photo-tube, an ionization chamber, or a high resistance) until tube *V1* reaches its cut-off. At this moment the triggering mechanism starts and pulls down the current-drawing cathode of *V2*; and as the current in *V1* is limited by the anode resistor *R2*, the cathode falls to a potential of a few volts above ground, depending upon the type of *V1* being used. The grid current of *V1* discharges the condenser *C1*. The coupling circuit *R3 C3* is chosen to have an *RC*-time long enough to provide for this discharge. After this, the flip-flop returns to its zero condition and the cycle begins again. Since *V1* is used below cut-off during the greatest part of the cycle, the major part of the leakage is due to insulation faults in this tube. Grid current is drawn only at the end of the cycle; but as the anode current remains very small, the grid current will be small also.

A tube particularly well suited to this application is the Philips type CF 50. This tube is to be recommended particularly because of its high insulation (10^{13} ohms or better) and its high transconductance at low anode currents. This high transconductance is important to minimize the fluctuations in the voltage at which triggering action starts. Variations in this triggering voltage result from variations of the contact potential of *V1* and of the bias at which *V2* draws a current given in the first approximation by V_g^2/R_k.

If desired, the cathode potential can be given continuously by a meter connected to the common cathodes. When used as a dosimeter the cathodes may be adjusted at approximately 15 volts using a variable resistor to give one roentgen per cycle. The apparatus behaves extremely well in a current range from 10^{-9} to 10^{-11} ampere.

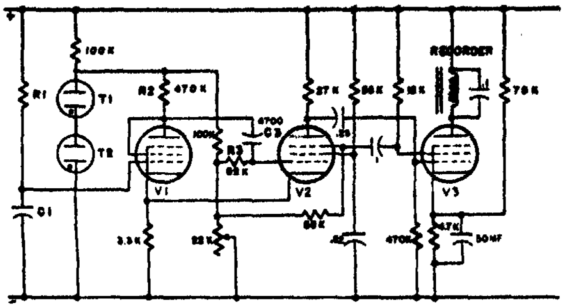

FIG. 1. Circuit diagram of current integrator.

Other types of trigger units may also be used but the author has only tried this one believing it to have certain advantages. The rest of the circuit is designed to lengthen the pulse with a minimum of parts. It consists of a multivibrator coupled to the suppressor of the EF 50 tube; but any conventional pulse-lengthener may be used.

I wish to express my sincere thanks to Professor Dr. J. Clay of the Amsterdam Laboratory for Cosmic Radiation, for his hospitality, and to Dr. H. den Hartog and Mr. F. A. Muller who added so much to the development of this instrument.

A Modification of the Gouy Modulator

L. S. Darken
Research Laboratory, United States Steel Corporation of Delaware, Kearny, New Jersey

February 1, 1949

GOUY,[1] in attempting to improve the automatic temperature control of an ordinary laboratory water thermostat, found he could decrease the cyclic temperature variation by a factor of twenty by substituting a mechanically driven oscillating contact for the normally stationary contact in his mercury in glass thermoregulator. Reid[2] describes a modification for furnace control involving the addition of an oscillating voltage to the thermocouple voltage. He obtained this oscillating voltage by passing a small current through a resistance consisting of a resistance wire immersed to a periodically varying depth in mercury. Reid reports a fifteenfold increase in the sensitivity of the controller by means of this device. Several other modifications of the Gouy modulator have been reported, at least one of which is commercially available.

This communication describes a small simple generator which may be used to produce the oscillating voltage in series with the thermocouple. It may also be used in conjunction with other types of elements which respond electrically to temperature variation. This generator is shown in Fig. 1. It consists of an Alnico magnet which is rotated by an electric motor about a fixed coil. The Alnico magnet is about 2½ inches in diameter; pole pieces ½″×½″×1½″ of soft iron were added. The synchronous motor is geared down to rotate the magnet at one revolution per minute. The coil (20 ohms) is an old galvanometer coil of about one hundred turns on a rectangular form about ½″×1″. The electromotive force produced was nearly sinusoidal with a maximum of 0.7 mv. To reduce this voltage to the optimum, a variable shunt (50 ohms) was initially used. This may be replaced by a fixed shunt when the proper resistance is determined. A schematic diagram is shown in Fig. 2. This modulator is now used in conjunction with a platinum-platinrhodium thermocouple and a commercial controller to control a tubular "Globar" furnace

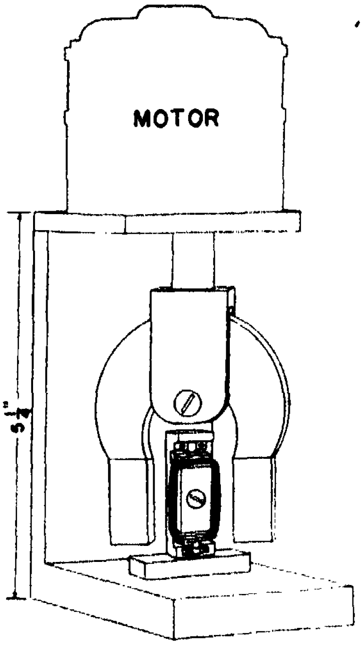

FIG. 1. Gouy modulator (modified).

at temperatures up to 1650°C. The cyclic temperature variation (near 900°C) was reduced from 8°C to 0.3°C by the use of this modulator. An 8-ohm shunt which leads to the addition of ±0.1 mv (corresponding to ±9°C) to the thermocouple voltage was found satisfactory. The cyclic voltage may be varied over rather wide limits (perhaps a factor of two) without markedly affecting the sensitivity but should not be less than the initial sensitivity of the controller else the gain in sensitivity is markedly decreased. On the other hand too large a cyclic voltage leads to drift—i.e., response to line voltage changes.

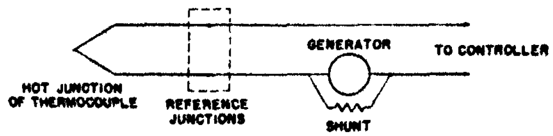

FIG. 2. Modulator circuit.

The advantages of the above described modulator over others include: (1) Absence of any moving contacts in the thermocouple circuit; (2) absence of any wired connection between thermocouple circuit and any other circuit (no leaks are likely); (3) true zero mean cyclic voltage; (4) failure of the modulator leads merely to absence of modulation and does not otherwise disrupt control; (5) no metal other than copper is used in the circuit.

---

A Flexible Vacuum Seal

OTTO RETZLOFF
Department of Physics, Washington University, St. Louis, Missouri
February 9, 1949

IT is often necessary to move an object inside a vacuum from outside. The Wilson seal is perhaps the best known of the devices which have been invented for this purpose. This note describes a device which enables one to rotate an object in a vacuum and also to displace it in any direction within wide limits. It consists essentially of a sphere fitting in a spherical socket and made vacuum tight by an O-ring (Fig. 1). The center rod A slides along a diameter of the sphere and the junction is made vacuum tight by an O-ring. The sphere B, 1 inch in diameter, fits in a spherical socket which consists of two parts, C and C_1 as shown. The sphere and spherical sockets are machined to within 0.001″ accuracy by means of two homemade tools of simple design. The vacuum is maintained by a suitable O-ring between the sphere and the spherical socket. The half of the spherical socket, C_1, next to the vacuum chamber can be attached to it in many ways, two of which are shown in the diagram. In the left half of Fig. 1 is shown a way of attaching C_1 by means of a set of bolts (one of which is shown) and a suitable O-ring. In the right half of Fig. 1 is shown how it may be attached by soldering.

The O-rings used in this seal can be purchased from the Linear, Inc., State Road and Levick, Philadelphia, Pennsylvania. If the proper O-rings are used and the grooves cut according to the instructions of the Linear company there is no difficulty at all in securing vacuum tight joints. With a vacuum of 10^{-4} mm or more inside the vacuum chamber, it is possible to rotate the sphere in any direction within 30° of the central position as well as to push the center rod in and out and also to rotate it, without impairing the vacuum.

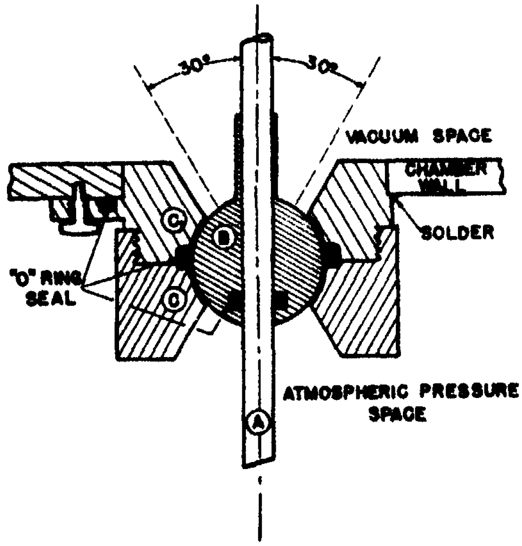

FIG. 1.

A Device for Producing an Easily Identified Area on the Electron Microscope Specimen Screen*

FRANCIS W. BISHOP
Department of Radiation Biology, University of Rochester, School of Medicine and Dentistry, Rochester, New York
November 22, 1948

THERE occasionally arises the need of examining a specimen both in the electron microscope and the optical microscope. It also may be desirable to reinsert given specimen into the electron microscope and relocate exact field.

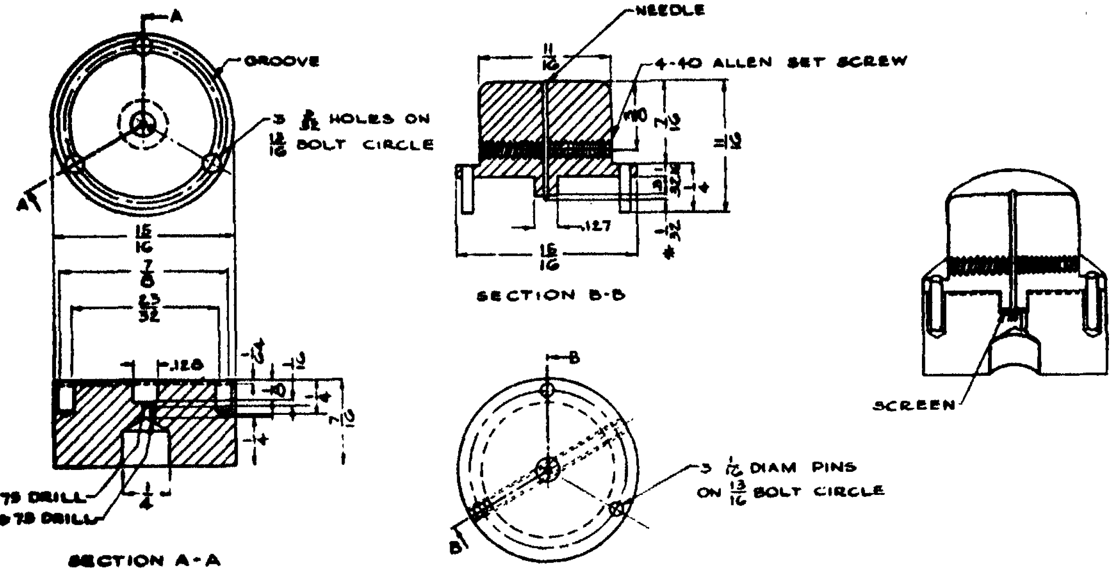

FIG. 1. Note: * dimensions adjustable according to size of hole desired in screen.

A device which would mark the specimen screen in some way would be of great assistance in providing a reference point in the relocation process. Many times the marked area of the screen itself will contain a suitable portion of the object to be examined in the microscope.

To achieve this end, a simple marking device was constructed in the laboratory. It consists of a female brass block, counter-bored to hold a specimen screen and a male element which holds a sewing needle of appropriate dimensions. The point of the needle may be adjusted for any degree of penetration into the specimen screen and is locked in place and centered by two opposing set screws (Fig. 1). When a wire mesh screen is used, the wires are forced slightly apart where the needle enters, resulting in a circular opening which is easily found and identified in either the optical or electron microscope (*A* in Fig. 2).

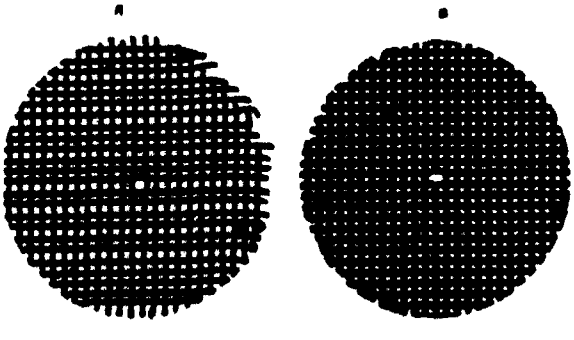

FIG. 2.

Lektromesh screens have no loose wire to be displaced by the needle, but usually a portion of the mesh is broken and may take the appearance of the screen *B* in Fig. 2. In either case, the hole is sufficiently distinctive to be used as a landmark.

As a result of the punching by the needle, the screen may bulge, and should therefore be flattened against a plane surface by means of a roller.

In order to facilitate the examination of the specimen in the optical microscope, a small brass specimen holder was constructed. It accommodates the usual specimen cap and specimen and permits examination with up to a high dry objective. When it is desired to save a specimen for a considerable time before it is examined, or if it is to be re-examined at a later date, we employ a small, knurled brass plug which is inserted into the specimen cap and holds the specimen firmly. This ensemble is kept in a suitable bottle until needed. It also provides a practical way of shipping a given specimen to another laboratory.

* This paper is based on work performed under contract with the United States Atomic Energy Commission at the University of Rochester Atomic Energy Project, Rochester, New York.

A Current Integrator

H. T. GITTINGS, JR.
University of California, Los Alamos Scientific Laboratory, Los Alamos, New Mexico

January 25, 1949

A CURRENT integrator has been developed to measure the number of positive ions in the ion beam of an electrostatic accelerator. The ions are collected in a Faraday cage with a secondary-electron barrier.

A capacitor between the cage and ground will accumulate a positive charge which is the integral of the beam current and is proportional to the number of ions collected. An amplifier with its input across the capacitor is designed to operate a relay when the capacitor has accumulated a predetermined amount of charge. The relay contacts short the capacitor which drops out the relay and restarts the cycle. The relay contacts also operate a mechanical counter which is calibrated in microcoulombs per count.

There are, however, several factors to be taken into consideration before such a system will be adequate. The relay must operate at precisely the same value of coil current each time and it must operate fast. A very satisfactory relay is the Western Electric 275B, which is a sealed, mercury type. The capacitor must have low dielectric absorption. Polystyrene or Glassmike capacitors are suitable. The Faraday cage should not swing in potential with respect to ground, if it does leakage current will be more troublesome, the cage and cable

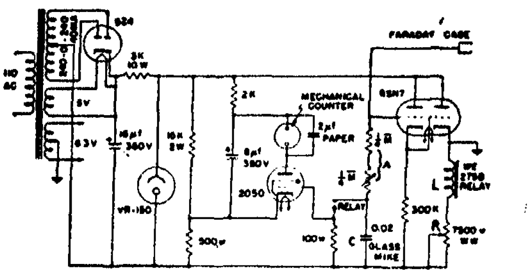

FIG. 1.

w = ohms
K = ohms × 10³
M = ohms × 10⁶
WW = wire wound
W = watts

capacity to ground will appear as an undesired shunt capacity (appreciable when high accuracy is desired), and the electron barrier potential will vary. The amplifier across the capacitor must have very high input impedance and low output impedance. The relay inductance introduces into the relay circuit a voltage proportional to the rate of change of the relay coil current and hence to the rate of change of charge on the capacitor, which is proportional to the beam current. It can be shown that precise compensation for this voltage, irrespective of time-variations of beam current, can be achieved for any capacitor, C, and relay (inductance, L, resistance, R)-if a particular value of resistance, $r=L/(RC)$, is placed in series with the capacitor (Fig. 1).

When the relay contacts short the capacitor, the discharge current is limited by a 100-ohm resistor. If the relay has double-pole contacts the other contacts may be used to operate a mechanical counter, if not, the voltage pulse across the 100-ohm resistor can be used to trigger a thyratron which will operate the counter.

It can be seen from Fig. 1 that the Faraday cage (the input grid) varies in potential only a very small amount since the power supply swings with respect to ground.

The calibration procedure is to adjust the rheostat in series with the relay coil to give the desired sensitivity using a very low value of charging current so the inductive effect is small. The charge, q, is determined by measuring the current with a potentiometer and the time with a stop clock. Then at the highest charging current the compensating resistor is adjusted to give the same sensitivity. Careful tests have shown the sensitivity of 1.00 microcoulomb per count to be constant to within 0.2 percent from 0.005 microampere to 10 microamperes. Changing relays will probably require recalibration but the sensitivity is practically independent of the 6SN7.

New Instruments

W. A. Wildhack: Associate Editor
in Charge of this Section
National Bureau of Standards, Washington, D. C.

These descriptions are based on information supplied by the manufacturer and in some cases from independent sources. THE REVIEW *assumes no responsibility for their correctness.*

Infra-Red Analyzer

The Perkin-Elmer Corporation announces the development of the Model 12-D infra-red analyzer for continuous automatic analysis of as many as six different components in a flowing stream of sample. The stream may be either in the liquid or gas phase.

The instrument consists of the following units:

Infra-red Monochromator—Similar to that used in the Perkin-Elmer Infra-red Spectrometer.

Turret—Automatically driven, twelve point (one reference standardization point and one absorption point for each of six components).

Recorder—Leeds and Northrup, 12-point, strip chart, specially designed for this instrument. Automatically synchronized with turret.

Amplifying Circuit—Highly stable, a.c. operation. Compensates for changes in ambient temperature, source intensity, window dirt, etc.

The cycling time for a six-component analysis is about 6 minutes.

The analyzer is particularly time-saving in the pilot plant in determining optimum process conditions. Operating variables such as temperature, contact time, flow rate, etc., may be varied continuously and evaluated immediately from the automatic analytical record. In a continuous, multi-stage process, sampling may be performed at intermediate stages for independent evaluation.

In the process plant, the instrument provides a permanent, accurate record of product concentration and purity, as well as an immediate indication warning of process troubles.—THE PERKIN-ELMER CORPORATION, *Glenbrook, Connecticut.*

Color Computing Device

The General Aniline-Librascope tristimulus integrator integrates continuously over all portions of the visible spectrum, will tell immediately whether a given color will match another color, and, if not, will describe the difference between them. Without the integrator, an answer to this question may take hours to get, and even then be less accurate.

The instrument was designed for use with the General Electric spectrophotometer invented by Professor Arthur C. Hardy, of M.I.T. Only minor modifications of the spectrophotometer are required, and the computer may be placed inside the existing case.

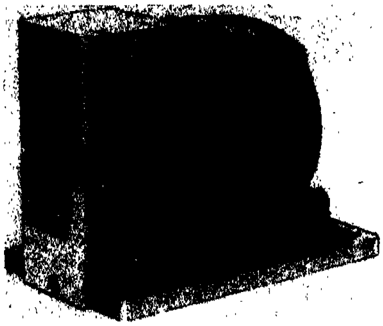
Although the eye can tell whether or not two colors are the same, no one can describe color differences in words which mean the same thing to everybody. Color scientists, however, have developed an internationally accepted mathematical procedure for obtaining numbers which unambiguously specify any color.

In order to understand this method and the operation of the new computer, it is necessary to know that color as we see it is composed of three parts: first the light, which is energy radiating from the sun or a lamp; second the dyed, painted, or naturally colored material under observation which reflects or transmits varying percentages of light of different wavelengths, and finally the eye itself. Internationally accepted data on the light and the eye are available, and reflectance or transmittance may be measured on a spectrophotometer. These three factors must be combined mathematically to give three numbers, known as the tristimulus values, which are a unique specification of any color observed. Even a color-blind person can make the necessary calculations and evaluate the color of any material.

Until the invention of the tristimulus integrator, this procedure required multiplication of the three values at scores of wave-lengths and addition of the products. The integrator, an electronically controlled ball and disk mechanism which is connected directly to the spectrophotometer, instantly gives the correct result with a precision of five-hundredths of one percent. Together, the two instruments—the recording spectrophotometer and the tristimulus integrator—not only measure and analyze color in 2½ minutes, but yield a numerical specification of what we see with hitherto unobtainable accuracy.—General Aniline and Film Corporation, *230 Park Avenue, New York 17, New York.*

Multichannel Switch

The Applied Science Corporation of Princeton announces the development of a new multichannel switch driven by a 60-cycle synchronous motor. The use of a synchronous motor assures constant sampling rates and allows the convenient use of an a.c. line voltage source whose frequency is automatically synchronized with the sampling operation. The 4-pole model shown here is 2″×3″×4″ in physical size and has 30 contacts per pole. The wiper is of the shorting type for flexibility of use. Standard models have sampling rates of 720, 360, 240, 180, or 90 r.p.m.



These switches facilitate investigation of a large number of separate quantities or of a single quantity under a number of various conditions. In addition to telemetering applications, they may be used for the display of characteristic curves and multichannel voltage comparison. Electrical operations may be synchronized with mechanical motion by appropriate attachment of switch rotor.—The Applied Science Corporation of Princeton, *P. O. Box No. 44, Princeton, New Jersey.*

Hivolt Power Supplies

Condenser Products Company announces the addition to their line of Hivolt power supplies of Numbers PS-5, PS-10, and PS-30, which have respective outputs of 5000, 10,000, and 30,000 volts. Input voltage is 118 volts, 60 cycles. Containers are gray, lacquer-coated terne or tin-plated and are hermetically sealed and oil-filled.

Hivolt power supplies are used for oscilloscopes, radiation counters, insulation testers, electrostatic precipitators, photoflash devices, projection television, spectrographic analyzers, Van de Graaff generators, etc.

The new Hivolt power supplies weigh:

PS-5	8.5 lb.
PS-10	10 lb.
PS-30	21.5 lb.

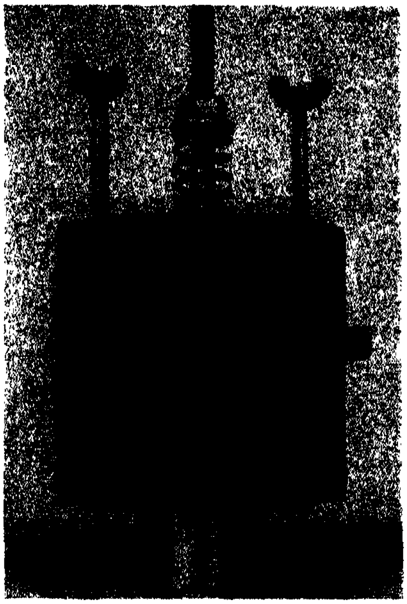
The PS-1 (2400 volts) weighs 2.2 lb.; PS-2 (2000 volts) weighs 2.5 lb. These two models are already widely used.

For further information on the complete Hivolt power supplies, write for specification sheet showing regulation and ripple curves and other pertinent information. Special output 60-cycle and higher frequency input supplies on request.—Condenser Products Company, *1375 North Branch Street, Chicago 22, Illinois.*

Low Range Air Cells

Two new Tate-Emery air cells having load ranges of 0–1.2 to 0–6 lb. and 0–2 to 0–10 lb. in tension and compression are announced by The Baldwin Locomotive Works, Philadelphia 42, Pennsylvania. The lowest capacity previously available was 0–30 lb. Other air cells are built with capacities up to 1200 lb. These load-weighing devices were designed for use on testing machines of any type or capacity to give high precision measurement of small loads such as in testing plastics, textiles, cord, paper, and other material. They can also be used independently for such purposes as weighing chemicals, or controlling chemical processes.

When a standard Tate-Emery indicator with 66-in. scale is connected with the cell, the 0–2-lb. range shows a pointer movement of approximately 2 in. for one ounce or 1/16 in. for one gram. Ranges are changed in the indicator.



Portable Bourdon gauge type indicators with 22-in. scale are available with these cells when existing indicators do not readily accommodate additional ranges. The minimum range with this type indicator is 0–10 lb.

An air jet and baffle within the cell controls the action of a pneumatic force balance system, so that air pressure automatically balances the load. Total movement of the load-sensitive member is less than 0.0005 in. This air pressure is transmitted to the load indicator.

Accuracy of load measurement is within ½ percent of reading or 0.15 percent of capacity, whichever is greater, when Bourdon gauge type indicators are used. This becomes ½ percent of reading or 0.1 percent of capacity, whichever is greater, for the Tate-Emery load indicator.—The Baldwin Locomotive Works, *Philadelphia 42, Pennsylvania.*

Gyros

Production of telemetering rate gyros calibrated for rotational measurements from 10° to 1000° per second and position gyros with one- and two-axis electrical sensory elements is announced by the G. M. Giannini Company

Gyro accuracies of better than ± 2 percent are offered and production gyros have been standardized with 2000-ohm, 2500-ohm, and 5000-ohm resistance pick-offs. Other resistance ranges furnished on request.

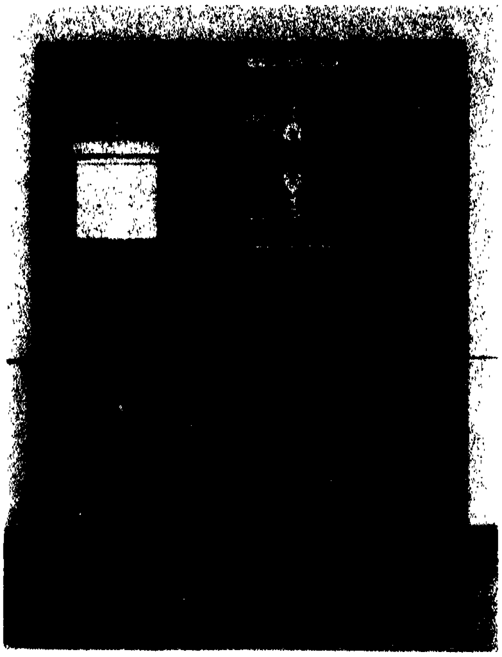
Telemetering rate gyros offer natural frequencies to 40 cycles per second and are available damped or undamped.

Additional detailed information available.—G. M. Giannini and Company, Inc., *254 West Colorado, Pasadena 1, California.*

Tensile Tester

The Instron tensile tester is a new, versatile, precision instrument based on electronic principles that make possible the accurate load-elongation measurements of plastic and textile materials, wire, paper, rubber, adhesives, and similar specimens.

Full-scale load range of the unit extends from 2 grams up to 5000 pounds in some models, representing a spread of approximately a million to one, and a choice of jaw speeds is incorporated ranging from 0.02 to 20 inches per minute. By virtue of the flexibility of the controls, both for changing the sensitivity of the load recording system and for operating the motion of the pulling jaw, a variety of unique testing techniques is available for the determination of special properties, as well as for routine measurements.



The instrument utilizes an electronic weighing system based on the electric strain gage principle for detecting and recording the load applied to the sample under test. The pulling jaw is operated by an unusual drive that provides a controlled rate of elongation of the sample over a wide range of speeds, in either direction of travel and with instant reversibility. The chart of the high speed recorder is driven at various speed ratios with respect to this jaw, so that tensile load-elongation curves of the material are made accurately at constant rate of elongation.

The main power to actuate the moving crosshead is derived from a servo-controlled drive acting as a "positional follow-up" system. By this means, a low power reference unit, which is driven synchronously at various speeds through a set of light change gears, is able at all times to determine the position of the moving jaw. Instantaneous starting, stopping, and reversal of direction of travel of this jaw is affected through fast-acting computer-type magnetic clutches operating on the reference unit.

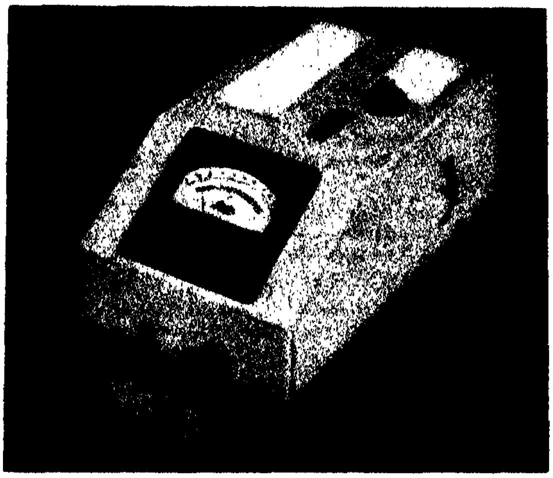
As almost no lag or error is introduced at reversal, this system enables measurements to be made of hysteresis under cyclic conditions with accurate correspondence between head position and chart travel being maintained at all times. Operation of the pulling head is controlled by pushbuttons located on the right side of the unit. The operation can be made automatic by adjustable, close-tolerance switches which control the gage length, cycling points, and other functions.

Chart speeds range from 0.2 to 50 inches per minute, which, in combination with the available head speeds, provide magnification ratios up to 1000 to 1.—Instron Engineering Corporation, *2 Hancock Street, Quincy, Massachusetts.*

Rouy Photrometer

Reflecting the latest electronic developments, the new Photrometer is faster, more accurate, and simple to operate, having only two movable parts. It is pre-calibrated for 38 of the most common clinical tests, making it unnecessary to keep a supply of standard solutions on hand. Supplied with every Photrometer is a handbook containing calibration tables for each clinical method, thus eliminating calculation.

The optical system consists of a lamp, precision ground mirror, filters and absorption cell. Light traversing this system falls upon a barrier layer photoelectric cell, generating a current which actuates a direct-reading microammeter.



Of twelve filter spaces provided, ten contain narrow spectral band filters which cover the entire visible spectrum. Two other spaces are supplied to allow for special work by the user.

Housed in a compact, white enameled cabinet, the Photrometer is mounted on a base cast from high strength aluminum alloy, making the unit lightweight and easy to handle.—E. Leitz, Inc., *304 Hudson Street, New York 13, New York.*

Precision Warburg Apparatus

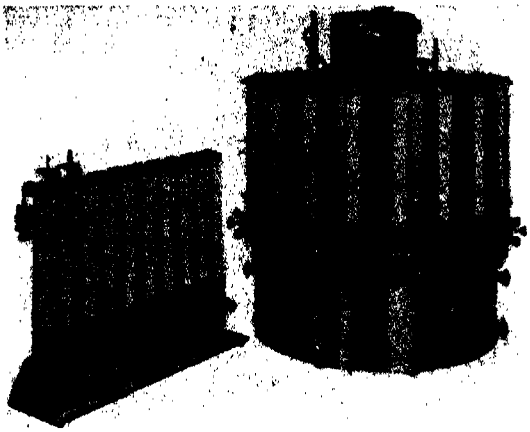
Precision Scientific Company has developed an advanced Warburg apparatus for the following uses:

1. For measuring respiratory exchange in yeast, bacteria spores, plant and animal tissues, and for the measurement of lactic acid production by normal and tumor tissues.
2. For reactions in which acid or alkali is produced or consumed in bicarbonate solutions in equilibrium with CO_2 gas mixtures.
3. For the measurement of blood gases and for investigating the reactions of hemoglobin and other blood pigments.

A time-saving convenience is found in that the entire manometer bank can be rotated through 360° in either direction for as many revolutions as desired. The apparatus holds 20 Warburg manometers (or 10 Summerson differential manometers) which can be read in motion or stopped in pairs by an operator from a fixed position.

Operation is further simplified by the simultaneous adjustment of shaking amplitude of the entire range from 1 to 4 centimeters. The shaking rate is also adjustable at any interval from 50 to 150 oscillations per minute.

The function of holding the guaranteed temperature sensitivity of 0.02°C is performed by three units. An improved adjustable Micro-Set Thermoregulator in conjunction with a Merc-to-Merc relay has shown in tests that it responds to temperature changes of less than 0.01°C. The noiseless powerful "Precision" Octo-Mix stirrer circulates approximately 60 gallons of water per minute to assure uniform bath temperature. The auxiliary heater will bring bath temperatures from cold to operating in approximately an hour. Temperature range of heated model is from room temperature to 60°C.



Stainless steel manometer supports with built-in manometer guards have bridge-type construction which eliminates quiviering or wobbling. No twisting motion is employed in their operation. Glassware can be removed from manometer supports by loosening only three thumbscrews.

Careful designing has enabled "Precision" to incorporate these advances in a circular stainless steel apparatus with over-all dimensions only 27″ in diameter by 41″ in height. The Precision Warburg apparatus is available also in a combination heated and refrigerated model with a temperature range of 10°C to 60°C. Apparatus for temperatures lower thân 10°C can be supplied in custom built models.—Precision Scientific Company, *Chicago 47, Illinois.*

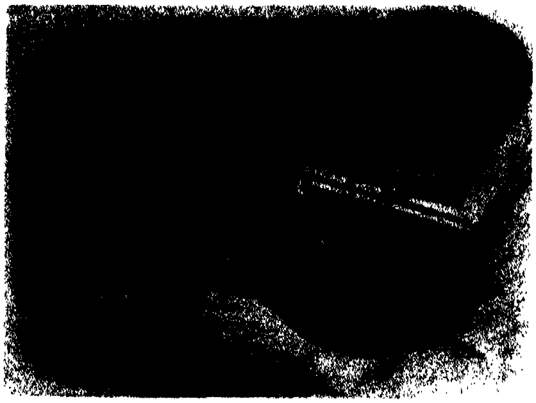
Thermoregulator

A new immersion-type Micro-Set Thermoregulator for laboratory use in controlling liquid temperatures in water and oil baths, or air temperature in ovens, etc., has a sensitivity of ±0.02°F over a range of 50 to 220°F. Only 15″ long, its patented design eliminates an outer shell so that there is a minimum of lag in response to slight temperature changes.

The Thermoregulator features a quick-adjustment sleeve which magnetically moves one of two electrodes so that the regulator will turn heating devices on and off to maintain any temperature within its range. The thermometer-shaped device has two capillaries, one with mercury which rises and falls with temperature to make or break contact with the upper metallic electrode. Contact points are sealed in hydrogen under pressure, eliminating corrosion, and load terminals are enclosed to eliminate danger from sparks. The device is for operation with relays such as the Fisher-Serfass Electronic Relay.—Fisher Scientific Company, *717 Forbes Street, Pittsburgh 19, Pennsylvania.*

Hand Torch

The new Torchmaster is a general utility, self-contained hand torch only 2¼" by 13" burning liquid petroleum gas (butane, propane, etc.). It holds enough fuel for an average day's burning. The torch will do light brazing, soldering, and innumerable heating operations. It burns upside down or at any angle and has a filtered "Wind-Pruf" burner that will not clog or blow out. It is of steel construction, satin-chrome finished, and of precision manufacture throughout. A single control valve turns the torch on and off and adjusts the flame from a pencil point to a roaring blowtorch. It is easy to handle, invaluable in cramped quarters, and can be carried or stored anywhere. Amazingly economical, it can be filled from standard containers for three or five cents.—Industrial Engineered Products Company, *7416 Melrose Avenue, Los Angeles 46, California.*



High Stability Carbon Resistors

A new resistor of outstanding characteristics is now available from Welwyn Electronic Components, Inc. Of the "cracked carbon" process of manufacture, the resistor element is a homogeneous film of pure carbon deposited on a porcelain tube. After aging, carefully fitted turned brass end caps are applied, into which the terminal leads are staked and soldered; the completed resistor is then brought to the required resistance value by spiraling in automatic machinery. The completed resistor is then given several coats of silicone, containing lacquer, to protect it from moisture and mechanical damage. This manufacturing technique assures high stability and careful adherence to tolerances. Normally made to 1 percent tolerance, it is expected that all resistors delivered in the American market will adhere to that figure for the life of the component. They can also be had in 2 percent and 5 percent tolerances, and in the sizes of ¼, ½, 1, and 2 watts capacity. American stocks in decade and RMA preferred values will be maintained at New York for immediate deliveries.

The lacquer coating is capable of operating at 150°C, and this factor can permit the resistor to dissipate full power rating in ambient temperatures of 100°C. The temperature coefficient of resistance of cracked carbon is of the order of 0.02 percent/°C, and this value can be taken to hold over the major range of resistance values. Voltage coefficient of resistance can be taken as of the order of 0.002 percent of the resistance value per volt applied.

The noise level to which Welwyn resistors approach is within a very few decibels of the minimum value as determined by the Johnson formula. As the resistance element is a homogeneous layer of carbon of almost monomolecular thinness in the higher resistance values, it can be appreciated that they are free from the customary sizzling and frying noises, so commonly associated with the composition carbon resistors.

The development technique has been so far perfected that these ***high stability*** resistors are offered in a range from 100 ohms to 50 M ohms in 1 percent tolerance, and wider ranges in a 5 percent tolerance of resistance values.—Welwyn Electronic Components, Inc., *234 East 46th Street, New York 17, New York.*

Laboratory Balance

New instrument-making methods and materials have made possible a radically new torsion-principle balance for general laboratory use. With a sensitivity rating of 2 milligrams (1/32 grain), and a capacity of 120 grams (4 oz.) a fast weighing balance of this type has manifold uses below the delicate work for which the accuracy of the enclosed-case, ultra-refined precision balance alone suffices.

The new balance is a torsion balance, with no departure from the principle of a beam balancing by means of ribbon metal bands acting in torsion, rather than pivoting on knife edges. Other than adherence to basic principle, the new product has undergone a complete re-engineering and modernization of design.

The beam graduations are in two parallel scales, one in grains, the other in grams—and one in black and the other in red to guard against confusion.—The Torsion Balance Company, *Clifton, New Jersey.*

Manufacturers' Literature

Technical Review—No. 1, an 8-page illustrated periodical, features a new electrodynamic high speed level recorder with writing speeds up to 1000 db/sec. and a new beat-frequency oscillator with regulating compressor, making possible recordings of frequency responses of microphones, amplifiers, loudspeakers, etc., building-acoustic recordings of sound insulation of walls, and automatic recordings of reverberation curves in halls.—Brüel & Kjaer, *Naerum, Denmark.*

Tracerlog—No. 15, 12-page house organ, includes a description of techniques for the use of beta-radiation and photon absorbers, a description and specifications of the SU-3A Laboratory Monitor for determining small amounts of radiation, and a list of uses for radioisotopes, Part II. Also contains index of all Tracerlog technical articles and data (January 1947 to December 1948).—Tracerlab, Inc., *55 Oliver Street, Boston 10, Massachusetts.*

Recording Paper—A 12-page illustrated reprint from Western Union *Technical Review* describes "Teledeltos," a dry electrosensitive recording paper for facsimile telegraph apparatus and graphic chart instruments. This non-electrolytic recording material is insensitive to light, not readily marked by heat, unaffected by cold, and impervious to fungus growth and parasitic organisms.—Development and Research Department, The Western Union Telegraph Company, *60 Hudson Street, New York 13, New York.*

Oscillographer—Vol. 11, No. 1, 16 pages, features an illustrated article on the Type 250 cathode-ray oscillograph. Other items are notes on improving the performance of Types 248 and 248-A cathode-ray oscillographs, an oscillographic crystal mode analyzer, and a bibliography of papers in contemporary publications of interest to those engaged in the application of the oscillograph.—Instrument Division, Allen B. DuMont Laboratories, Inc., *1000 Main Avenue, Clifton, New Jersey.*

Apparatus Notes—No. 502, a 12-page bulletin, contains detailed information on a variety of laboratory apparatus, including box furnaces, salt fog cabinets, mercury filters, pocket microscopes, program timers, tally counters, microscope lamps, weights, and support frames.—Andrew Technical Service, *4747 North Damen Avenue, Chicago 25, Illinois.*

Dynamometer—Bulletin D, a 4-page bulletin describes the Dillon Dynamometer, a portable, individually calibrated, fatigue-tested dynamometer for measuring traction, tension, or weight from 0–500 lb. to 0–20,000 lb. Unlike ordinary "spring" measuring devices, it operates through deflection of a special alloy steel beam, requiring only 0.040-inch movement to indicate a full-scale reading.—W. C. Dillon & Company, Inc., *5410 West Harrison Street, Chicago 44, Illinois.*

Current Data on High Vacuum Apparatus—8-page bulletin contains article on measurement of low pressures and notes on developments in the field of high vacuum.—Distillation Products, Inc., *755 Ridge Road West, Rochester 13, New York.*

Oscillo-Record Camera Accessories—Details on request of a new universal mount which is adjustable in height to suit any standard oscilloscope, a new adapter for mounting standard 35-mm 1000-ft or 400-ft magazines, and a Binocular Split Beam Viewer. These accessories are for the manufacturers' Oscillo-Record Camera.—W. J. Schubert, Special Camera Division, Fairchild Camera and Instrument Corporation, *88–06 Van Wyck Boulevard, Jamaica 1, New York.*

D.C.-A.C. Chopper—Single page Form 233C lists and describes a new Type 240 Chopper, designed specifically for operation at 0.050 ampere or less, and Type 222 Chopper, listed at 0.5 ampere or less.—Stevens-Arnold, Inc., *22 Elkins Street, South Boston 27, Massachusetts.*

Hermetic Seals

Cerroseal-35 is an indium solder that adheres directly to glass, mica, and some ceramics, and also bonds to the same metals as ordinary solder. It can therefore be used for hermetically sealing glass to glass or glass to metal. Its working temperature is approximately 260°F on glass, and it can be used for the sealing of glass dial covers on instruments, vacuum seals in glass laboratory apparatus, etc. It has the following advantages over the litharge-glycerine seal: it does not pull loose under vibration; is not dissolved by various vapors to which it is exposed in use; provides leak-tight joints which may be tested immediately after setting; less skill is required for assembling. Samples of this solder together with instructions for its use are available from the manufacturer.—Cerro De Pasco Copper Corporation, *40 Wall Street, New York 5, New York.*

Ductile Cast Iron

Magnesium has been considered to be completely unalloyable with iron but, if properly controlled, it can be incorporated in molten iron to bring about desirable changes. An effective way of doing this is by incorporating a nickel-magnesium alloy in molten iron. The cast alloy is characterized by a graphite structure in the form of spheroids, flake graphite being entirely absent.

The process is operative with practically all types of cast iron including hypo- and hypereutectic, ferritic, pearlitic, acicular, and austenitic varieties. For pearlitic grades of cupola-melted material containing 3.2–3.6 percent of carbon and 1.8–2.8 percent of silicon, the ductile iron (as cast) provides a combination of 85–105,000 p.s.i. tensile strength with some ductility. In contrast to gray cast iron, its strength is only moderately affected by section thickness. Under stress it behaves elastically like cast steel rather than cast iron up to high loads, with a modulus of elasticity of 25×10^6 p.s.i.

The high strength and rigidity of ductile cast iron make it applicable to heavy industrial machinery, while its ductility may provide thermal shock resistance far greater than has previously been available in high carbon castings. Resistance to growth and oxidation give promise of its usefulness in high temperature applications. A number of foundries have arranged manufacturing licenses under the pending patent application.—International Nickel Company, *67 Wall Street, New York 5, New York.*

Flexible Conduit

Flexpansion is a flexible metallic electrical conduit with a Neoprene coating bonded to the metal. The conduit and its fittings are liquid proof, airtight, and chemical resistant, and are stated to completely eliminate the danger that the wire within the conduit will be damaged by oil, grease, or other liquid. It has been developed for use on machine tools, chemical plant wiring, underground wiring, or other places in which ordinary conduit is likely to be short-lived. Nominal sizes range from ¼ to 2 inches. Lengths and end fittings may be specified.—TECHNIFLEX CORPORATION, *55 Jersey Avenue, Port Jervis, New York.*

High Temperature Flexible Tubing

Flextite Hytem is a plastic tubing developed for electrical insulation applications. This tubing is stated to have unusual resistance to high temperatures, good dielectric strength, high resistance to stretching, tearing, or abrasion, and to withstand exposure to oils, acids, and alkalies. Manufacturer's tests show that the tubing is not brittle and will not crack when flexed after 100-hour exposure to heat at 300°C. It is recommended for use under continuous operating temperatures up to 150°C.—MITCHELL-RAND INSULATION COMPANY, *51 Murray Street, New York 7, New York.*

Heat Exchange Tubing

A new fin design on heat exchange tubing makes use of crimped or corrugated helical fins. Tubing with this construction is available in lengths up to 25 feet. Tube diameters range from ⅜ to 1 inch and fin widths from ¼ to ⅜ inch. A typical application is in the construction of blast air-heating and -cooling equipment.—ROME-TURNEY RADIATOR COMPANY, *107 Canal Street, Rome, New York.*

Strapping Tape

No. 320 is a new Scotch paper tape, 13–15 mils thick, reinforced with thread-like fibers running lengthwise through it. It has a tensile strength of 180 pounds per inch of width. Faced with a pressure-sensitive adhesive, it adheres to the work and to itself as it is wound in place. It may be used in packaging structural shapes, pipe, rod, coils, etc., and in preparing such products as plate glass, plastic sheets, etc., for shipment. It is available in 60-yard rolls, in widths from ¼" to 23".—MINNESOTA MINING AND MANUFACTURING COMPANY, *902 Fauquier Avenue, St. Paul 6, Minnesota.*

Fire-Retardant Paint

Flame-Seal is a new fire-retardant and non-toxic paint which does not require mixing and which can be applied directly with brush or spray gun. This paint, when attacked by flame, undergoes a physical transformation, forming a hard protective crust at least 8 times the thickness of the original paint. Sustained exposure for 30 minutes at a single spot to flame from a blow torch at 2000°F is stated to cause some charring, but the coating will not at any time support combustion.

This paint is said to be moisture-proof and termite-proof, and will not craze, chip, peel, or crack. It can be washed with any standard cleaning powder or soap without decreasing its effectiveness as a flame-retardant. It is recommended by the manufacturer for use on all interior raw-wood surfaces.—STALLTON CHEMICAL CORPORATION, *8–14 37th Avenue, Long Island City 1, New York.*

Temperature Indicators

Tempilstiks, *Tempil Pellets*, and *Tempilaq* are the three forms in which this temperature indicator is available. The first is a crayon to mark a surface where temperature is to be read, the second is a pellet to be placed on the surface, and the third is a liquid that is spread or spotted on the surface and allowed to dry. Each will melt at the temperature for which it has been specified. These products are now available with melting points at intervals of 12½°F throughout the temperature range from 113 to 400°F, and with larger intervals up to 1600°F.—TEMPIL CORPORATION, *132 West 22nd Street, New York 11, New York.*

Dry Cell

The *Eveready Ignitor* No. 6 dry cell has been improved to provide 25 percent and 20 percent increase, respectively, in the ASA light intermittent and heavy intermittent test. This should be of advantage to those who use this cell for testing instruments, alarm systems, and similar applications.—NATIONAL CARBON COMPANY, *30 East 42nd Street, New York 17, New York.*

Neoprene Floor Mat

Neo-Sponge Comfort Mat is designed for use by workers who have to stand at their job. It is constructed of Neoprene rubber filled with minute nitrogen bubbles, and has a triangular raised pattern on both sides of the reversible unit. It is not subject to attack by oils, greases, or acids and is stated to be an excellent insulator both against electricity and heat. It is available in 18- and 36-inch widths, in lengths up to 9½ feet, and in ¼- or ⅜-inch thicknesses.—AMERICAN FLOOR PRODUCTS COMPANY, *1524 M Street, N. W., Washington 5, D. C.*

A Mass Spectrometer for Continuous Gas Analysis*

JACK A. HUNTER, RALPH W. STACY, AND FRED A. HITCHCOCK
Laboratory of Aviation Physiology and Medicine, The Ohio State University, Columbus, Ohio
(Received October 18, 1948)

An instrument for recording continuously the relative abundance of gases in a three component mixture is described. High accuracy of analysis has been sacrificed in favor of high speed response since the instrument was designed primarily for use in the investigation of respiratory problems. An instantaneous change in gas composition will appear on the record with a lag of less than 0.2 second and will require approximately 0.1 second to settle on this new value.

INTRODUCTION

PROBLEMS existing in several fields have shown the desirability of recording the composition of gas mixtures at various stages of a continuous process. The particular problem that prompted the development of this instrument concerned the changing composition of respired air. In the investigation of such respiratory problems it is necessary that the instrument have a "rise time"** less than 0.2 second with minimum lag.

It was deemed advisable to take the design of an instrument which had already proven itself and incorporate only the necessary modifications to achieve the desired performance. Accordingly, the instrument described in A. O. Nier's papers[1,2] was used as a basis for the design of this spectrometer.

GENERAL DESCRIPTION

Figure 1 is a schematic diagram of the general layout of the mass spectrometer. Air is drawn into the sampling system through a hypodermic needle (B) by a vacuum pump (A). It flows past a needle valve orifice (C) and a portion is drawn into the ion source (D). The ions pass into the magnetic field (E) and the components are deflected to fall on the collector plates (F, F′, F″). Static potentials on plates (G, G′) serve to bring the two outside components to bear on their respective collector plates. The electrometer tubes and the input resistors are mounted inside the receiver end of the spectrometer tube, and connection is made to the preamplifier through shielded cables. The output of the amplifiers is fed into mirror galvanometers which reflect beams of light onto a moving strip of photographic paper.

THE SAMPLING SYSTEM

The sample to be analyzed is pulled through a number 24 hypodermic needle and past the leak by a small vacuum pump,[3] as shown in Fig. 1. The line between the hypodermic needle and the leak has great effect on both time lag of response and the response time, and, therefore, should be kept as short as possible. A six-foot length of ¼″ O.D. copper tubing has been used satisfactorily.

The leak itself, shown in Fig. 2, consists of a needle valve. The needle used was an ordinary sewing needle usually designated as a No. 3 "between" needle, mounted in a brass bolt with a ¼-28-N.F. thread. The seat consists of a cylindrical brass rod 3 mm in diameter and 5 mm in length through which a 0.7-mm hole has been drilled. The variable constriction produced by the needle valve is introduced into the stream of gas in such a way as to obtain a very short flushing time. Readjustment of the needle valve is rarely necessary. The use of a pumping system somewhat larger than usual permits a leak of such dimensions as to reduce the effect of fractionation[4] to below the sensitivity of the instrument for a wide range of operating conditions. To demonstrate this, measurements of apparent relative abundance were made on CO_2 and O_2 in O_2-CO_2-N_2 mixtures. If fractionation exists, then varying the ratio of leak dimensions to mean free path would cause a change in the measured ratio of CO_2 to O_2. The fore pressure on the leak was held constant while the leak dimensions were varied sufficiently to change the vacuum from 10^{-5} to 2×10^{-6} mm Hg, and the ratio of CO_2 to O_2 remained constant to within experimental accuracy (±0.5 mm; 11 cm full scale galvanometer deflection).

---

* The work described in this paper was carried out under contract between the ONR and the Ohio State University Research Foundation.

** "Rise time" is defined as the elapsed time from the beginning of the response to the attainment of a new value, stable to within experimental accuracy, for an instantaneous input change.

THE SPECTROMETER TUBE

The spectrometer tube is constructed of metal throughout. That portion of the tube which passes through the magnetic field was flattened to slip between the pole faces of the magnet and curved to accommodate the ion beam curvature. This portion was formed from copper tubing $2\frac{1}{4}''$ in diameter with $\frac{1}{16}''$ walls. To this is attached a copper tee, one leg of which goes to the vacuum system. At the other end of the tee, a sylphon bellows is attached to facilitate focusing of the ion beam.[5] The ion source is mounted on a brass plate, which is bolted onto the sylphon end of the spectrometer tube. All temporary connections of the tube are made with grooved flanges fitted with Neoprene gaskets. Permanent connections are made with silver solder. Electrical connections are made through Stupakoff seals soldered into the tube. The receiver end of the tube is constructed from $4\frac{1}{2}''$ diameter brass tubing and is about 18'' long. The receiver assembly is mounted on a brass plate which is bolted onto the spectrometer tube in a manner similar to the ion source.

THE VACUUM SYSTEM

The vacuum system consists of the forepump,[6] a diffusion pump with a capacity of 250 liters per second at 10^{-6} mm Hg,[7] a cold trap in which liquid air is used routinely, a thermocouple gauge, and a Philips ion gauge. All metal parts of the vacuum system except the pumps were boiled in a bright plating bath to clean the surfaces. In practice, we have had no difficulty getting a vacuum of 5×10^{-6}

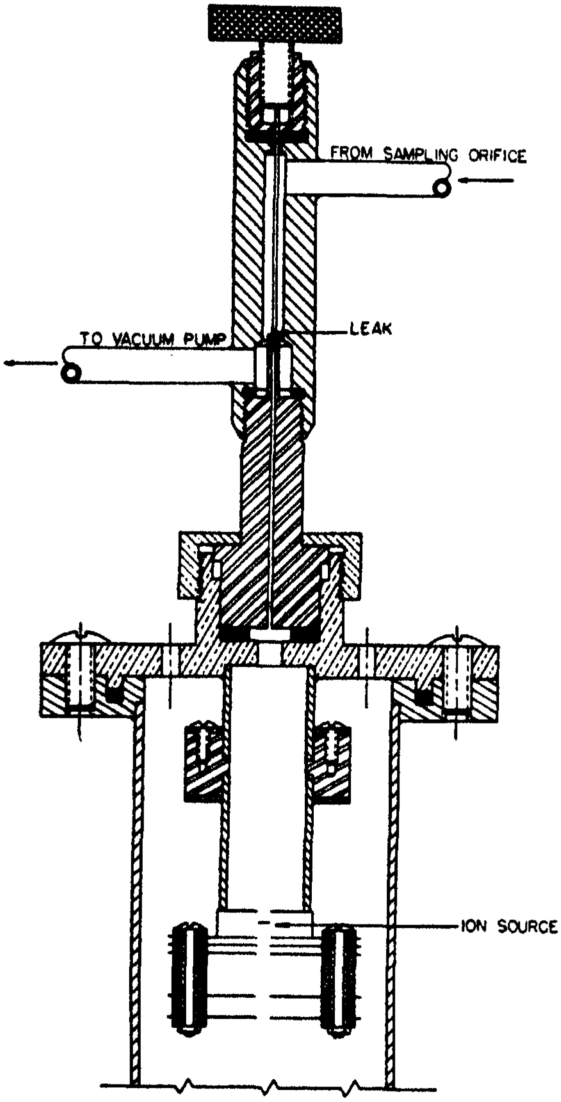

FIG. 2. Leak and ion source.

mm Hg without degassing. After the pressure has been reduced to about 5×10^{-6} mm, the needle valve is opened until the gas flow into the spectrometer tube is sufficient to raise the pressure to 10^{-5} mm Hg.

THE ION SOURCE

The ion source used is basically the same as that of Nier's instrument, except that tantalum was used instead of Nichrome V, and the ionization chamber was so designed as to offer appreciable resistance to flow of gas into the main vacuum chamber. This causes the pressure in the ionization chamber to be about 80 times that in the main vacuum chamber and thus permits the use of an oil diffusion pump even though we are working in the same mass range as the oil vapors. With this ion source total positive ion currents of 10^{-9} ampere are easily obtained with 200 microamperes total emission current.

The design for the electromagnet we have used is taken from Nier.[2]

THE RECEIVER ASSEMBLY

The problem of collecting a multiple beam becomes relatively simple when the masses are as widely separated as in the case of carbon dioxide, oxygen, and nitrogen. The receiver assembly (Fig. 3) consists of three sections, each composed of a

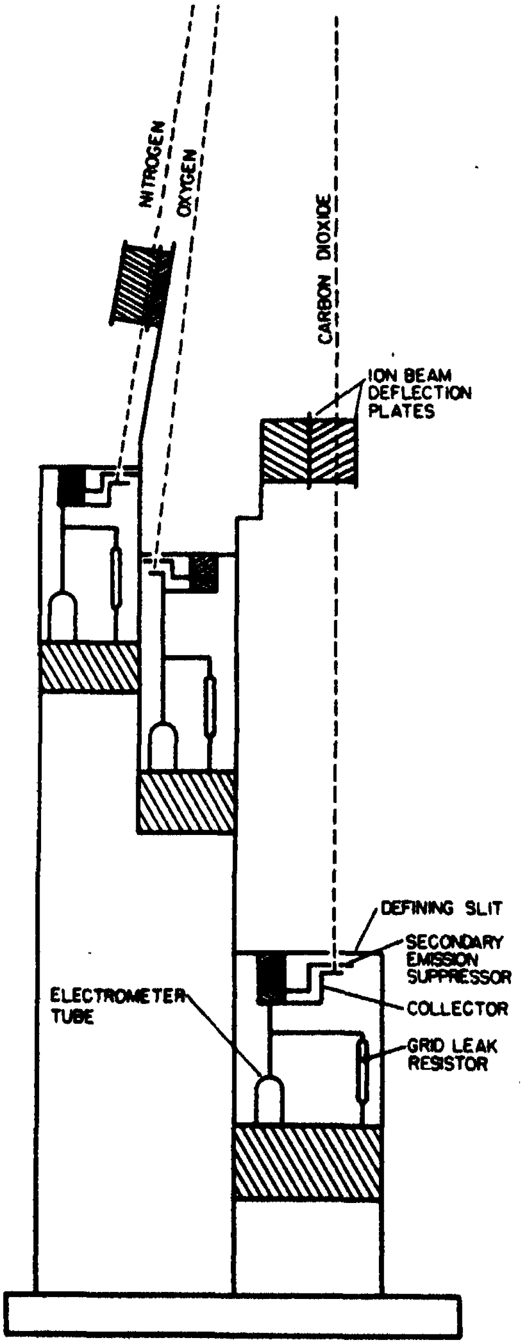

FIG. 3. Receiver assembly.

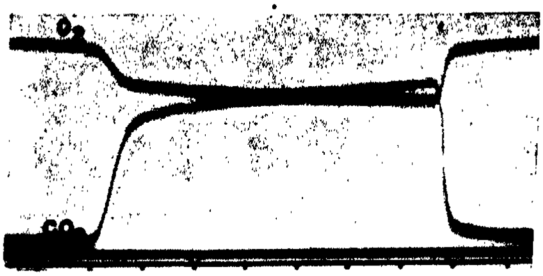

FIG. 4. A typical record of expiration.

defining slit, a secondary emission suppressor slit, and a receiving plate. Since it is difficult to determine exactly the separation between the three components, two sets of deflecting plates were added, through which the CO_2 and N_2 beams pass and are shifted slightly to bring them to bear exactly on their collecting plates when the middle beam is centered on its collector. A stabilized potential of 225 volts is taken from the amplifier power supply and brought to the plates through potentiometers and reversing switches. To reduce the capacitance of the collecting plates and their leads, the preamplifier stages are mounted in the receiver assembly. It is necessary to maintain great rigidity of the receiving plates relative to their surroundings inasmuch as there is appreciable response to low sonic frequencies.

ELECTRONIC COMPONENTS

With the exceptions to be noted for the amplifier and its power supply, the electronic equipment is the same as that of the Nier instrument. The first modification consists of omitting the condensers across the preamplifier grid leak resistors. These condensers were used by Nier to match the time constants of the channels, which is not necessary in our work.

The second modification consists of changing circuit elements of the power supply to increase its current capacity to one-half ampere in order to permit the addition of a third channel in the amplifier, and an extra stage of amplification to each channel in order to drive the relatively insensitive galvanometers we have used.

Finally, the addition of a third channel made necessary some change in the filament supply of the amplifier. In order to keep the filaments of the various stages near the cathode potentials the 12-volt filament tubes were changed to 6-volt tubes and ballast resistors introduced at appropriate points. Similar changes were made in the preamplifiers.

The recording has been accomplished with three type G-6 G. E. galvanometers reflecting light beams onto the lens of a 12-cm Cambridge strip camera. In operation, a film speed of one inch per second has been used. The galvanometers are of the ribbon type and are serviceable up to 500 c.p.s., which, along with their rather low current sensitivity, has been found to be a handicap, since any "hash" picked up from other apparatus is recorded. These galvanometers are to be replaced with recorders[8] which have a full scale response of 250 microamperes in less than 0.25 second.

PERFORMANCE

Figure 4 is a record which is typical of that obtained when a normal expiration is recorded with the sampling orifice placed just in front of the lips. The instrument is calibrated at the end of each recording with a gas mixture of known oxygen and carbon dioxide content. By setting up the relations between calibration excursions and experimental excursions in a simple algebraic ratio, results have been obtained which are consistently accurate to one millimeter partial pressure of oxygen or carbon dioxide. That the oxygen in air sampled had no effect on the carbon dioxide reading was demonstrated by transferring the sampling needle from a stream of 100 percent nitrogen to 100 percent oxygen. When this was done the carbon dioxide reading remained consistently on zero. In a similar manner it was demonstrated that the carbon dioxide in the sample had no effect on the oxygen reading.

The rise time of the instrument was determined by placing the needle orifice in a stream of gas mixture which differed in oxygen and carbon dioxide content from room air, then suddenly removing the needle into room air. The change thus observed begins about 0.2 second after the movement of the needle, and is complete within 0.1 second of the time it begins. The rise time is essentially the same for oxygen and carbon dioxide, indicating that the memory effect due to adsorption of gases onto the metal parts of the ion source (which is seen to the greatest extent in carbon dioxide) is negligible.

ACKNOWLEDGMENTS

The cooperation of the Betatron Laboratory at Ohio State University and of its director, Dr. T. J. Wang has been of great value in the design and construction of the instrument.

THE REVIEW OF SCIENTIFIC INSTRUMENTS VOLUME 20, NUMBER 5 MAY, 1949

A Microwave Polarimeter

ALFRED E. SCHWANEKE[*] AND ZABOJ V. HARVALIK[**]
University of Missouri, School of Mines and Metallurgy, Rolla, Missouri

(Received December 6, 1948)

A microwave polarimeter is described which enables the determination of rotation of the plane of polarization of microwaves in the 3.2-cm band. The transmitter-analyzer utilizes klystron tube 723 A/B. The microwaves are fed into a horn which acts as a polarizing agent. The analyzer-receiver consists of a horn antenna, rotatable wave guide, a crystal detector, and an indicator. The microwaves are rectified by a crystal rectifier, and are either detected by a microammeter, a galvanometer, or by an amplifier of appropriate design. Changes of angles of rotation can be detected if they are not less than 2° to 3°.

INVESTIGATIONS regarding the behavior of microwaves have disclosed that their physical properties are more or less identical with those of visible light. A certain kind of phenomenon of interaction of microwaves with matter will show a pronounced difference, however, due to differences in wave-length. This difference is even more pronounced with respect to absorption and reflection when microwaves are directed against matter. This paper describes a microwave polarimeter which might prove useful in the investigation of polarized microwaves and their interaction with reflecting and absorbing substances.

The microwave polarimeter, like the optical polarimeter, uses a polarizer and an analyzer, but it differs in that the microwave-polarizer also includes a microwave-generator. A klystron tube (723 A/B) generates microwaves of 3.2-cm wave-length and about 25 milliwatts. The microwaves are fed by a wave guide into a horn which acts as the polarizing agent. In the analyzer a system of horn and wave guide also is used. The microwaves reaching the horn of the analyzer are transmitted by a wave guide to a loop. The microwave energy induced in the loop is transmitted to a coaxial line, which permits the rotation of the horn over a range of 360°. Using a coupling antenna, the energy from the coaxial line is transferred into a wave guide, into which a 1N21 crystal detector is inserted. The output current is fed from the detector into an amplifier or microammeter or galvanometer.

The essential features of the polarimeter are shown in Fig. 1. The polarizer portion consists of a type 723 A/B klystron generator coupled to a short section of a wave guide which radiates energy into space through a pyramidal horn antenna. This antenna radiates a plane-polarized wave that is intercepted by another horn which serves as the antenna of the receiver-analyzer. A special coaxial-line-rotating joint allows the analyzer horn to be rotated in order to measure the polarization characteristics of the received energy. This special joint couples the energy to a semi-resonant section of wave guide terminated in a silicon crystal rectifier (1N23). The output of the polarizer can be fed either into a galvanometer or into an amplifier with the following modification: If the output of the polarizer is amplitude modulated by a 1000-cycle/second wave, this modulation is appearing as a 1000-cycle varying voltage across the crystal rectifier with a steady, true current component of the rectified carrier. This complex current is passed through an impedance transformer (T3 of Fig. 8). The resulting 1000/cycle-second square wave is then sent through the amplifier to a vacuum tube voltmeter which indicates the received signal in-

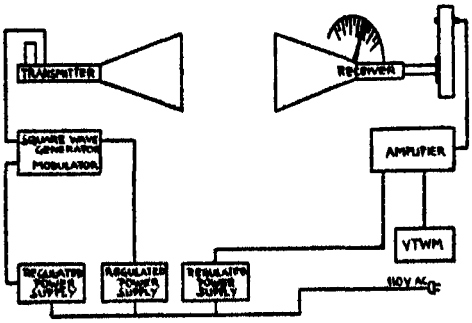

FIG. 1.

[*] Now at Central Missouri State Teachers College, Warrensburg, Missouri.

[**] Now at Institute of Science and Technology, University of Arkansas, Fayetteville, Arkansas.

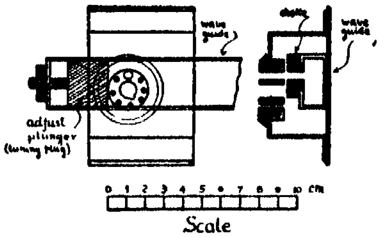

FIG. 3.

tensity. Any change of amplitude in the receiver is recorded by the voltmeter.

Variations in the line voltage would cause variations in frequency and amplitude of currents and voltages appearing in all components of the above described system. Therefore, the power supply must be regulated. The connection of power supply with the transmitter-polarizer is shown in Fig. 2. If an amplifier is used with the analyzer-receiver, an identical power supply is recommended for the amplifier, as well as for the modulator which causes the 1000-cycle/second signal in the transmitter polarizer. These power supplies show a regulation better than 1 percent over the range of 150 to 350 volts output.

TRANSMITTER POLARIZER

The transmitter-polarizer section of the polarimeter is relatively simple in its construction. One end of a wave guide, 15 cm long, is terminated in a flange; the other end is terminated with a close-fitting, rectangular, machined brass plug, which includes an adjusting screw to vary the plug position over a range of about 1 cm. At a distance of 1.0 cm from the central region of travel of the brass plug, a hole is drilled to mount a quarter-wave choke coupling to take the coaxial output line from the klystron. This choke coupling is used to insulate the wave guide from the flange of the line, since the flange is at a beam potential of +250 to +300 volts. A small chassis is placed above this hole. On it is mounted a modified octal socket to receive the klystron, and an octal plug to furnish the various voltages to the klystron. Detail of the klystron mount and the wave guide connection is shown in Fig. 3. The horn antenna is attached to the choke flange at the other end of the wave guide section. This type of construction enables the guide to be excited in its simplest mode, namely, the TE 1.0 mode which radiates a wave from the horn that is plane-polarized parallel to the short dimension of the guide, which, in this case, is vertically polarized.

If the reflector or repeller voltage of a klystron is varied sinusoidally or by a saw-toothed wave shape, the resulting radiofrequency output will undergo ordinary frequency modulation at the rate of the varying voltages applied.

If a square wave variation is applied to the repeller potential, the result will be amplitude modulation of the klystron output power.

To simplify the receiving system, the klystron is amplitude-modulated with a square wave of approximately 1000 cycles/second. The modulator consists of a multi-vibrator which produces essentially a square wave voltage, a positive peak-type tube circuit to insure a flat-topped positive peak, and an amplifier to produce the power output required for best modulation. The output of the square wave amplifier is coupled to the klystron repeller through a 0.5-microfarad capacitor. A diagram of the modulator and its controls is shown in Fig. 4.

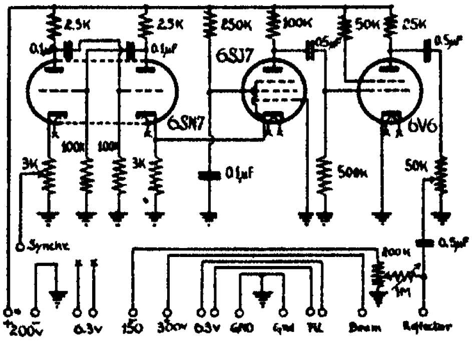

FIG. 4.

RECEIVER ANALYZER

Rotating joints for wave guides have been used extensively in radar work. These joints allowed lateral or azimuth rotation without rotation of the plane of polarization, and a search revealed that no type was suitable for sensitivity to only one plane. Therefore, the receiver analyzer for this instrument, in order to fulfill the requirement of being sensitive to only one plane of polarization, had to be of a special construction. Furthermore, it must contain a device which permits the continuous rotation of the plane of polarization to an axis in line with the transmitted energy from the polarizer. The receiver developed for this instrument is shown in Fig. 5.

A wave guide similar to that used in the transmitter polarizer, with its associated flange, is mounted in lubricated bearings cast of lead with brass sleeves. These bearings allow a free axial rotation of the wave guide. The receiving horn is attached to the flange. The opposite end of the section of the wave guide supports a special rotatable coupling.

A machined brass plug fits tightly into the end of the wave guide. A brass tube, 3.2-cm inside diameter, extends through this plug and serves as the outside conductor of a coaxial line centered in this tube. A wire terminating at the inside of the brass plug in a small loop 0.4 cm in diameter serves as the center conductor of the line. The orientation of this loop determines the response of the receiver to the plane of polarization or the energy in the wave guide. In this case the response must be limited to transverse electro-magnetic fields only (TE 1.0). As all waves have associated magnetic fields at right angles to the electric field, the solution to obtaining a plane-polarization response at the end (plug) of the guide is to mount the loop to respond only to the magnetic lines of force which are parallel to the long dimension of the guide.

The use of the loop with its axis parallel to the long dimension of the guide, in order to link only the magnetic lines of force appearing across the long dimension of the guide, allows a coaxial line to pass out of the geometric center of the plug in the guide. As far as could be determined, this type of coupling has not been used before, for all commercial line-to-wave guide couplings make use of a quarter-wave probe placed parallel to the electric lines of force in the guide. This requires a wire across the short dimension of the guide which necessitates a connection through the sides of the guide. In this case the connection would interfere with the rotation of the receiving horn. A detail of the special coupling is shown in Fig. 6. The loop supports the center wire of the coaxial tube and is soldered to the plug. This makes a rigid support without the use of insulating materials.

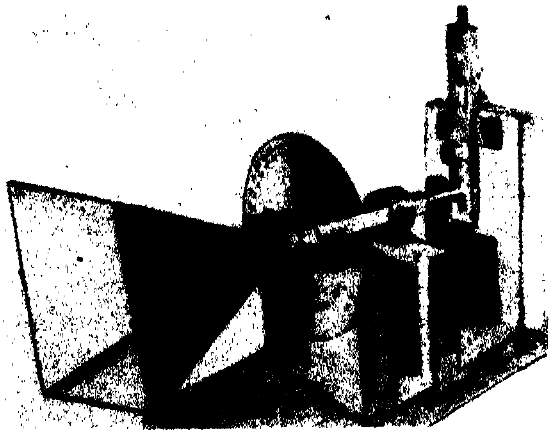

FIG. 5.

The other end of the coaxial tube rotates in a slip ring arranged to allow free mechanical movement and yet maintain good electrical contact. A quarter-wave choke here would reflect high resistance to the two contacting surfaces and would be a desirable refinement. The coupling to the wave guide semi-resonant cavity is usually the familiar quarter-wave probe inserted through the side of the guide. This probe at this end of the coaxial tube is supported by a thin filament of acetate glue placed at a point of high electrical impedance. This movable tubing plug shown in Fig. 6 assures the passage of energy from the probe toward the crystal detector. The crystal is placed slightly off center across the short dimension of the wave guide cavity to afford a better impedance match of the crystal characteristics to the guide or cavity impedance. The systems can be tuned with great ease and stability.

A microammeter or galvanometer attached to the crystal was first used to receive the signal. To increase sensitivity, however, the amplitude modulation voltage appearing across the crystal was amplified and then measured with a vacuum tube voltmeter. A Silver Vomax, Model 900, vacuum tube voltmeter was used. A circuit of the receiver amplifier is shown in Fig. 7.

HORN ANTENNAS

The antennas used in this instrument are identical for receiver and transmitter, and are of standard pyramidal form. Other types can be attached to the choke flanges whenever a special wave, such as a circular polarized one, is desired.

The pyramidal horns are constructed of copper sheeting and are soldered to the flanges. This enables the horns to be attached to the standard flange of the wave guide.

The angle of flare in the horizontal plane is 40°. This angle was chosen to obtain the greatest attenuation of other unwanted modes or planes of polarization while gaining the maximum intensity of the transverse electrostatic plane of polarization. The length of the horns, five wave-lengths or 16 cm, was chosen for constructional ease. The flare in the vertical plane is also 40°. The flare in this plane is not absolutely necessary, but was in-

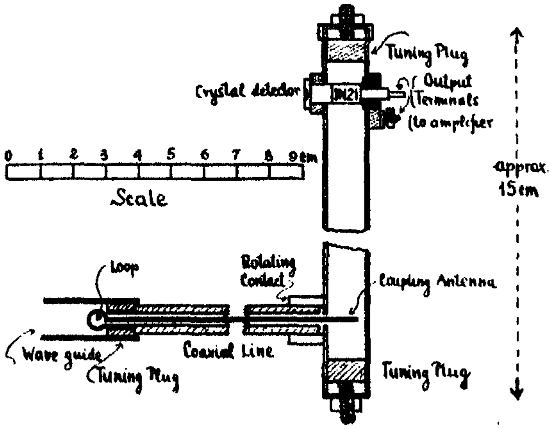

FIG. 6.

corporated to obtain a sharper beam of energy in the vertical plane. The angle used was selected for the same reasons as the other 40° angle, merely for attenuation of unwanted modes and gain for the preferred planes of operation. The calculated beam width, considering the dimensions used, is approximately 20°.

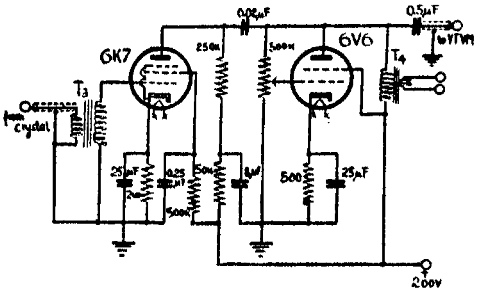

FIG. 7.

According to theory, the area of the opening of the horn becomes a phantom array of phased dipoles: the greater the area, the larger the number of phased units. This accounts for the sharp response of the horn antenna.

OPERATION OF THE POLARIMETER

In operation, the polarizer is clamped to one end of a table, while the receiver-analyzer is clamped a short distance away, facing the transmitter. Celluloid protractors are fixed to the base of the receiver, with the rotating section of wave guide passing through its center. A pointer on the rotating part indicates the angle of movement of the horn. These protractors are marked to 30 minutes of a degree.

With the correct voltages applied to both transmitter and receiver, the receiver-analyzer horn is rotated in small angular steps, and the readings on the vacuum tube voltmeter are recorded for graphing on polar coordinate paper for calibration. Then the samples are placed between the polarizer and analyzer, with the resulting data recorded as above.

The graphs of the voltage readings are not true pictures of the polarization planes or polarization characteristics of the received waves, but the following characteristics may be deduced from them: If the resulting curves do not reach true nodes at two separate 180° settings of the horn, the analyzer waves are probably elliptically polarized. The shape of this ellipse may be shown by drawing the normals to the angular lines representing the voltage for that angle. These normals will be tangent to the ellipse of the received waves. If the normals do not produce an ellipse and the voltages show true nulls, the received waves are plane-polarized. The plane of polarization is then parallel to a line drawn through the nulls. Calibration graph is shown in Fig. 8 and will clarify this point.

It was contemplated to increase the sensitivity as well as a continuous recording of the polarization properties of the sample by rotating the analyzer horn continuously about half a revolution per second with a Selsyn motor. This motor can be synchronized by applying a circular sweep to an oscilloscope with a long persistance screen somewhat on the order of a PP1 radar system. The plane of polarization would then appear instantaneously, and any change in the polarization characteristics of the received wave could be easily recorded.

CALIBRATION OF THE INSTRUMENT

The calibration showed that this instrument is accurate enough to read planes of polarization to within 3°. This calibration graph is shown in Fig. 8 and was taken without any obstructing sample between the polarizer and analyzer. The reference zero is determined by allowing the receiver-amplifier to operate with the transmitter and modulator turned off. The voltage indicated under these conditions will be the noise output generated in the circuit of the amplifier. In all of the measurements made, this reference zero was 0.8 volt or less.

This microwave polarizer is intended to be used to investigate polarization phenomena of materials placed between the transmitter-polarizer and analyzer-receiver.

Of interest are investigations of the Faraday effect in the region of microwaves, rotation of polarization planes by different dielectric materials, refractions in connection with polarization and rotation, phase relationships, and similar phenomena.

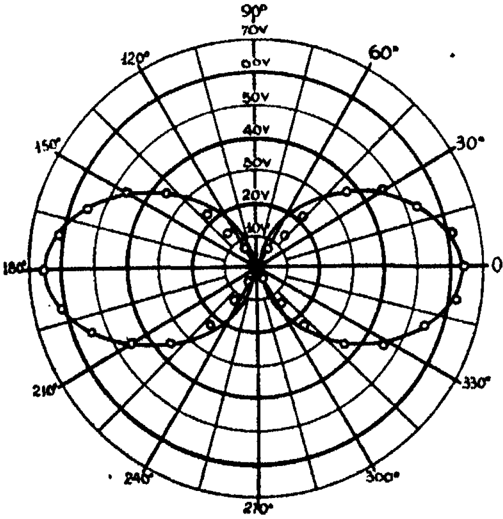

FIG. 8.

This paper is essentially the content of the thesis for partial fulfillment of the requirements for the degree of Master of Science in Physics at the University of Missouri, School of Mines and Metallurgy, Rolla, Missouri. The complete thesis of Mr. A. E. Schwaneke is deposited with the library of said institution.

The microwave polarimeter has been exhibited at the student exhibit of the Colloquium of the College Physicists, S.U.I., Department of Physics, Iowa City, Iowa, June, 1948.

Photomicrography of Tracks in Nuclear Research Emulsions

Adair Morrison and Fred Morton
Physics Division, National Research Laboratories, Ottawa, Ontario, Canada

(Received November 8, 1948)

A simple projection system and film holder for taking photomicrographs of particle tracks in photographic emulsions of the type used for nuclear research is described. With this film holder a series of exposures covering a considerable length of the track image is obtained on a single film as adjacent segments of track are brought successively into sharp focus and recorded.

In reporting experiments in which nuclear disintegrations, produced by cosmic rays and by fast neutrons, were observed in photographic emulsions, it was found very difficult to produce good photomicrographs of the events. The tracks to be photographed were often several hundred microns long and they usually slanted through the emulsion. With the conventional photomicrographic equipment, a very large number of photographs was required and on each of these only a short length of the track was in focus. The amount of time and material required was excessive and the accurate alignment and assembly of the short lengths into a mosaic was difficult so another method was sought. A fairly successful solution of the problem was found by using a rather simple projection system and a special film holder.

The projection system consisted of a microscope lamp, a shutter, the microscope, a right-angle prism with the 45° surface silvered, and a front-surface mirror. (See Fig. 1.) The beam of light through the microscope, after two reflections, formed an image on the table top beside the microscope. An oil immersion objective and a low power eyepiece (3× or 5×) were used. Either a filament or vacuum-arc type of lamp was used.

The film holder, designed to expose—a few millimeters at a time—a strip of film aligned with

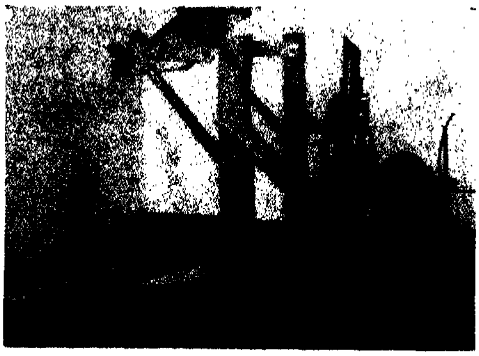

Fig. 1. Projection apparatus consisting of microscope lamp, shutter, microscope, right-angle reflection prism, and front-surface mirror. Microscope and mirror are mounted on a heavy metal base. Film holder in place on white circle representing illuminated field of view.

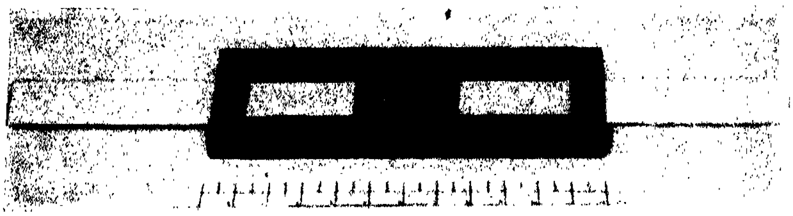

FIG. 2. Film holder for photomicrography of tracks in nuclear research emulsions.

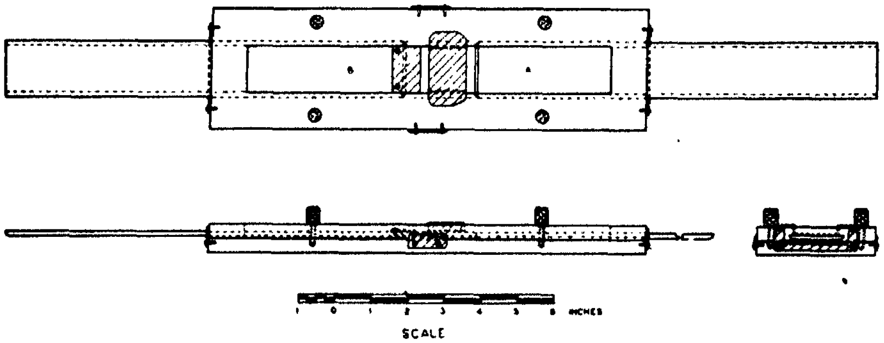

FIG. 3. Drawing showing construction of film holder.

the track, consisted of two pieces of black Bakelite, with the film between them, clamped together with thumb screws. The upper piece had a rectangular opening cut through it directly above the film; this opening could be partly or completely closed by two white slides traveling just above the surface of the film. These traveled in a channel cut into the lower face of the upper Bakelite piece from one end to the other. The dimensions and details of construction are shown in Figs. 2 and 3.

In the first design the ends of the slides were accurately fitted so that they were light-tight when butted together and each was beveled so that it would not cast a shadow on the film when used near the end of its travel. By moving either slide *A* or *B* (Fig. 3) a length of film was exposed and the amount exposed was determined by the separation of the ends. An improvement was made by adding to the end of slide *B* a piece of brass which projected about half an inch over slide *A*, and by placing a brass runner an inch wide in the opening above slide *A*. These then had the function of limiting the length of the exposed area, while slide *A* now acted only as a shutter. The runner was held firmly in place by the spring pressure of its two vertical portions against the walls of the opening. The horizontal portion of this brass piece was just above slide *A*, but not touching it, and was at the same level as the brass piece attached to slide *B*.

Ease of loading in the dark was assured by the guides attached to the lower piece, by the symmetrical placement of the thumbscrews, and by the clamping of the film between the surfaces of the two pieces so that its exact size and position did not matter. Since the device was used in a darkroom, no protection was necessary for the edge of the film.

The loaded film holder, with slide *B* in its extreme withdrawn position, was placed on the table top aligned with the track to be photographed. The runner and the microscope fine control were adjusted so that the sharply focused part of the image lay between the runner and the brass piece on slide *B*. With the shutter in the light beam closed the film was uncovered by moving slide *A* till its end was under the runner. After making the exposure, slide *B* was moved over till the brass extension reached the runner, and slide *A* was moved back till it again touched slide *B*. This process was repeated along the whole length of the film.

With successive strips of this kind, long tracks were conveniently photographed and, from contact prints, a mosaic of the track was assembled on a large sheet of white cardboard. The completed mosaic was photographed to secure final prints of the desired size. The film used was "Kodalith Ortho Thin Base Film," chosen because of fine grain, high contrast, and availability.

It was necessary to adjust the lamp and the microscope very carefully so that the whole field of the projected image was uniformly illuminated.

The particular advantages of this method may be summarized as:

(1) No special photomicrographic camera is needed, since prism and mirror can be obtained cheaply, if not already on hand, and the film holder can be built locally.

(2) Long tracks, either single or radiating from stars, can be quickly photographed on a few films; thus the amount of processing and printing is reduced and the construction of a mosaic is greatly simplified.

A High Temperature X-Ray Diffraction Camera* †

JAMES W. EDWARDS, RUDOLPH SPEISER, AND HERRICK L. JOHNSTON
The Ohio State University, Columbus, Ohio

(Received January 3, 1949)

A high temperature x-ray powder diffraction camera has been designed to yield patterns at temperatures in excess of 2500°K. The sample, in form of a wire, compacted rod, or contained (wherever suitable) in a thin walled quartz or ceramic tube, is heated indirectly by conduction and radiation in a thin walled molybdenum, tantalum, or platinum furnace. The furnace is heated by high frequency (0.5 megacycles) eddy currents induced by a small induction coil. The cylindrically shaped furnace and the sample are held coaxially in the induction coil and slowly revolved. The specimen temperature is maintained constant to ±0.2 percent by an especially designed temperature regulator. A water-cooled copper jacket with slots covered with metal foil to filter the diffracted x-radiation surrounds the furnace and is used to protect the x-ray film from heat and light. The temperature of the specimen is measured with a disappearing filament optical pyrometer at temperatures in excess of 1100°K and a platinum, platinum-rhodium thermocouple at lower temperatures. The camera is either operated with a high vacuum or with an inert gas atmosphere.

INTRODUCTION

THE camera described in this paper has been developed as a part of a research program devoted to the study of the thermodynamic and physical properties of inorganic solids at elevated temperatures. With the aid of induction heating, a high temperature powder diffraction camera has been designed which will yield x-ray photographs at temperatures in excess of 2500°K.

Induction heating[1] was chosen for several reasons:

1. The very high temperatures readily attainable—virtually limited only by the melting points of the furnace elements.
2. The simplicity of camera design possible.
3. The elimination of ceramic material for the support of heating elements—thus problems of extensive outgassing and thermal shock and the use of substances with unfavorably high total emissivity are avoided.
4. The robust construction of the heating elements possible lead to long life furnaces.
5. The very rapid attainment of temperature equilibrium within the furnace—one minute or less—leads to an efficient use of the camera.

In induction heating, the object to be heated (which must be a conductor) is placed in the center of a work coil where it is heated by the eddy currents induced by the r-f current flowing in the work coil. Non-conductors can only be heated by radiation and conduction. For this reason and the fact that conductors of very small diameter cannot be effectively heated by low frequency oscillators, the furnace of the x-ray camera is designed to heat the specimen indirectly. This is accomplished by supporting the specimen to be studied inside a chamber made of a refractory conductor (e.g., tungsten, tantalum, molybdenum, graphite, or platinum). The chamber (furnace) is then placed in a suitable work coil and heated by the induced eddy currents. The minimum size of the furnace is dictated by the frequency of the power source and the maximum size is set by the total allowable radiation losses from the surface of the furnace. Cylindrical chambers of $\frac{3}{8}''$ to $\frac{3}{4}''$ diameter and 1″ high were found to work well with the equipment used in this laboratory.

The x-ray film is effectively protected from the intense heat and light emitted by the furnace by the use of a water-cooled copper radiation shield which completely surrounds the work coil and furnace. The shield is slotted and the slots are covered by metal foil transparent to x-rays of the desired wave-length.

Depending upon the nature of the specimen and furnace elements, the x-ray camera can either be operated at high vacuum or with suitable inert gaseous atmospheres. If platinum furnace elements are used, the camera can be operated in air up to temperatures where the vaporization of platinum becomes excessive—about 1500°C. Tantalum furnace elements have been successfully used in high vacuum up to 2250°C. Undoubtedly, furnace elements made of sintered tungsten would increase the practical temperature limit of operation several hundred degrees.

At low temperatures (room temperature—1500°C), the temperature is measured with a platinum-platinum 10 percent rhodium thermocouple. The thermocouple is shielded to a considerable degree from the r-f-field by the furnace elements, their supporting members and the copper

cooling jacket and is further shielded by shielding tape outside the heating zone. A filter network is used to eliminate the very small r-f-pick-up that does occur. No difficulty has been experienced in measuring temperatures accurately in this manner.

High temperatures—850°C and up—are measured with an optical pyrometer.

DESCRIPTION OF CAMERA

A general view of the camera is shown in Fig. 1. The specimen in the form of a wire or compacted rod is mounted vertically in tube E (Fig. 2) in the center of the lower furnace element, and extends upward into the upper furnace element. These elements are constructed from 0.010″-tantalum sheet, the inside and outside open-ended cylinders being drawn in suitable dies. The furnace elements are $\frac{9}{16}$″ high by $\frac{3}{4}$″ O.D. and $\frac{1}{2}$″ I.D. The sample holder, E, in the lower cylinder is a tantalum tube 0.03″ I.D. The various parts of the furnace are either riveted or welded together. The holes, D, in the outer cylinder (4 holes in the upper and 4 in the lower furnace elements, 90° apart) are sighted upon with the optical pyrometer in making temperature measurements. The vanes, F, set in at 45° to the axis of the holes help to create a "hohlraum." The furnace elements are supported by tantalum strips which in turn are fastened to small tantalum radiation shields. If these shields absorb too much of the r-f energy, they are cut by several radial slots which minimizes this effect. The open ends of the furnace elements are about 2 mm apart in the assembled camera; the space between being for passage of incident and diffracted x-radiation. The furnace is surrounded by a 1″-I.D. coil (4 or 6 turns) of $\frac{3}{16}$″-copper tubing.[2] This coil is wound so that the turns are essentially horizontal with spacing $\frac{1}{16}$″ except for the middle spacing which is $\frac{1}{8}$″. The latter spacing is for passage of x-rays. The furnace is heated by induced eddy currents when an r-f-current is passed through the work coil.

---

[2] The detailed design of the work coil, that is, the coupling to the work and the number of turns to be used, depends upon the energy input into the work required. An excellent book discussing the theory of induction heating is G. H. Brown, C. N. Hoyler, and R. A. Bierwirth, *Theory and Application of Radio-Frequency Heating* (D. Van Nostrand Company, Inc., New York City, 1947).

A cylindrical copper cooling jacket (see Fig. 1) surrounds the furnace and work coil. This jacket is wound with $\frac{1}{4}''$-copper tubing through which water is passed for cooling. The upper end of the cooling jacket is closed with a closely fitting copper plate $\frac{1}{8}''$-thick. This plate supports the upper furnace element. A monel tube for support of the lower part of the furnace passes through the center of cooling jacket base plate. A $\frac{3}{8}''$-wide horizontal slot around the cooling jacket allows diffracted x-rays to pass. This slot is covered with metal foil (Ni where CuK α-radiation is being used) to prevent heat and light from striking the film as well as for filtering the x-radiation.

The film is held inside a cassette of 11.459 cm diameter and the Straumanis arrangement is used. The ends of the film fall in the shadow cast by the section of the work coil which crosses the specimen level. The film is further protected from light by a slotted mask which slides into the cassette and is held in place by two threaded collars. The slot in the mask is covered with metal foil.

The top of the cassette fits into a shoulder in the body cylinder. This joint is made vacuum-tight by a $\frac{1}{16}''$-thick Neoprene gasket which is held down with a brass ring. The body cylinder is fastened to the base plate in the same way.

The collimator fits into a hole in the body cylinder and passes through holes in the cassette and cooling jacket. A copper jacket fastened to the cooling jacket surrounds the collimator to prevent it from being heated. The hole through the collimator is covered with aluminum foil to maintain a vacuum.

Opposite the collimator are holes through the cooling jacket, cassette, and body cylinder through which the emergent beam passes and through which the furnace can be observed with an optical pyrometer through a lead glass window. Inside the window is a shutter which is actuated from the outside by a small magnet. This shutter is normally closed to prevent material evaporated from specimen and furnace from condensing on the window causing pyrometric readings to be low. The shutter can be opened for observations or moved so as to interpose a fluorescent screen in the x-ray beam.

The specimen is rotated by means of a shaft passing through a double Wilson[8] seal in the center of the base. The upper end of the shaft terminates at a friction joint. A monel tube in the upper part of this joint supports the lower furnace element. By means of the adjusting arm the upper member of the friction joint can be moved laterally to adjust for eccentricity of the specimen. The lower furnace element and specimen can also be adjusted vertically by the vertical adjustment lever. All adjustments of the specimen can be made externally while the camera is in operation.

The vacuum system is connected through the bottom of the camera. (See Fig. 2.) A Distillation Products oil diffusion pump VM2 and a Duoseal fore pump are used to maintain the high vacuum.

TEMPERATURE MEASUREMENT AND CONTROL

The temperatures in the range 850°C and higher are measured with a Leeds and Northrup Model 8622-C disappearing filament optical pyrometer. The pyrometer is sighted through the observation window into the "hohlraum," D (Fig. 2), in the furnace elements. The temperatures in the upper and lower furnace elements are measured. The rotation of the lower furnace element is interrupted momentarily to read the temperature in each quadrant. These temperatures are then averaged to determine the temperature of the specimen. The pyrometer used is calibrated every 100 degrees between 800°C and 2300°C using a General Electric ribbon filament tungsten lamp standardized at 100 degree intervals by the National Bureau of Standards.

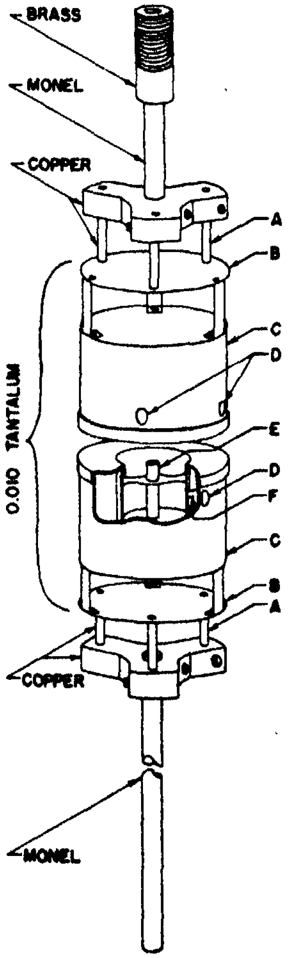

FIG. 2. Tantalum furnace.

[8] R. T. Wilson, Rev. Sci. Inst. 12, 91 (1941).

b

a

FIG. 3a. Tantalum-room temperature. FIG. 3b. Tantalum 2000°K.

Since a small temperature difference exists between the furnace elements and specimen, the temperature scale in the camera is established by observing the melting points of small samples of metals such as copper, iron, and platinum placed at the specimen level. The calibrating substances are set in the specimen holder and observed with the optical pyrometer at the same time the temperature of the furnace elements is measured. The accuracy of the temperature measured in this manner is limited by the precision of the pyrometer. The precision of the pyrometer is about 0.2 percent of the absolute temperature at 2000°K depending upon the observer.

For making diffraction patterns of certain oxides in air (in the temperature range room temperature—1400°C), platinum heating elements may be used.

These elements are similar to the design shown in Fig. 2, except that double furnace walls are not used and no holes are drilled in the cylinder walls. Also the copper and brass parts are replaced by monel. The stem that supports the upper furnace element is a hollow monel tube through which a platinum, platinum—10 percent rhodium thermocouple (wire size B and S No. 36) passes into the furnace through the upper element. The junction of the thermocouple is to one side and at the same level at which the x-ray beam passes through the specimen. The thermocouple is placed so that it is in the shadow cast by the work coil and in line with the position where the x-ray film is clasped in the cassette. Thus, no shadow of the thermocouple appears on the exposed part of the film. The thermocouple leads are brought through the bottom of the camera through insulated Stupakoff seals and then over the copper radiation shield to the top where they then pass downward through the hollow tube that supports the upper furnace element. The thermocouple and thermocouple leads as well as the cold junction of the thermocouple are well shielded inside and outside the camera against r-f pick-up. The very small amount of r-f that is absorbed by the thermocouple is eliminated with an r-f filter. A potentiometer of high sensitivity is used to measure the e.m.f. generated by the thermocouple. The rotation of the lower furnace element is interrupted while making the potential measurement. The thermocouple is calibrated against melting point standards supplied by the National Bureau of Standards, and then calibrated again by melting the standards in the camera, the melting point standards being placed in the specimen holder. The accuracy of the temperature measurement is only limited by the precision of temperature control.

The temperature is controlled either manually or automatically to 0.2 percent of the absolute temperature at temperatures above 800°C. This is accomplished in the case of the General Electric oscillator by holding the current in the work coil constant with the aid of a variable inductance placed in series with the work coil.[4] At temperatures less than 800°C the variometer is connected as a variable output transformer. In the case of the Westinghouse oscillator the temperature can be regulated by adjusting the plate voltage.

FILM SHRINKAGE AND CALIBRATION

Since the x-ray film shrinks when placed in a vacuum it is desirable to preshrink the cut film in a vacuum chamber prior to loading into the camera. No additional shrinkage has been observed in film which has been kept in a vacuum for about 24 hours; such film remains tight against the cassette wall.

Each film may be calibrated for shrinkage (or elongation) after being developed by locating centers of symmetrically spaced arcs around incident and emergent beam positions in cases where back reflections are obtained. When suitable back reflections are not obtained calibration is accomplished by measuring distances between shadows cast by the mask.

OUTGASSING

In a high vacuum, the furnace occasionally outgasses as the temperature increases, causing the pressure suddenly to rise high enough to sustain a gaseous discharge. It is then necessary to turn off the r-f current in order to prevent arcing. The system must be allowed to pump down before the power can be applied again. However, arcing within the camera usually does no damage since the overload relays in the oscillator automatically cut off the high voltage to the oscillator tube. Outgassing is minimized by frequent removal of evaporated metal from the work coil and cooling jacket.

---

[4] R. Speiser, G. W. Ziegler, Jr., and H. L. Johnston, Rev. Sci. Inst. (in press).

RESULTS

Using a four turn work coil and exposures of 1¼ to 2 hours, satisfactory diffraction patterns of tantalum and molybdenum have been obtained using a tantalum furnace at high vacuum in the range of temperature 1500° to 2500°K. Satisfactory diffraction patterns of $BaTiO_3$ have also been obtained with a platinum furnace operating in air in the range of temperature 400° to 1600°K.

A diffraction pattern of tantalum at 2000°K is shown in Fig. 3b.

Lattice parameters calculated from back reflections can be obtained with an accuracy of 0.02 percent or better.

A Methane Flow Beta-Proportional Counter*

WILLIAM BERNSTEIN AND ROBERT BALLENTINE
Brookhaven National Laboratory, Upton, New York

(Received January 25, 1949)

A methane flow beta-proportional counter has been designed to detect the high and low energy solid beta-emitters used in tracer experiments. At present, both C^{14} and P^{32} are being counted. The use of a sintered-glass Gooch crucible, both as a filter and sample holder, greatly simplifies the analytical technique involved in such experiments. The instrument is stable and the results are reproducible over long time periods.

CHEMISTS have long accepted the sintered-glass Gooch crucible as an adequate tool in gravimetric analysis. The desirability of combining both the standard analysis for an element with the simultaneous determination of a tracer radioactive isotope has led to the design of a counter adapted to count the sample directly in such a crucible. Figures 1a and 1b show the design finally adopted, which employs the well-known methane-flow proportional counter principle in an end-on version.

This technique has a number of desirable properties. Absence of a window makes it particularly useful for tracers with low beta-energy such as C^{14} and S^{35} (0.15 and 0.16 Mev). It determines high energy betas (P^{32} at 1.7 Mev) equally well. The low background (8–10 c.p.m.) facilitates measure-

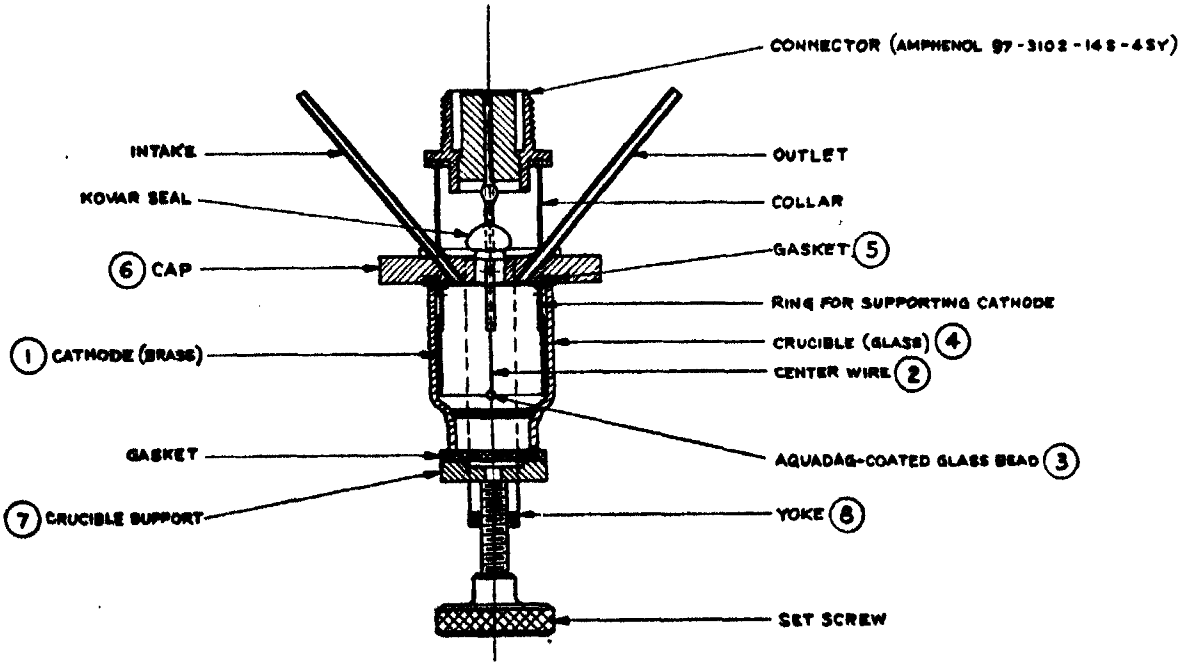

FIG. 1a.

* Research work done at Brookhaven National Laboratory under the auspices of AEC.

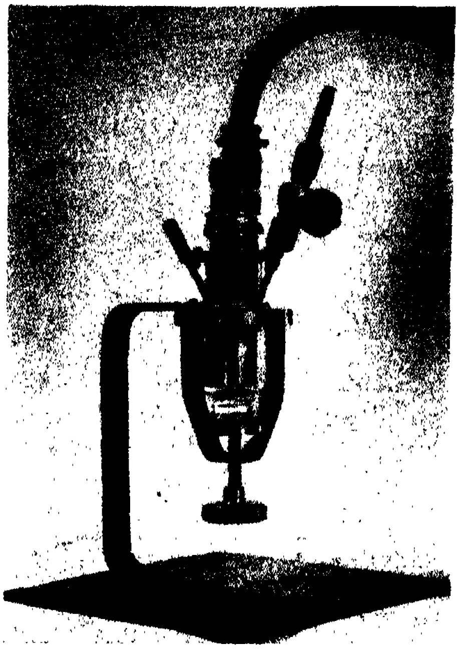

FIG. 1b.

ments on samples of low specific activity, while the coincidence correction factor is negligible even at high counting rates (5×10^4 c.p.m.). Thus, the wide range of both particle energy and sample activity accommodated, coupled with the great stability of this counter, provides a precision instrument for solid sample counting in gravimetric tracer investigations.

The design adopted (see Figs. 1a and 1b) is a cylindrical methane-flow counter. The cathode (1) is constructed of brass tubing and is split to facilitate the dismantling of the counter if decontamination is necessary. The center wire (2) is 2-mil tungsten with an Aquadag-coated glass bead (3) at the end to eliminate sparking and charge accumulation. The weld is shielded by the Kovar lead-through to cover possible points. The Gooch crucible (4), forming the sample holder, and the seal (5) to the brass Cover (6), is held in position by the crucible support (7) and yoke (8). The crucible may be changed by lowering the thumb screw, and swinging the yoke to one side. Crucibles are selected for constant height to maintain the same geometry. A filtration procedure has been discussed by J. Sacks.[1]

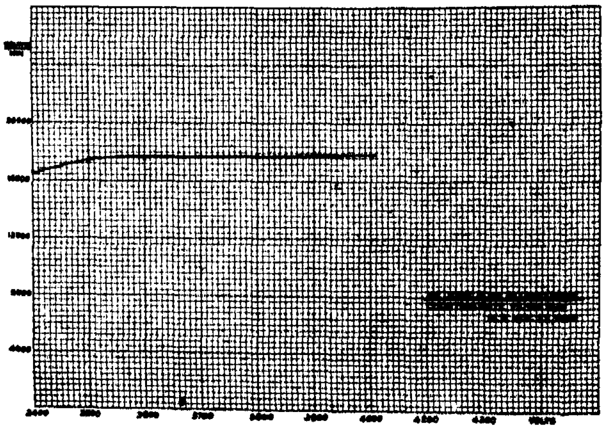

FIG. 2.

The electronic components of this instrument are slight modifications of the IDL proportional counter scaler, Model 162, and the IDL 5000-volt power supply. Since there is still a wide distribution of pulse heights, the input time constant is reduced by a factor of ten to prevent overloading of the amplifier by large broad pulses. This overloading usually results in multiple counting of single pulses. This change does not result in any shift in the operating characteristic of the counter, since the time constant is longer than the rise time of the pulse. Later models will be constructed with a cathode follower mounted directly on the counter to eliminate the effects of cable capacitance, and thereby enable operation at reduced voltages.

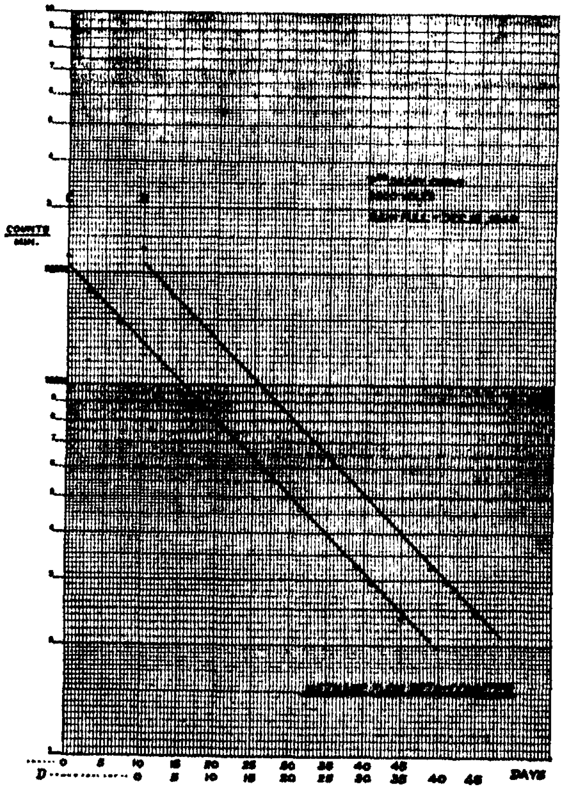

FIG. 3.

The counter has been in use for several months and considerable data has been gathered to date.

---

[1] J. Sacks, *Analytical Chemistry* (in press).

Most data at hand is based on the use of P^{32} betas as the source, although solid barium carbonate sources have been used. The geometry of the instrument is 35 percent according to measurements with a calibrated RaE source by Dr. Benjamin Burtt of the Chemistry Department. Figure 2 is a plot of counting rate against voltage, showing a slope of only about 1.1 percent per hundred volts in the operating region.

The low slope indicates that the counter is operating in the limited proportional region, counting virtually all the beta-particles entering the sensitive volume. Secondly, pulse-height limitation occurs because the more energetic particles expend only a small fraction of their energy in the relatively small sensitive volume. All these factors plus the renewal of the counting gas account for the excellent reproducibility of counts over short and long time periods (decay curve of P^{32}) Fig. 3.[3]

The instrument is sensitive to r-f interference, and some line filtering must be used. Precautions are necessary with the high voltage insulation to eliminate leakage counts. These disadvantages of the described counter are common in all proportional counter work, and in general, they have produced little difficulty in successful operation of the instrument.

The authors wish to acknowledge the interest and advice of many of the members of the laboratory, and the suggestion of Dr. Vaughan T. Bowen and Dr. Jacob Sacks of placing the counter cathode within the crucible.

---

[3] The authors are grateful to Dr. J. Sacks for the data which is not corrected to any standard reference source.

Ionization Flame Detectors[1]

HARTWELL F. CALCOTE[2]
Frick Chemical Laboratory, Princeton University, Princeton, New Jersey

(Received April 23, 1948)

Two new ionization methods of detecting flames are described for use in the measurement of flame speeds. In one the loading characteristics of a high frequency oscillator are utilized by causing the flame to pass through an oscillator tank coil. The second method employs the flame conductivity by placing two ring electrodes around the exterior of a combustion tube, and applying a d.c. voltage across them through a large series resistance. The voltage pulse created by either method when the flame passes the detector is used to trigger an electronic chronoscope.

Both methods have the distinct advantage over previous methods of flame detection in that the direct measurement of flame speeds can be made without the introduction of electrodes or wires into the combustion tube. The oscillator detector has the additional advantage that the point at which the measurement is made can be varied at will.

INTRODUCTION

SINCE the publication in 1883 by Mallard and Le Chatelier[3] of the photographic method of determining flame velocities in tubes, various methods of flame detection for the purpose of measuring flame velocities have been developed. In some cases these were necessitated by the low luminosity of the flame while others were developed as a matter of convenience to avoid the development of film. Thus far all such methods require the presence of electrodes or similar pick-up elements inside the combustion tube, which is undesirable because of the possibility of distorting the flow of flame gases and thus altering the flame velocity.[4]

In both the "spark method"[5] (in which a pair of electrodes, charged just below the sparking potential, are discharged by the high degree of ionization in the flame gases), and in the "flame conductivity method"[6] (in which the ionization in the flame causes an increase in current between two electrodes) it is necessary to have metal probes in the tube. In the "method of melting screen wires"[7] (in

which an electric circuit is broken when the hot flame melts a thin wire) it is not only necessary to have a thin wire stretched across the inside of the tube, but it is also necessary that after each measurement the screen wires be replaced.

Two novel methods of flame detection have been developed by the author which avoid these difficulties. In both methods the passage of the flame through the detector generates an electrical pulse which can be used to trigger an electronic chronoscope, or can be used as a time-marker on an oscilloscope screen. One detector utilizes the loading characteristics of a high frequency oscillator; the other relies upon the small change in impedance between two metal rings around the exterior of the combustion tube.

I. THE HIGH FREQUENCY OSCILLATOR AS A FLAME DETECTOR

An increase in ionization of the gas within a coil through which a high frequency current is passing will cause an increase in the absorption of energy from the oscillator, effectively lowering the *Q* of the coil. The coil can be wound around the tube through which the flame is propagated, and, in addition to avoiding the introduction of probes, the coil can be simply moved from one point on the tube to another so that measurements are not confined to one region of the tube. In the measurement of flame speeds two such oscillators are used to trigger a chronoscope "on" and then "off."

Similar applications of loading tank coils to detect ionization have recently been made in electrolytic solutions. Bradhurst[8] used a Hartley oscillator with the tank coil wound around a sector of glass tube in a "decant line." Oscillations were obtained when oil passed through the coil but stopped when a conducting acid entered. Jensen and Parrack[9] used a tuned plate—tuned grid oscillator with the tank coil of the oscillator wound around a titrating flask. The change in plate current due to loading was used as a measure of the change in solution conductivity.

300	8.5	—
500	10.	4.3

[a] Not "motorboating."

Circuit Considerations

Since this application of an oscillator depends on the loading of the circuit, i.e., on an increase in the dissipation of energy in the tank coil, it is important that: (1) the normal circuit losses be negligible and (2) the circuit be sensitive to any change in loading of the tank coil. Both requirements demand a high *Q* circuit.[10] In addition, the second requirement suggests that the inductance in the tank circuit should be large compared to the capacity.

Assuming the same type of argument for losses in a conducting flame as for eddy current losses in an iron core transformer,[11] the power loss will be proportional to the square of the frequency so that high frequencies will be required. Yet as the frequency is increased, the effective *Q* of the coil is decreased because of the skin effect so that in practice a compromise must be obtained between the two effects.

The above considerations can be fulfilled by many types of oscillators. However, in addition to changing the efficiency of oscillation, changing the equivalent resistance in an LCR circuit will also change the frequency of oscillation. Therefore additional advantage may be taken of the change in frequency due to a change in the effective resistance of the coil. This can be done by using an oscillator with more than one tuned circuit, such as a tuned plate-tuned grid oscillator. Greater sensitivity could be obtained by placing a crystal in the circuit but this was found unnecessary.

[10] A high *Q* means a reduction in time resolving power due to the flywheel effect in a tuned circuit. Therefore if *Q* is made very high a flame which is in the detector for only a short time might give a weak pulse.

Description and Operation of Oscillator

A tuned plate-tuned grid oscillator, Fig. 1, was used with the plate tank coil wound close-spaced around the reaction tube. In order to obtain the maximum L/C ratio no additional capacity was placed in parallel with this coil, the stray capacity and plate-to-cathode capacity of the tube being utilized. The resulting frequency was approximately 65 megacycles when a 6J5 tube was used and 100 megacycles with a 955 acorn tube.

The coil and circuit components were mounted together to avoid any unnecessary losses in the lead from the coil to the oscillator. The Lucite mounting was supported by a steel rod parallel to the Pyrex combustion tube, thus permitting the measurement of flame speeds over any section of the combustion tube by merely moving the coil and oscillator along the tube.

Tuning of the oscillator was achieved by tuning C_1 for a maximum voltage drop across R_1 or a minimum current in the plate circuit. C_2, which controls the feedback, was then adjusted until the circuit went "in" and "out" of oscillation easily.

The circuit values are not critical, although maximum sensitivity will be obtained when R_1 is as large as feasible. In order to obtain a high Q for the over-all circuit, C_1 should be large compared to L_1, and R_2 should be large. The value of R_2 is usually limited by the fact that when it becomes excessively large the time constant of R_2C_2 will cause the grid bias to build up until the phenomena known as "motorboating" takes place. Although in most oscillators this cannot be tolerated, in this application "motorboating" at a frequency sufficiently high to be filtered out by the choke coil, L_3, is not objectionable. It has, in fact, been found to increase the sensitivity considerably.

With a power supply voltage of 400 volts the d.c. voltage at the point "output pulse" was 35 volts and a pulse of approximately 4 volts peak was obtained. When "motorboating" was allowed the d.c. voltage was 80 volts, and the pulse voltage was approximately 15 volts peak. A few other typical results are recorded in Table I. The pulse shapes were dependent upon the flame, usually having a sharp leading edge with a rather ragged decay.

II. TWO-RING FLAME DETECTOR

A much simpler system for detecting ionization in flames consists of two aluminum foil electrodes wrapped around the outside of the Pyrex combustion tube, a large resistance, and a source of d.c. voltage. The experimental arrangement is shown in Fig. 2.

Theory of Operation

The detector does not act due to a change in the capacity between the electrodes as one might at first assume. An analysis of the circuit shows that, if this were so, a decrease in capacity due to ion formation would produce a positive pulse. The pulse actually obtained is negative as seen on a cathode-ray oscilloscope screen and as deduced from its ability to trigger the electronic chronoscope used.

The two-ring detector may be assumed to depend for its operation upon the momentary migration of charged particles (ions and electrons) in the electric field between the electrodes. The equivalent electrical circuit would then be as shown in Fig. 3. The two condensers are formed by the two metal electrodes, M, and the glass surface, S, inside the tube opposite each electrode.[12] The resistance R' represents the resistance between the two inner glass surface "condenser plates." With no flame in the detector, R' will be determined by the surface resistance of the glass and will be very large. The

Peak pulse voltage	0.42	1.4	1.5

presence of ions in the flame will reduce this resistance when the flame passes through the detector, so that a very small current, approximately 10^{-6} ampere, will flow in the circuit, producing a voltage drop of the proper sign across R.

Characterization of Detector

A few preliminary observations of the effect of varying certain parameters on the size and type of pulse obtained from the detector were made. Since the pulse was taken from across a 10 megohm resistance, and the input of the C. R. O. used to observe the pulse was only 1 megohm, a cathode follower was used as an impedance matching device.

The effect of varying the electrode width and the gap space is shown in Table II. The output voltage increases with increasing electrode width and decreases with increasing gap width, possibly going through a maximum.

The effect of the power supply voltage is demonstrated in Table III. An increase in power supply voltage causes an increase in the output pulse voltage.

In a *n*-butane-oxygen mixture at a considerably lower pressure the output pulse is much larger than in the air mixtures above. A mixture of 15.5 percent *n*-butane in oxygen at 42 mm of Hg pressure, with the detector described in Table III ($E = 600$ volts), gave a voltage pulse of 18 volts.

The flame speeds in the air mixtures were of the order of 60 cm/sec. and the pulse width at the base approximately 40×10^{-3} sec.; the pulses came to a point and were symmetrical. Several times, particularly at higher pressures, two pulses were observed. In the oxygen mixture the flame speed was approximately 9000 cm/sec. and the electrical disturbance was actually a group of very sharp pulses over a period of approximately 40×10^{-3} sec.

Comparison of Detectors

A comparison of the two-ring flame detector with the high frequency oscillator detector is presented in Table I. Although the two-ring detector has the advantage of simplicity, it is less sensitive than the oscillator detector and has the disadvantage of requiring high voltages which in some instances appeared to give a slight vibration to the flame. Nevertheless, flame speeds measured by the two methods agreed within an experimental error of less than 2 percent.

Other applications readily suggest themselves for these devices. For example, they might be used as "combustion protection control"[13] or the oscillator detector might be used as a quantitative measure of gaseous ionization in the range of 10^8 ions/cc[14] and higher.

Experiments in the Possibility of Increasing the Efficiency of Gamma-Counters*

HILDING SLÄTIS
Nobel Institute for Physics, Stockholm, Sweden

(Received January 3, 1949)

The efficiency of G-M tubes for recording γ-quanta is increased by insertion of concentric ring systems of metal between the wire and the cylinder. When the ring systems get suitable voltages, good plateaus and resolving times are obtained. The efficiency of a counter, which had 3 ring systems with 24 rings in each system, was 2.5 times that of a conventional counter of the same size. This means an increase of 6 times in $\gamma-\gamma$-coincidence measurements. The efficiency of an improved tube (see note added in proof) is 3.2 times that of a conventional counter.

I. PRINCIPLE AND CONSTRUCTION OF THE NEW GAMMA-COUNTERS

AMONG earlier attempts to increase the efficiency of γ-counters may here be mentioned only the multi-cellular γ-counter by Dumond.[1]

With the aim to raise the efficiency, some experiments have been carried out with G-M tubes, where a system of concentric rings was introduced (Fig. 1). The rings were made in three different sizes B_1, B_2, B_3 (see Table I), and all rings of the same size were held together by three axial rods (drill rod), one of which was brought out through the envelope at the end of the tube (only one of these rods is drawn in Fig. 1, namely that from the rings B_3 to the electrode W_3). The ring systems were supported by mica plates M at the ends of the cylinder C. The cylinder C and the rings were made of brass. The anode wire was of tungsten and was stretched by a spring S.

Besides a tube A of common type for comparison purposes, which did not contain any ring system, there were made three γ-tubes B, C, and D of the new type, with 12, 22, and 43 rings of each of the three sizes. The cylinders C and the glasswalls G were exactly equal for all four counters. The tubes were filled with 90-mm argon and 10-mm alcohol vapor.

II. VOLTAGES OF THE RING SYSTEMS

In order to avoid an undesirable deformation of the electric field between anode (wire) and cathode (cylinder) by introducing the ring systems, these should be kept at voltages which correspond to their place in the undisturbed electric field between wire and cylinder. The voltages, which may be given to B_1, B_2, and B_3, assuming that the voltage of the wire is V_a and that of the cylinder 0, are

$$V = V_a[\log(r_c/r)/\log(r_c/a)],$$

if r is the distance of the points considered (the ring) from the axis of the cylinders, r_a the radius of the wire, and r_c that of the cylinder. Assuming that $V_a = 1000$ volt, we obtain for the mean distances from the wire given in Table I, the voltages 179, 92, and 30 volt for the ring systems B_1, B_2, and B_3 respectively.

It was desirable to make the voltages of the ring systems change in the same proportion as the voltage of the wire. Therefore the desired voltage for the ring systems were taken from a potentiometer arrangement connected to the high tension stabilizer.

Figure 2 shows the characteristic curves of the counter C for different voltages on the ring systems. The figures in brackets indicate the voltages for the systems B_1, B_2, and B_3 respectively, for the case in which the anode voltage is 1000 volt. It is seen that the best plateau occurs for values which are in close agreement with the theoretical ones. The curve *a* shows that the plateau is very bad when the rings are at the same voltage as the cylinder. For the rest it is obvious, that a good plateau is attained also for voltages, which are only in the vicinity of the ideal values.

TABLE I. Diameter of the wire: 0.15 mm; dimensions of the cylinder: length 88 mm, thickness 1 mm, inside diameter 25 mm.

Ring system	Inside diam. mm	Outside diam. mm	Mean distance from the wire, mm
B_1	8.00	12.06	5.0
B_2	13.66	17.72	7.8
B_3	19.32	23.38	10.7

III. COMPARISON BETWEEN THE EFFICIENCIES AND RESOLVING TIMES OF THE COUNTERS

The counters were investigated for three different radiations, namely the γ-radiation from Ra, filtered

TABLE II.

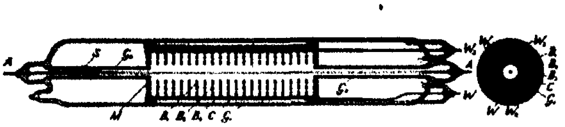

FIG. 1. The new γ-counter.

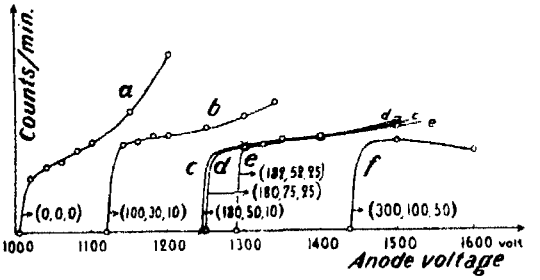

FIG. 2. Characteristic curves for the counter C. The figures in brackets are the voltages of the ring systems B_1, B_2, and B_3, respectively, when $V_a = 1000$ volts.

by 1-cm Pb (≈ 2 Mev), that from Co^{60} (≈ 1.2 Mev) as well as that from Hg^{203} (0.27 Mev). The result was that the relative efficiencies for the different counters were proportional to 100, 182, 244, and 206 for the counters A, B, C, and D, respectively.

Thus, the best result was obtained with the counter C, which contained 22×3 rings. The fourth tube D had almost the double number of rings but with half the thickness. Therefore, the absorbing matter was equal for C and D. It will be seen that the efficiency for the latter tube is a little lower, obviously because a part of the ejected electrons is absorbed in an adjacent ring before the ionization in the gas has occurred (the order of magnitude for the number of ionizations per cm is the same as the number of rings per cm).**

The resolving time for the counters A, B, and C was $(6 \pm 1) \cdot 10^{-4}$, $(1 \pm 0.5) \cdot 10^{-4}$, and $(2 \pm 1) \cdot 10^{-4}$ sec., respectively. The measurements confirm the observations of other authors[2] that the insertion of a grid increases the resolving power of a counter.

IV. THE EFFICIENCY AS A FUNCTION OF THE DIRECTION OF THE INCIDENT GAMMA-RADIATION

The efficiency of the counters was investigated for different angles φ of incidence between the γ-radiation and the "equatorial plane" of the counter. The source was a Ra sample at a distance of 120 cm from the counter. Figure 3 shows diagrammatically the result. The number of counts measured with the tubes A, B, and C are here plotted as a function (radius vector) of the angle φ. Two results of interest are to be noted: (a) the efficiency for the tubes B and C is highest at an angle of incidence 10°–20°; (b) the efficiency is diminished only slightly when φ goes to 90°. In this position, however, the tube will be seen under the smallest space angle from the sample. Hence, the efficiency per space angle is highest for $\varphi = 90°$. This is important by absorption measurements, where a canalized beam is used to reach a right angle traversing of the γ-quanta through the absorbers.

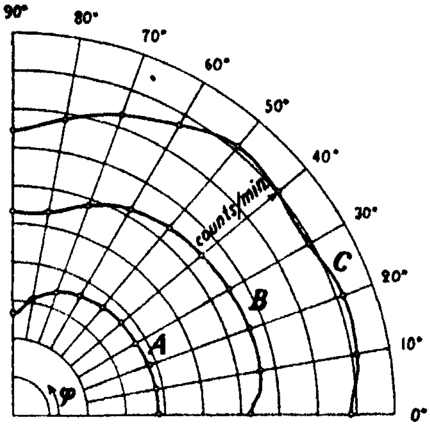

FIG. 3. The measured intensity (radius vector) of the γ-radiation as a function of the angle (φ) of incidence for the tubes A, B, and C.

A more complete description of these experiments appears in Arkiv f. Mat. Astr. o. Fys.[3]

** *Note added in proof:* This interpretation was confirmed by the following experiment. The tube D was filled with 190-mm argon and 10-mm alcohol (e.g. the pressure doubled). Furthermore, in order to prevent the necessary anode voltage from increasing due to higher pressure the central wire was replaced by one of 0.05-mm diameter. The relative efficiency of the counter was by that increased from 206 to 320, or 3.2 times that of a conventional counter of the same size (this means an increase of 10 times in γ–γ-coincidence measurements). Experiments with improved counters will be continued.

An Improved Low Angle X-Ray Diffraction Camera

BARBARA A. WRIGHT AND PETER A. COLE*
United Shoe Machinery Corporation, Research Division, Beverly, Massachusetts

(Received January 25, 1949)

A description is given of a low angle x-ray diffraction camera which incorporates both high resolution and facility in adjustment and alignment of components. A diffraction pattern of the low angle pattern of collagen photographed with this instrument is compared with a similar pattern photographed with commercially available equipment.

INTRODUCTION

THE x-ray diffraction studies of collagen which are being conducted in this laboratory have imposed rigorous instrumental requirements which are not satisfied by the available commercial equipment. The lack of adequate commmercial low angle diffraction equipment has prompted workers in this field to design x-ray diffraction cameras which would be suitable for the examination of collagen. Low angle cameras for this application have been developed by Corey and Wyckoff[1] and by Bear.[2]

The double crystal spectrometer was first used in the study of low angle scattering by Fankuchen and Jellinek[3] and has recently been applied by Kaesberg, Ritland, and Beeman[4] to a direct intensity determination of the low angle diffraction pattern of collagen, thus eliminating the difficulties encountered in photographic intensity measurements.

It would appear that the photographic method will continue to have application in exploratory work and in the study of materials which require the recording of diffraction orders of very low intensity.

It was found that a satisfactory low angle diffraction camera should incorporate the following features:

(1) Sufficient refinements to permit the recording of reflections from molecular spacings as great as 1200A.
(2) Resolution of 3 lines per millimeter at 300 millimeters.
(3) Adjustable slit-widths.
(4) A minimum of scattered radiation.
(5) Sample holder in which the material may be maintained at controlled temperature and humidity.
(6) Facility in alignment of components.

DESCRIPTION

It was desirable to use slits of adjustable width and separation to permit operation of the camera at the optimum conditions for the particular material under investigation. For this purpose, Gaertner bilateral slit mechanisms were employed. Two of the slits were used to collimate the beam. These were mounted separately on stands of adjustable height. In order to minimize the scattered radiation, special lead jaws were required which were flat and parallel to a tolerance of 0.01 mm and tapered to an edge thickness of 0.1 mm. A third slit of similar construction was also used to reduce scatter. This was attached rigidly to a chamber in which the sample was to be located. This last unit was mounted on a separate adjustable stand.

Around the cylindrical sample chamber there was wound a heating coil which operated through a variac. A layer of asbestos paper three-sixteenths of an inch thick was used as insulation for the camera. Within a quarter of an inch of the sample there was located a copper-constantan thermocouple which was connected to a Leeds and Northrup Portable Precision Potentiometer. It was possible to control the temperature of the sample to within 2°F in the range from 75°F to 200°F. Any desired humidity could be maintained within the chamber by introducing air of controlled water vapor content. The air leaving the chamber was passed through a Foxboro Humidity Recorder. With this equipment it has been possible to run a sixty-hour exposure with less than ten percent variation in the relative humidity of the air in the sample chamber.

The sample holder consisted of a pair of parallel jaws of variable separation. These jaws could be translated vertically and rotated as much as 60°

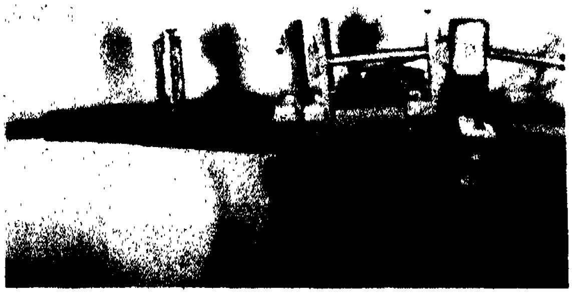

FIG. 1. Improved low angle x-ray diffraction camera.

FIG. 2. Collagen diffraction pattern photographed with commercially available low angle camera.

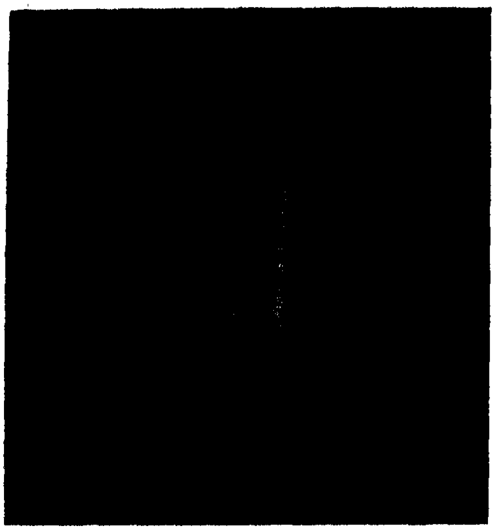

FIG. 3. Collagen diffraction pattern photographed with improved low angle camera.

in the plane perpendicular to the beam. This mechanism provided ease and accuracy in sample alignment. The x-ray beam passed through double mica windows 0.001″ thick separated by a dead air space. These windows made the chamber air tight and minimized x-ray absorption and scatter which would be caused by the condensation of water at high humidity. This construction would also permit the evacuation of the sample chamber or its operation at elevated pressures.

A fourth stand supported a film holder with a beam stop, adjustable both in height and rotation. All stands were mounted on a rigid rail one meter long. The entire assembly was attached to the diffraction unit as shown in Fig. 1. The tube which separated the collimating slits contained limiting diaphragms to reduce scatter occurring between these slits.

DISCUSSION

Figures 2 and 3 are comparable low angle x-ray diffraction patterns of collagen from kangaroo tail tendon. Both patterns were photographed with copper $K\alpha$-radiation, with a distance of 30 cm between the specimen and the photographic film, and with a separation of 30 cm between the collimating slits. For both photographs, the specimens were maintained at 100°F and 40 percent relative humidity. As calculated from the films, the fundamental spacings of both patterns was 627A.

The pattern of Fig. 2 was photographed with a commercially available low angle camera employing silver slits of 0.3-mm opening; that of Fig. 2 was photographed with the improved diffraction camera described above with the slits adjusted to a width of 0.15 mm. In Fig. 3 it is apparent that the first order has been resolved from the main beam, and that all orders are more sharply resolved than in Fig. 2. The effort required for aligning the instrument has been reduced from three hours' work and three six-hour exposures, to ten minutes' work and one six-hour exposure.

In the results of Kaesberg and his associates, the ratio of peak separation to peak width is greater than 10:1. This ratio indicates that the collagen periodicity is much more regular than has been previously supposed from published photographs of collagen diffraction patterns. Figure 3, taken with the new camera described above, provides photographic evidence which begins to approach, in resolving power, the measurements made with the double crystal spectrometer.

A Simple Calorimeter for the Simultaneous Determination of Heat Loss and Heat Production in Animals*

LAWRENCE R. PROUTY, MARTHA J. BARRETT, JAMES D. HARDY
Department of Physiology, Cornell University Medical College, New York, New York

(Received October 18, 1948)

This paper describes a new type of gradient calorimeter which permits the rapid simultaneous measurement of respiratory metabolism and heat loss. It uses the temperature difference between the inner and outer aspect of a fixed transitional layer of air rather than adiabatic principles. (W. O. Atwater and F. G. Benedict, "A respiration calorimeter with appliances for the direct determination of oxygen," Publication 42, Carnegie Institute of Washington (1905); G. Lusk, Arch. Int. Med. **15**, 793 (1915); E. F. DuBois, *Basal Metabolism in Health and Disease* (Lea and Febiger, Philadelphia, 1936), third edition; Forester, Ferris, and Day, Am. J. Physiol. **146**, 600 (1946); L. Love and H. C. Bazett, Fed. Proc. **7**, 74 (1948); C. P. Yaglou, "Thermal insulation of clothing," unpublished data; T. Benzinger, personal communication.) Application of gradient principles to calorimetry so simplifies heat loss determinations that they become the easiest and most accurate part of the procedure.

DESCRIPTION OF CALORIMETER

Measurement of Heat Production

THE apparatus used for metabolic studies is shown in Fig. 1. Outdoor air is drawn into the system through bottles (*A* and *B*) containing soda lime and sulfuric acid for the removal of carbon dioxide and water vapor, respectively, and then, into the respiration chamber through the air inlet (*C*). The calorimeter proper is composed of two concentric sheet copper (0.02-inch thick) cylinders (*D* and *E*). The animal is placed in a covered wire cage which is thermally insulated from the inner cylinder. The cage rests upon a pan containing a small quantity of mineral oil for the collection of excreta. The calorimeter sets upon rubber insulators on an activity platform for recording animal movements. As the air passes from the calorimeter through the outlet (*H*), aliquot samples are taken for the determination of respiratory metabolism, by means of a Barker gas sampling device.[1] Samples thus received into a master cylinder are transferred to a second sampler which can be attached directly to the Carpenter gas analysis apparatus,[2,3] for the quantitative estimation of carbon dioxide and oxygen. Heat production can be calculated by the usual methods of indirect calorimetry.

Measurement of Heat Loss

An animal placed inside the inner copper cylinder of the calorimeter will lose its heat by radiation and convection to this cylinder. The heat loss by evaporation was measured by collecting and weighing the moisture given off by the animal. The heat loss due to radiation, conduction, and convection is for the most part absorbed by the copper wall of the inner cylinder. There is, however, a small amount of heat which is carried out by the air stream and for which correction must be made. As the inner cylinder is always warmer than the outer cylinder, there will be a transfer of heat between them, and the rate of exchange will be directly proportional to the temperature difference between the two cylinders. That is,

$$Q=K(T_1-T_2), \qquad (1)$$

where $Q=R+C+D$, K = the heat flow constant, T_1 = temperature of the inner cylinder, T_2 = temperature of the outer cylinder. Providing the conditions between the two cylinder walls remain fixed, K is a constant and can be determined experimentally by measuring the other factors in Eq. (1). K, the heat flow constant, thus depends upon the construction of the calorimeter, and it is essential, having once calibrated the instrument, to allow no alteration of conditions between the calorimeter walls. Changes in position of the animal inside the calorimeter have no effect on K, as it is affected only by changes between the calorimeter walls. The use of the outer calorimeter cylinder makes it unnecessary to have a constant temperature room such as was required for the calorimeter described by Day and Hardy.[4]

The calorimeter is shown in more detail in Fig. 2. The two concentric copper shells (*A* and *B*) are separated by an air layer one centimeter in width, this separation being rigidly maintained by small rubber insulators. The inner chamber contains a wire cage, fourteen centimeters in height and twenty-two centimeters in diameter, which will accommodate a full-sized cat. Thermocouples, (*D* and *E*) placed in the air inlet and outlet, give the temperature of the air as it enters and leaves the chamber. The top of the inner shell (*H*) is machined to fit tightly and is made air-tight by a seal of stopcock grease. The top of the outer shell (*I*) need not be air-tight as long as there is no appreciable circulation of air between the walls from outside sources.

An electric fan in fixed position is turned directly on the calorimeter. This assists in maintaining the outer shell at room temperature and eliminates the thermal effects of experimenters moving in the neighborhood of the calorimeter. The outer cylinder together with the electric fan thus acts as a heat absorber of large capacity insofar as the movement of heat from the inner wall is concerned. Thermocouples connected in parallel are attached to the surfaces of the inner and outer copper cylinder. These sets of thermocouples can be balanced one against the other to determine temperature difference between the calorimeter walls as shown in Fig. 3. The thermocouples for the inner shell are also arranged to be balanced against a reference standard in order to determine the actual temperature of this inner shell. This is important in making corrections for the heat capacity of the calorimeter. Thermocouples for determining body and skin temperature of the animal are admitted through a latex seal situated just below the air outlet (*I*, Fig. 1).

Electrical Circuit

Figure 3 shows a diagram of the potentiometric circuit used. All temperatures are taken with

[4] R. Day and J. D. Hardy, "A calorimeter for measuring the heat loss of premature infants," Am. J. Dis. Child. **63**, 1086 (1942).

copper-constantan (size No. 28 wire) thermocouples connected as shown, the solid lines representing copper and the broken lines constantan leads. The minimum requirements for the circuit are a sensitive galvanometer, a dependable slide wire, and a standard cell or meter to insure a constant, known current input. A milliammeter** is used in this case and is more useful than a standard cell because the current input could be altered as desired.

CALIBRATION PROCEDURES

Electric Checks

The heat flow constant, K, is determined by introducing a known amount of heat into the calorimeter and, following establishment of thermal equilibrium, measuring the temperature gradient between the walls, over the range of heat loss value expected during animal experimentation. A ten-watt electric bulb is used as a source of heat, with suitable provisions for shielding, as described by Day and Hardy.[4] The shielding provides more equal distribution of heat in the calorimeter and thereby simulates more closely the situation applicable to an experimental animal. A carefully standardized ammeter and voltmeter are used to measure the heat input. No air was circulated through the calorimeter during the electric checks.

At equilibrium for an electric check we have

$$H=K\times(T_1-T_2), \qquad (2)$$

where $H=0.432\times\text{volts}\times\text{amperes}$ (kg cal./$\frac{1}{2}$ hr.), K = heat flow constant, T_1 and T_2 = temperature of inner and outer walls, respectively. The experimental periods are one-half hour in length as the thermal response time of the lamp and calorimeter system is such that sixty-six percent of thermal equilibrium is obtained in approximately that time. The heat input for this series of electric checks varied from 1.2 to 2.3 kg cal. per half-hour. The temperatures of the inner and outer shells are taken at ten-minute intervals and the average gradient during a half-hour period computed. In order to eliminate the factor of heat storage in the calorimeter, only those periods during which the system is near equilibrium are used to calculate the heat flow constant. Heat input is plotted as a function of the temperature gradient between the inner and outer shells, and is expressed in drum divisions (Fig. 4). The relationship is linear, and the heat flow constant, measured by the slope of the line, is equal to 0.0181±0.004 kg cal. per drum division for a half-hour period.

The value of K is independent of the environmental temperature and the rate of heat loss. It is dependent, however, on the physical situation of the calorimeter relative to its surroundings. Should the position of the calorimeter be changed, particularly with respect to the electric fan, it is necessary to redetermine the constant. The value of K will also shift if the arrangement of thermocouples on the walls of the cylinders is altered. Physical changes made within the inner shell will not affect the heat flow constant, but will alter its heat capacity.

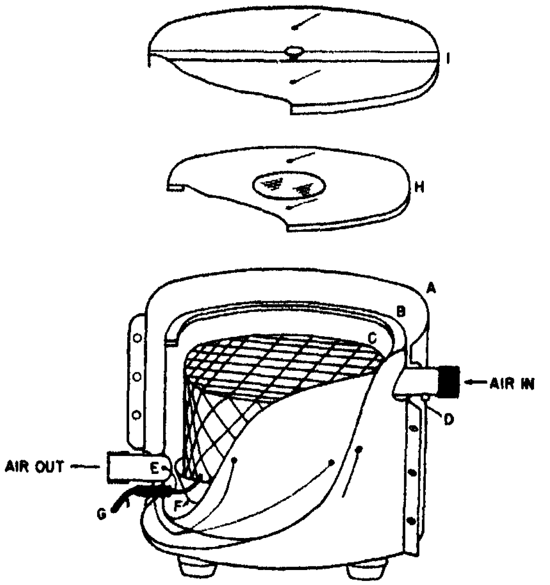

FIG. 2. Cutaway view of small animal calorimeter. *A*—outer shell; *B*—inner shell; *C*—wire cage; *D*—ingoing air thermocouple lead; *E*—outgoing air thermocouples; *F*—oil pan; *G*—thermocouple leads emerging from latex seal; *H*—inner top; *I*—outer top.

The time required for the inner and outer shells to adjust to thermal equilibrium is fifty minutes. Figure 5 shows the temperature changes in the inner and outer shells as well as the changes in thermal gradient and room temperature. It will be noticed that the thermal gradient becomes level fifty minutes after the heat is turned on, although the temperatures of the inner and outer shells continue to rise due to increase in room temperature. Forty minutes after the heat was turned on, the room temperature dropped from 23.3 to 22.8°C, and this produced a change in the temperature of the inner and outer shells as indicated. The effect upon the gradient (lower curve, Fig. 5) is less marked, although it will be seen that errors will be introduced into the measurements of heat loss if rapid changes in room temperature occur during an experimental period. Thus, although, as stated above, a constant temperature room is not required for this calorimeter, it is important that rapid changes in room temperature be avoided. To the right in Fig. 5 are shown the results of an experiment in which the effects of room temperature

---

** Weston, Model No. 62.

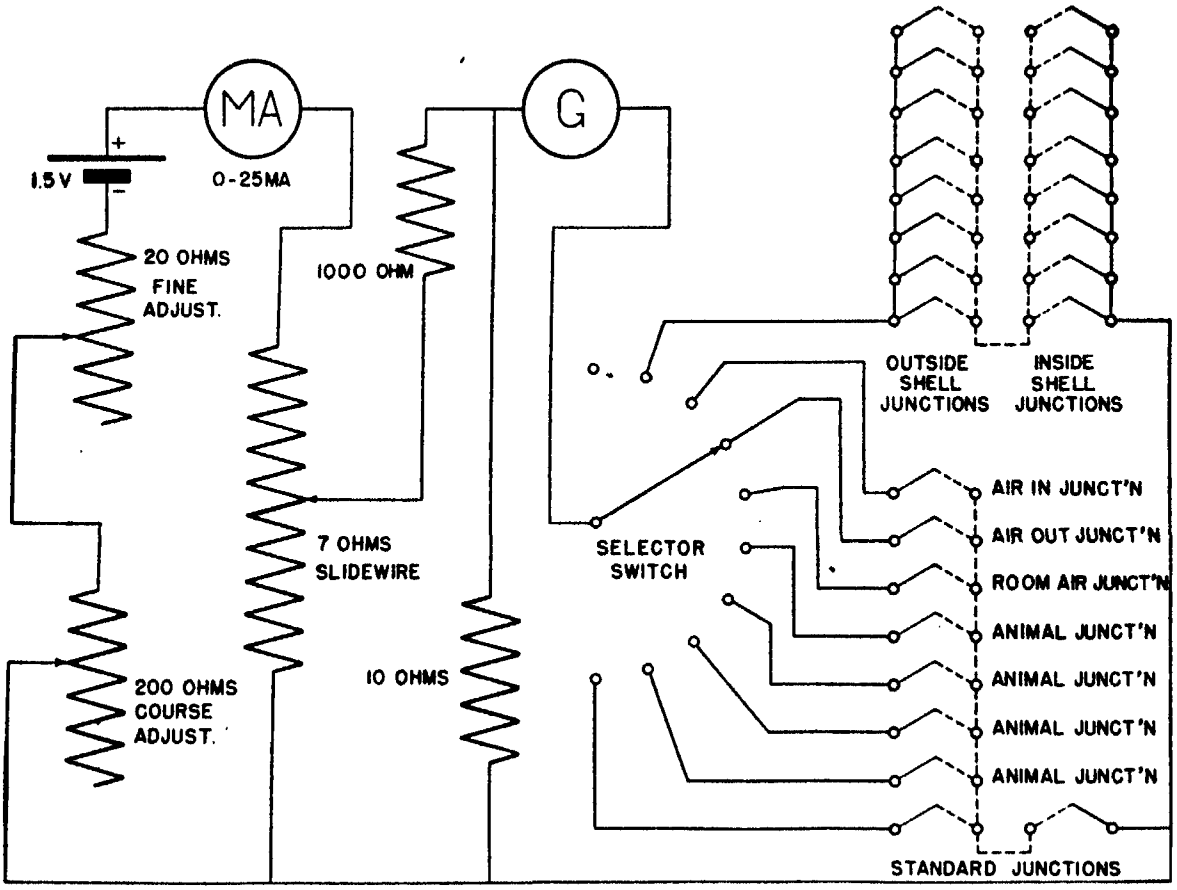

FIG. 3. Electrical circuit diagram. Thermo-junctions on right, potentiometric circuit on left.

changes are pronounced. The heat input during this experiment was maintained at a constant level, and just before the end of the experiment, the room temperature rose 1.6°C in twenty minutes. As this produced a more rapid change in the temperature of the outer shell than of the inner shell, there was an apparent fall in the thermal gradient, indicating a decrease in heat input which did not occur.

Determination of Heat Capacity of Calorimeter

When equilibrium conditions are not present, a correction must be made for the heat which is stored in the walls of the calorimeter. The heat given off by a source within the calorimeter then becomes:

$$H=K(T_1-T_2)\pm S, \qquad (3)$$

where S represents kilogram calories stored, and may be positive if the calorimeter is retaining heat, or negative if losing heat. Both the inner and outer walls may theoretically contribute to this storage factor. In practice, however, it has been found that since the outer shell follows the room temperature so closely, it stores very little heat which is attributable to the source within the calorimeter. The heat storage in the outer wall has been calculated in a large series of experiments, and in every case has been found to represent less than one percent of the total heat loss. Thus, the total storage may be considered as being derived from heat gained or lost by the inner wall.

The thermal capacity of the calorimeter and its contents was estimated from the sum of the weights and specific heat of the copper, rubber, and glass of which the calorimeter and calibrating equipment were constructed. It can also be measured from experiments in which the temperature of the calorimeter is allowed to change. The equation for heat loss by the calibrating lamp for such test periods is

$$H=K(T_1-T_2)+C(T_e-T_b). \qquad (4)$$

In this equation the last term represents the heat stored, S, the thermal capacity of the calorimeter being C. T_e and T_b are the temperatures of the inner and outer shell at the end and beginning of an experimental period, respectively. As pointed out above, K is determined for experimental periods during which there is thermal equilibrium and thus, the storage term is zero. Therefore, K can be used in Eq. (4) to determine the value of C.

The average value for C as determined for twelve experimental periods is 0.39, ±0.02 kg cal. per degree, a value which agrees with the one estimated on the basis of the weights and specific heats of the component parts.

Alcohol Checks

The equation for the heat loss from the alcohol lamp is

$$H = K(T_1 - T_2) + C(T_e - T_b) + 3.1 \times 10^{-4} V \times (T_0 - T_i) + 0.584w, \quad (5)$$

in which the symbols have the same meaning as in Eq. (4) except for V, which is the volume of air passing through the calorimeter during an experimental period, and w, which is the water collected in the sulfuric acid bottles. The last two terms of Eq. (5) represent the heat carried out of the calorimeter by the stream of ventilating air and the heat due to water vapor, respectively. Analyses of gas samples are the most tedious part of the experimental routine and are usually deferred until the day following the experiment or other convenient time, as the cylinders containing gas samples may be stored for several days without change or danger of contamination.

Table I contains the values obtained from six experiments, each experiment consisting of three half-hour periods. The average deviation from the theoretical heat production is +1.7 percent for the measurement of heat loss and −0.1 percent for heat produced. Close agreement between indirect and direct calorimetry indicates that all constants were accurately determined.

Operation of the Calorimeter

In the experimental routine a fasted animal which has been shaved several days prior, is brought to the laboratory about an hour before being put into the calorimeter. Thermocouples are placed on several parts of the body and in the rectum. The animal is weighed and placed in the cage inside the respiration chamber. The top is placed on the calorimeter, the air flow is started, and the first observation period is begun, not sooner than thirty minutes later. At this time the calorimeter begins to approach equilibrium and the experiment is begun. The calculations in a sample observation follow:

February 19, 1948—Cat *A*, fasted eighteen hours, weight—1750 g.

SUMMARY

A simple heat flow or "gradient type" calorimeter is described, based upon the principle that heat loss by a body contained within two concentric thermally conductive cylinders insulated from one another, will be proportional to the temperature

---

*** *K* here has a value for use with shell temperatures in °C.

gradient between the cylinders. An instrument large enough to contain a full-sized cat, used in connection with the gas sampling apparatus described by Barker, was constructed and tested. The calorimeter may be used with any other satisfactory method of measuring the respiratory quotient.

Electric and alcohol checks were carried out for half-hour periods. The precision of the calorimeter is ±2 percent for an individual period under favorable conditions.

Complete procedure for obtaining heat loss and heat production is described, together with sample calculation for an animal experiment.

The advantages of the calorimeter are: (1) Adequate precision is obtained with inexpensive construction and simple measuring equipment. (2) Rapidity of response permits short experimental periods. (3) Simplicity of operation permits one observer to carry through the complete procedure. (4) It is flexible in application, particularly with regard to study of heat loss and heat production at different environmental temperatures for animals of any size.

Laboratory and Shop Notes

A New Vacuum Gauge

CARLTON F. JOHNSON
Ordnance Research Laboratory, Pennsylvania State College, State College, Pennsylvania
March 8, 1949

OBSERVATIONS have been made in this laboratory on the variation of the motional impedance of a magnetostrictive transducer with air pressure on the face of the transducer.

As is generally known[1] both the resistive and reactive components of a transducer's impedance vary rapidly near the resonant frequency, and often represent a considerable departure from the off resonance, or clamped impedance. If a transducer is series tuned, its impedance at resonance is essentially resistive. The value of its radiation resistance at resonance is a function of the mass density and the velocity of sound of the medium into which the transducer is radiating. Thus, the electrical impedance of a transducer radiating into air should vary with the air pressure. Measurements made in this laboratory on a scroll type magnetostrictive transducer operated at approximately 63.1 kilocycles indicate that this is so, and the change in voltage across the transducer windings (a measure of its electrical impedance) appears to be linear with changes in pressure from atmospheric pressure to a pressure of a few millimeters of mercury.

The transducer and its series tuning capacitance are made one arm of a resistance bridge as shown in Fig. 1 so that when the bridge is balanced, only the *change* in voltage across the tuned circuit is measured. In the present case, when the bridge is fed at a level of about 2.5 volts r.m.s., the bridge can be balanced, at atmospheric pressure, to about 10 millivolts, and at a pressure of less than 10 millimeters of mercury the maximum bridge unbalance amounts to about 80 millivolts. When a pressure of about 1 millimeter of mercury is reached, the bridge unbalance decreases by about 10 millivolts as shown in Fig. 2 to the limit of the roughing pump used. The cause of this reversal is not explained, since accurate estimation of the ultimate degree of vacuum attained has not yet been attempted.

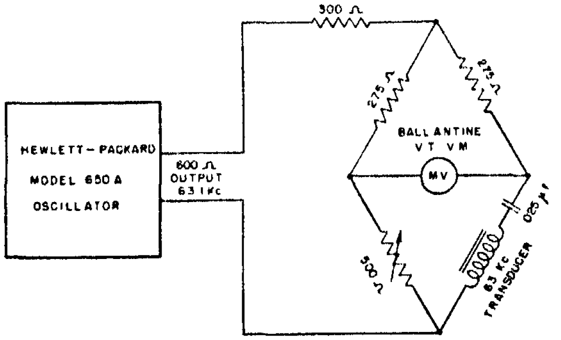

FIG. 1.

The transducer used was originally designed to work in water, hence a considerably greater effect might be measured with one designed to work in air, i.e., one which would be more loaded by air than is the present one. Lower frequency transducers could also probably be used more advantageously, provided that the frequencies chosen were high enough to avoid standing wave effects from reflections of the sound in the vacuum system. However, the standing wave effect would probably be negligible at low pressures. One advantage of the present transducer is that no standing wave effects are apparent in air owing to the relatively small amount of power radiated into the air at the frequency used.

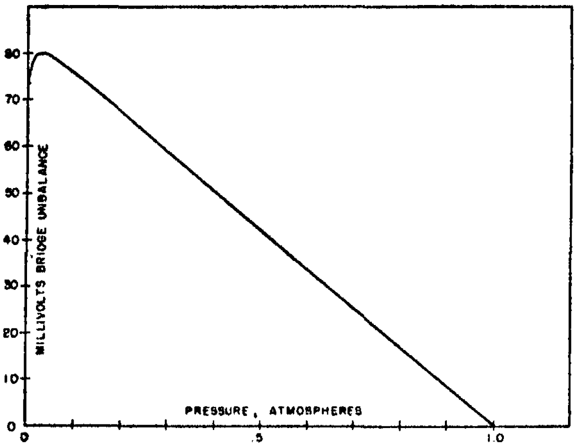

FIG. 2.

It is proposed that with suitable design features a transducer could be used as a vacuum gauge of fundamental nature.

A Simple Electronic Relay

ROBERT H. LINNELL* AND HELMUT M. HAENDLER
Department of Chemistry, University of New Hampshire, Durham, New Hampshire
August 30, 1948

AN electronic relay has been constructed using a thyraton tube, the load being placed in the anode circuit. Control of the tube was achieved by applying the filament voltage to the grid 180° out of phase with the anode voltage.

Figure 1 shows the schematic diagram. It is important to note that there is an internal connection in the tube between the heater and cathode (pins 2–4). There will be an a.c. potential difference between heater pin 1 and cathode pin 2, but not between heater pin 4 and cathode pin 2; if this potential is sufficiently large and of proper phase it can be used to control the tube's firing. When the anode of the tube swings

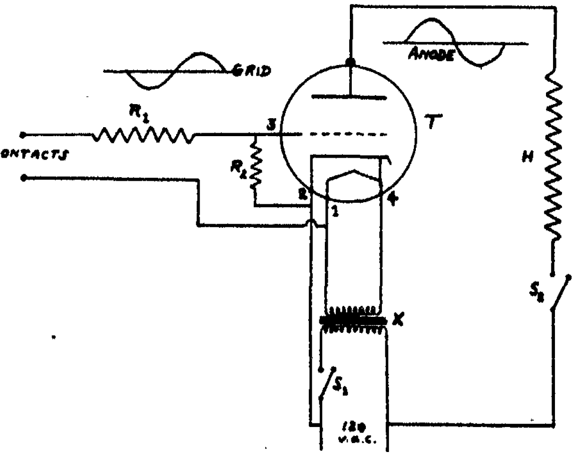

FIG. 1. R_1 2.7 megohm, ½ watt, R_2 330 kohm, ½ watt, S_1 filament switch S_2 anode switch, X transformer, 5 v.a.c. 5a. T General Electric GL-5559/FG57 H heaters.

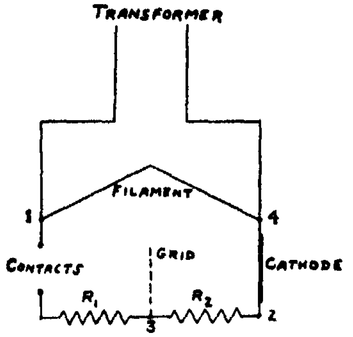

FIG. 2.

positive, the grid must swing sufficiently negative to prevent the tube from firing. Thus an 180° phase difference between grid and anode is necessary. The proper phase is determined by trial. If the tube fires continuously when first connected up, it is only necessary to disconnect the two leads from the filament transformer to the tube heater and switch them in reconnection. The magnitude of the voltage available between pins 1–2 is more than sufficient for grid control and the resistors R_1 and R_2 form a voltage divider circuit which determines the fraction of total filament voltage applied to the grid (see Fig. 2). The values indicated for R_1 and R_2 were chosen to give ample voltage at the grid to ensure control of the tube and yet have a very small grid current. Since the fraction of filament voltage available on the grid is $R_2/(R_1+R_2)$, increasing R_1 will decrease the control voltage put on the grid, and if R_1 becomes sufficiently large the voltage available will be insufficient for operation of the circuit as a relay. For best results the above fraction should be made near unity. It can be seen that decreasing R_1 will cause grid current to increase and since this is undesirable R_2 is made very large so that R_1 can have a large value without making the fraction $R_2/(R_1+R_2)$ significantly smaller than unity. However if R_2 is made excessively large the operation fails due to capacity effects.

In operation, the warming of mercury in the thermoregulator closes the contacts which put the fraction $R_2/(R_1+R_2)$ of the filament voltage on the grid and this prevents the tube from firing, thus heaters in the anode circuit cool. The mercury then contracts breaking the contacts and allowing the tube to fire which warms the heaters in the anode circuit.

The thyraton used (General Electric GL-5559/FG-57) has a rating of 2.5 amperes average anode current and 15 amperes peak anode current. Since the tube carries current only during positive voltage swings of the anode, these tube requirements may be met by using ordinary 120-volt a.c. knife heaters with a rating of 740 watts or less (if more than one heater is used, they should be wired in parallel for maximum power output). This is equivalent to a resistance of approximately 19.5 ohms in the anode circuit. Actually a maximum of about 300 watts will be delivered continuously by the anode load with the above heaters.

This relay has been used to control the temperature of a water bath. A mercury filled regulator with make-break contacts in air showed no appreciable oxidation of mercury after several months of operation. Temperature control to 25.000°C ±0.005° was achieved with an uninsulated Pyrex jar of water.

This same method could conceivably be used on other thyraton tubes, provided grid control voltage was less than filament voltage.

The authors wish to thank Dr. S. N. Van Voorhis of the University of Rochester Physics Department for helpful suggestions.

An Apparatus for Producing Powder-Like X-Ray Diffraction Patterns from Single Crystals

F. W. Matthews and A. O. McIntosh
Central Research Laboratory, Canadian Industries, Ltd.
McMasterville, Quebec, Canada

February 25, 1949

OCCASIONALLY it is desirable to identify single crystals without powdering the material. Single crystal rotation patterns can be used to obtain the "*d*" spacings and the unit cell dimensions but these data are not readily used for identification. There are, at present, no determinative tables based on unit cell measurements and the "*d*" spacings obtained from rotation photographs give no indication of the relative intensity of the powder lines. A comprehensive determinative table, based on diffraction powder data, is published by the American Society for Testing Materials.[1] This requires the interplanar spacings, "*d*" and the relative intensities of the powder lines. For identification purposes it is advantageous to obtain the powder data directly from the single crystal. This can be done by imparting to the crystal, placed in the x-ray beam, a very large number of orientations. A method has been described for use in the identification of gemstones.[2,3] This method, designed for use with large mounted specimens, recorded only in the back-reflection area and due to the limited rotations gave arcs in the pattern. For identification purposes the preparation of standard patterns was required. Since the method here described gives results similar to an ordinary powder pattern the standard x-ray powder index can be used.

The instrument (Figs. 1, 2) was constructed around a standard collimator of the General Electric XRD[4] equipment (1). The collimator holder (2) was machined to fit the bearing (3) of the large spur gear. A stationary driving disk (4) is attached to the collimator. Fastened to the large spur gear (5) is the bearing housing (6) which carries the shaft on which the sample is mounted. This shaft is fitted with a rubber disk (7) that is in contact with the driving disk (4). Recessed into the shaft is a small rod (8) at the extremity of which is a smooth surfaced platform (9). To the platform a small flat disk is attached by means of grease. The rod (8) can be adjusted as to height giving longitudinal adjustment of the specimen. The disk, to which the crystal is attached by a glass fiber, can be moved transversely giving the other motions necessary for adjustment. The sample holder is counterbalanced by the weight (11). When motion is transmitted to the large spur gear by the motor (12) through the gear (13) the sample holder rotates about the axis of the collimator. At the same time the disk (4) causes the specimen to rotate about an axis perpendicular to the collimator axis. Thus the crystal is made

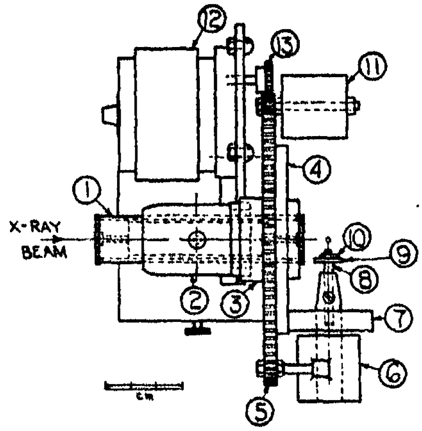

FIG. 1. Scaled drawing in plan of crystal rotating device.

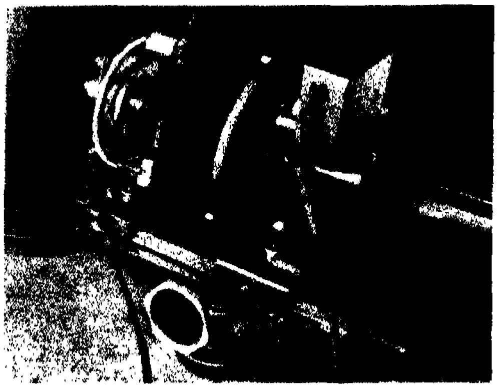

FIG. 2. Crystal rotating device mount on camera track of x-ray unit showing rotating flat film cassette.

to rotate about two mutually perpendicular axes. The pattern is recorded on a flat film rotated about the axis of the beam in the direction counter to the rotation of the crystal.

Patterns made with this apparatus will not be exact duplicates of normal powder patterns which require very many random orientations. Since the equipment described does not give random orientation, difference in intensities will exist. These might be sufficient to remove some lines of the pattern completely. In practice, however, there seems to be qualitative agreement between patterns made from single crystals by this instrument and those made from powdered material. Figure 3 shows the two types of patterns recorded on the same film. The relative line intensity is closely matched in this photograph of sodium chloride which is of high symmetry and in similar photographs of sucrose which has lower symmetry. A contributory factor is that in neither case was a main crystallographic axis used as an axis of rotation thus avoiding planes parallel to the beam, which do not come into the reflecting position.

The instrument can be used for identification of small crystals mounted in the manner usual for single crystal investigations. Larger crystals require an edge to be used so that absorption does not interfere with the relative line intensity. A possible use of this equipment is the quick checking of the identity of crystals before a single crystal pattern is obtained. In this connection it would be useful to design the equipment to take the goniometer head used in the single crystal equipment. A further improvement would be effected if the flat cassette were replaced by a semicylindrical cassette the radius of which was made the same as powder cameras used for routine identification.

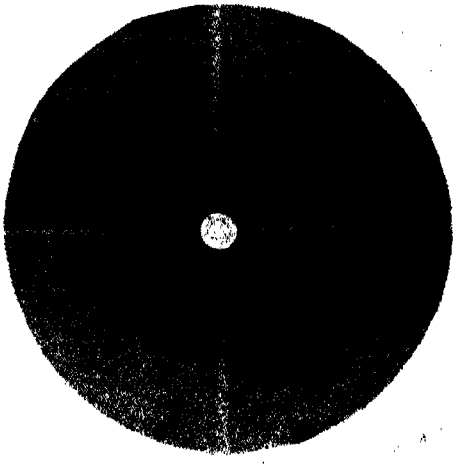

FIG. 3. Sodium chloride diffraction photograph (1) from single crystal (2) powdered sample.

We wish to acknowledge the help of Mr. R. V. Row in the construction of this instrument.

A Large Straight Through Vacuum Valve for Van de Graaff Generators

B. JENNINGS*
Westinghouse Research Laboratories, East Pittsburgh, Pennsylvania

March 17, 1949

IN order to change targets on an electrostatic generator or external beam cyclotron, it is necessary to have a vacuum valve on the beam tube of special characteristics. This valve must be very tight in the closed position to keep a good vacuum in the main system. It must have a large straight through opening so that the beam cannot splash on the valve parts and produce unwanted disintegrations, and must be easily and quickly closed in case of accident. The valve described here fulfills these requirements.

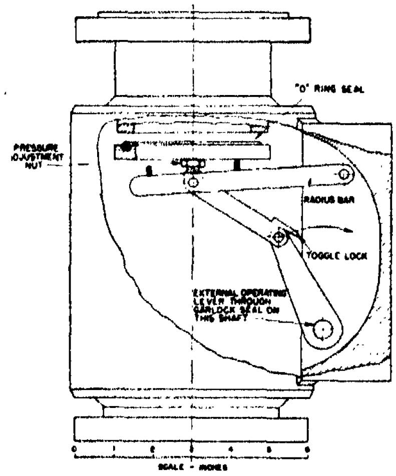

FIG. 1.

The valve[1] consists of a plate carrying a rubber seal of the type known as an "0" ring[2] which is held mechanically against a polished valve seat. This mechanical force is supplied by a lever structure consisting of three bars, one of which is a radius bar to hold the valve plate centrally over the valve seat. The other two form a toggle joint which acts as the compression member of the lever system in the closed position of the valve, as they are locked together in the closed position of the toggle and act as one bar. The mechanical compression on the valve plate can be adjusted by the spacing nut and thread in the valve plate.

To open the valve the lower member of this compression unit is turned clockwise by the outside handle so that the toggle joint unlocks, and the two parts of the cantilever compression member fold together allowing the valve plate to drop down out of the passage way. The radius bar, however, holds the valve plate so that it returns to the correct position when the valve is closed.

The mechanical advantage of the operating lever in starting to swing the valve plate up into position is poor but very little force is required. At the point where the valve is being closed against the valve seat the mechanical advantage has become much better and the force required to snap the toggle is not excessive. About a quarter of a turn of shaft rotation is necessary to close the valve and the action is easy enough so that it could be done by a motor or weight drive for automatic closing in case of vacuum trouble.

The operating shaft is brought outside through a commercial Wilson[3] seal which is applied in the conventional way for rotating a shaft through a vacuum seal.[1]

The valve has been checked for tightness in the closed position with a helium mass spectrograph leak detector, both with the vacuum above and below the seat. No indication of leaks has been found in either direction. This valve is being used as the target valve on the Westinghouse Electrostatic generator at East Pittsburgh, Pennsylvania.

Cells Drawn from Tantalum, Molybdenum, and Platinum for High Temperature Research*

George W. Ziegler, Jr., Rudolph Speiser, and Herrick L. Johnston
The Cryogenic Laboratory and The Department of Chemistry, The Ohio State University, Columbus, Ohio

March 17, 1949

CYLINDRICAL cells, containers, and furnace elements can be fabricated of tantalum, molybdenum, and platinum sheet for use in high temperature research. These refractory materials have been used to fabricate seamless Knudsen cells employed in vapor pressure measurements,[1] furnace elements in a high temperature x-ray camera,[2] and sample containers for high temperature calorimetry.[3] (In these examples it is important to use seamless cell containers since induction heating is used, and it is essential that the object be uniformly heated.)

Starting with a 0.010-inch tantalum blank, 2 inches in diameter, it takes four draws to make a cylinder ¾ inch in diameter and one inch high (see Fig. 1). The dies are made to nest one within the other. The schedule and die sizes are as follows:

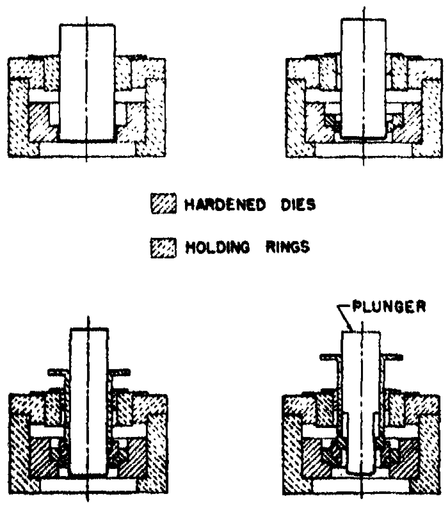

FIG. 1.

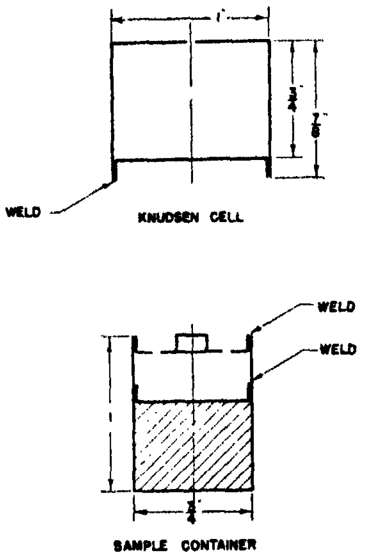

FIG. 2.

Draw	Die size	Radius of curvature of edges of stakes and punches
1st	2" to 1½"	5/32"
2nd	1½" to 1¼"	9/64"
3rd	1¼" to 1"	1/32"
4th	1" to ¾"	1/64"

An arbor press is employed to make the draw and the die assembly is *loosely* clamped with c-clamps.

Before each draw, the sheet, punch and die are thoroughly greased with Vaseline. After the draw, the Vaseline is removed with successive washes of benzene, acetone, and ether. Then the piece is annealed in vacuum (10^{-5} mm Hg with gradually increasing temperature and finally held at 1200°C for a few minutes. After the last draw the cell can be trimmed by placing the punch in a suitable collet and machining off the ragged edge at low speed. The lid is made from the same sheet with a similar die (not illustrated) so as to give a very snug fit inside the cell body as shown in Fig. 2. The lid is welded to the cell body with an electric arc (using a carbon electrode) in a hydrogen atmosphere.

The sample container (for use in a high temperature drop calorimeter) is suspended by a tantalum wire in the furnace. The bail to which the wire must be attached is formed with pliers and inserted into suitable slots cut into the lid and the ends are then melted down to the lid. The 1/32-inch holes drilled into the top of the lid are used for sighting into with an optical pyrometer when measuring temperatures. If the sample is volatile, the sample is sealed into the container with an inner lid as shown in Fig. 2. The space between the inner and outer lids creates a good "hohlraum" to sight into for accurate temperature measurements.

The Knudsen cell body is made from the same set of dies by utilizing only the first three draws. The orifice in the top of the Knudsen cell is made by reaming a hole of the desired size to a knife edge periphery.

The x-ray induction furnace elements are cut from the cylinders obtained from the fourth draw.

Platinum and molybdenum parts are also fabricated in the same manner. Platinum can be arc welded in air and is annealed at a temperature corresponding to a dull red color. Molybdenum is welded under a hydrogen atmosphere and annealed in vacuum (10^{-5} mm Hg) at 1100°C for a short time.

Non-Uniform Shrinkage of X-Ray Films

M. H. Jellinek
Laboratory, Linde Air Products Company, Tonawanda, New York
February 9, 1949

THE application of x-ray back reflection diagrams to measure solid solution compositions has been carried out in this laboratory on samples showing a maximum change of about 1 percent in lattice parameter. Sufficient accuracy was obtained by using Straumanis' type cameras of 57.3-mm diameter. Originally sodium chloride was tried as an internal standard to allow a determination of film shrinkage of no-screen x-ray film but it soon became apparent that non-uniform shrinkage was occurring about the hole punched in the film to accommodate the collimator.

To be able to measure this shrinkage as a function of position on the film a standard index was made by soldering ordinary needles at non-uniform distances to a steel strip. These needles were then used to prick the film in the region of interest before it was loaded to the camera. After the film was developed, fixed, and dried the spacings between pin pricks were measured with a traveling microscope reading to 0.001 mm. The standard was calibrated similarly without processing the film and a direct measure of film distortion was obtained.

The pricking device was made with a larger spacing between the central pins and this section was always placed across the center of the collimator hole in the film. In this way the standard was impressed in nearly the same location on each film. The average results of 37 sets of measurements are given in Table I.

Table I.

Standard pin spacing	Film distortion	Change in mm per mm of film in each region
8.023 mm	−0.016 mm	−0.0020
7.592	+0.003	+0.0004
13.077	−0.052	−0.0040
9.363	+0.015	+0.0016
8.235	−0.039	−0.0047

These results show that a large shrinkage occurred where the hole was punched through the film, that on either side of the hole there was a region where the film stretched slightly, followed in turn by a region of shrinkage.

The results for the region of expansion are probably too low because no attempt had been made to locate the region exactly and it is very possible that a small band showing a high degree of stretch exists.

The Use of Gas Traps in Barometers, Laboratory Mercury Lamps, etc.

E. L. Harrington
University of Saskatchewan, Saskatchewan, Canada
March 12, 1949

THE basic principle underlying the use of traps to capture and to retain residual gases in barometers, mercury lamps, or in other vacuum, mercury-containing chambers may not be new, but the author has noticed only one reference[1] to it in the literature and has not observed any practical application of it in any laboratory other than his own. Two important applications will be described, and two different forms of construction involving the same principle will be shown. Each depends for its action on the reluctance of mercury to enter a fine glass capillary, which makes it possible to trap any traces of gases left by imperfect exhaustion, accumulated from the gradual release of adsorbed gases, or due to other causes.

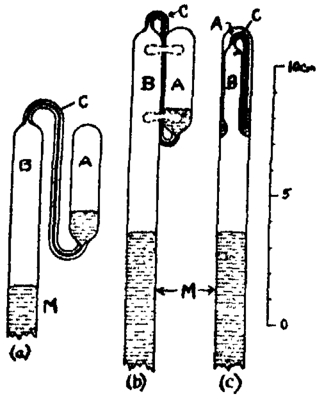

Fig. 1. (a) Diagrammatic representation of a gas trap; (b) the upper end of a barometer tube incorporating the gas trap shown in (a); (c) same except with a different type of trap.

Figure 1 is designed to illustrate the principle itself and also its application to the barometer or to mercury manometers. Referring to Fig. 1(a) it is evident that any trace of gas in the tube, B, above the surface of the mercury M, can be crowded through the capillary C into the chamber trap, A, simply by elevating the mercury in B until a small amount of mercury enters A. As M is lowered to its normal position the mercury thread will break at the upper end of B, leaving the space B free of gas. The amount of gas which normally would be collected in A would be quite insufficient to push the mercury into the A-end of the capillary and then to the height required to escape back into B. This simple operation might well precede any set of readings, but it is found that after the first few months the vacuum is so nearly perfect that little or no further gas is collected.

Figure 1(b) represents the upper end of a barometer tube incorporating the same arrangement as shown in Fig. 1(a) but in a more compact, practical form. It is seen that A is brought more closely adjacent to B and the two chambers are tied together by fused-on braces made of 3-mm solid glass rod in order to obtain greater mechanical strength. To free B from any trace of residual gas one has merely to swing the lower end of the barometer to one side until the surface of the mercury rises to the upper end of B and crowds any trace of gas through C, and then to return the lower end to its normal position. The tendency of the trapping mercury in A to return to B will depend on the pressure in A, but in the case of the first such barometer to be constructed in the laboratory of the Physics Department of the University of Saskatchewan not enough gas was accumulated in twelve years to untrap the gas collected. The form shown in Fig. 1(c) is identical in principle but somewhat neater in form, more compact, and sturdier. The choice between the two forms may depend on the skill of the glass blower and on the diameter of the tubing employed. The first form is easier to make and must be the choice where the tubing is too small in diameter to give room for an inner tube since the latter must be sufficiently large to prevent mercury forming a continuous column and emptying A through siphon action. The pressed-in lump shown in the throat of B in Fig. 1(c) is designed to prevent such action.

The advantages of the modification must be obvious. Our laboratory barometers incorporating this principle give higher readings than are given by the commercial barometers or by one supplied by the meterorological service. In the case of the standard form one is never certain as to whether any appreciable gas pressure exists in the relatively small space above the mercury in the tube, and the sharpness of the "click" made by the impact of M against the top of the tube is too insensitive to be of much use, besides being a risky test to make. One can hardly allow for the depression of the mercury due to

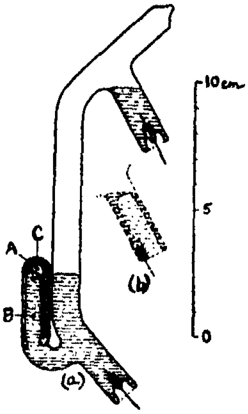

FIG. 2. (a) A laboratory mercury vapor lamp provided with a gas trap; (b) alternative form of electrode well.

this accumulated gas since its effect in any case must depend on the volume of the space above M, hence on the barometer height. Central meteorological stations may call in barometers for servicing, but this merely gives the barometer a fresh start in gas collecting and is both expensive and time consuming. With the improvement suggested even the remote observer can be sure that his reading is correct at all times. Even though with continued use the quantity of gas collectable becomes vanishingly small, it is a source of satisfaction to have at all times the means of quickly making certain of a reliable reading. In the case of mercury manometers forming a part of a McLeod gauge system, for example, where the operation of the trap cannot depend on inclining the apparatus the same result can be accomplished by applying to the system a positive pressure sufficient to cause M to go over the top.

Figure 2 shows the application of the trap to a laboratory mercury lamp of the type which is started by establishing a continuous mercury pool or stream between the two electrodes. To start such a lamp one rotates the lamp clockwise about an axis normal to the plane of Fig. 2 until the two pools are connected, and then very slowly brings it back to its normal vertical position. The arrangement of the trap addition is such that in the horizontal position chamber B is free of mercury and full of its share of any residual gas which may be present in the lamp. As the lamp is righted the gas in B including any extra swept in by the striking arc becomes trapped and crowded over into A through the action of the pressure normally developed during the operation of the lamp. Thus it is seen that with each starting of the lamp the vacuum is automatically improved, in sharp contrast with the usual lamp in which the vacuum gradually deteriorates with increasing life and use. The modified form for each electrode member, shown in Fig. 2(b) has a reentrant tube at the end. This modification reduces the weight of mercury required, almost eliminates hammering, and should greatly reduce the chance of breakage in shipment and in use. The two forms work equally well.

Aside from accidents, the failure of a laboratory mercury lamp is generally due to the gradual increase in the pressure of the residual gas. This gas may contaminate the mercury, but in any case the lamp becomes harder to start and the effective voltage required increases with time. This often leads to more violent mechanical treatment by the student attempting to start the lamp, too frequently ending in fracture. Partially to overcome this difficulty most such lamps have been provided with chambers large enough to take care of the residual gases without building up appreciable pressures, but this makes them more bulky and more fragile, and also reduces their efficiency since a larger radiating surface requires a larger wattage if the same operating temperature is to be maintained. Experience to date has shown that the lamps herein described operate more steadily than lamps of the usual type, that they are more easily started, and that the mercury remains clean. Incidentally, the "click" becomes sharper and this suggests greater caution against rapid turning or shaking just to hear it. All lamps which must be tipped in starting, should be provided with mechanical means of preventing the lamps from being turned in the wrong direction since the exposure of the tungsten leads is likely to cause the failure of the lamp. It will be observed that the upper end of the lamp slopes to the right, in contrast with its commercial prototype. While this aids in keeping full the upper electrode well and makes it possible to use either polarity, it is best to have the upper electrode serve as cathode. If the lower electrode were the cathode a large mercury drop might interrupt its flickering "hot spot," and stop the discharge.

A Vibration Absorber for Gas Holders*

R. S. Craig and W. E. Wallace
Department of Chemistry, University of Pittsburgh, Pittsburgh, Pennsylvania

March 12, 1949

THE vibration of gas holders has often been a source of annoyance to workers in cryogenic laboratories. This is particularly true in those cases in which the system is equipped with selsyn-level indicators or automatic switching devices which are controlled by the level of the holder.

The vibrations are usually caused by a coupling between the gas holder and the compressor. The movable portion of the gas holder and the cushion of enclosed gas effectively form a mass and spring system possessing a characteristic natural frequency. The natural frequency depends upon the quantity of gas enclosed, and hence upon the height of the holder. At some particular level the natural frequency of the gas holder may become equal to the frequency of the pulses from the compressor, under which conditions violent vibration of the gas holder may result. Systems which are particularly prone to vibrate in this manner are those in which the gas holder is

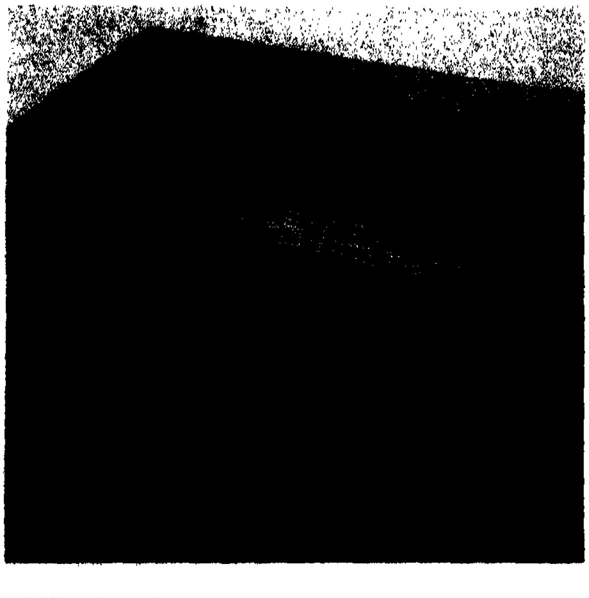

FIG. 1. View of top of gas holder, showing the vibration absorber in position.

designed so that it may be evacuated. In such cases the volume of enclosed gas becomes small as the float approaches its lower position, and the natural frequency may then become sufficiently high to equal the frequency of the pump.

The difficulty was eliminated in an installation in the University of Pittsburgh by a device known as a Dynamic Vibration Absorber.[1] This device consists of a relatively small m-k system in the form of a mass suspended from a spring. The spring is attached rigidly to the offending vibrating system and the magnitude of the mass is adjusted until the frequency of the absorber is equal to that of the forcing vibration (i.e., the frequency of the compressor). Under these circumstances the amplitude of vibration of the gas holder is reduced to a negligible value, and the energy is absorbed almost entirely by the small m-k system.

The gas holder to which this device was applied is a part of the standard equipment for use with the Collin's Helium Cryostat. The movable portion of this holder consists of a steel cylinder open at the top and closed at the bottom. The helium gas is enclosed in the space between the bottom of the floating portion and the outer container, where it is sealed by a large neoprene gasket. The spring was fastened to a support bolted across the top of the gas holder as shown in Fig. 1. The spring had a stiffness coefficient of approximately 500 lb./in., and the magnitude of the suspended mass was 50.4 pounds. This device has proved entirely satisfactory in operation.

Construction of Beta-Geiger Counters from Prefabricated Thin Wall Tubing*

F. E. Senftle, W. Havercroft, and P. Hernandez
Radioactivity Section, Bureau of Mines, Canada

March 8, 1949

The construction of thin beta-Geiger counters has been described in the literature and textbooks. The usual method to obtain thin walls has been to draw the glass very thin. Although this can be done manually with some difficulty by a skilled glass-blower, it has become common practice to use a glass lathe where any quantity of tubes are to be made.

Recently the Corning Glass Works has made commercially available, thin wall etched borosilicate glass tubing (Code No. 7740) which has been found to have certain distinct advantages in the construction of Geiger tubes. This prefabricated thin walled tubing is particularly useful where Geiger tubes of uniform diameter are needed or where it is necessary to build a number of tubes with limited glass-blowing facilities. It is the purpose of this paper to describe the new tubing and Geiger tubes made from it. The use of this special tubing has facilitated the construction of certain types of cathodes for Geiger counters, and the increased mechanical strength of such tubes also admits their use in environments of higher than atmospheric pressure.

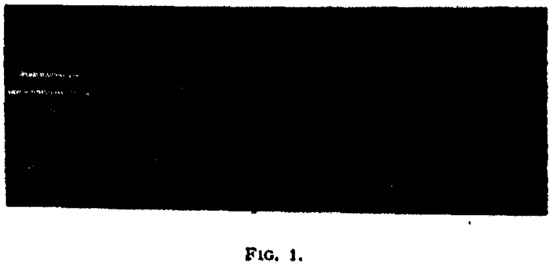

Fig. 1.

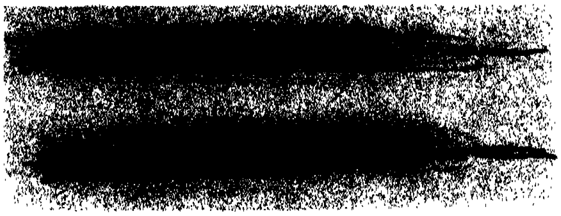

Fig. 2.

Fig. 3.

The thin glass etched blank as received from the manufacturer and the first steps in the construction of the Geiger tubes are shown in Fig. 1. The central section of the blank is the thin wall, and on either end is a short section of ordinary unetched borosilicate glass tubing. The over-all length of the blank is 6″ to 8″. At present two diameters are obtainable, 19-mm and 25-mm O.D. The thin central section is slightly smaller on the O.D. and slightly larger on the I.D. than the heavy section at the end. The wall thickness of the thin section is remarkably uniform, and, depending on the particular blank, the thickness is between 0.006″ to 0.016″, which is about 41 to 110 mg per cm^2. The maximum variation of thickness of the individual blanks tested was found to be about ±0.002″. For low energy beta-counters it is necessary to select blanks with the thinnest wall. However, the majority of blanks which have been tested to date have been found to be sufficiently thin for most work.

The blanks of thin tubing have a substantially uniform bore, and are less fragile than hand-drawn tubing, since they have no extremely thin mid-section which thickens toward the ends. In the hand-drawn and to a lesser extent in the lathe-drawn tubes, the central diameter is slightly smaller than that of the extremities. Hence, any uniform cylindrical cathode could not be conveniently put inside such an envelope. On the other hand, the uniform bore tubing allows the use of a wide copper spiral or open screen as a cathode. These open cathodes allow a free passage of the beta-particles into the active volume while still maintaining a uniform field. Although a close wound wire helix or fairly fine copper screen has an inside area greater than that of a solid cylinder, a condition tending to increase the gamma-efficiency, it has been found that a good beta-counter can be made, if the wires are not too close together. The sectional area to gamma-rays perpendicular to the tube axis is small for an open helix.

Figure 2 shows a typical copper spiral beta-counter and also one with a conventional deposited silver cathode. Both were made with Code No. 7740 glass. If a silver surface is used for a cathode, it is more convenient to deposit it on the thin glass blank prior to any glass-blowing steps as shown in Fig. 1.

Tests on a small number of tubes indicate that they will stand a maximum of 60 p.s.i. external pressure. It is obvious that Geiger tubes made from such tubing would be particularly suitable for beta-measurements under a considerable head of liquid. A tube with a liquid jacket is shown in Fig. 3.

Where radioactive elements or tracers can be used, a constant check on concentration may be maintained. In certain industrial processes, the active solutions are circulated under pressure through the jacket, and the concentration of the beta-active tracer may be continuously monitored. The relatively strong thin wall of these Geiger tubes makes such an arrangement feasible.

Our thanks are due the Corning Glass Works for providing helpful information.

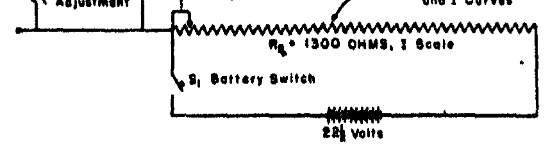
Percent Transmission Computer for Infra-Red Spectra*

C. E. Zerwekh, Jr.
Humble Oil and Refining Company, Baytown, Texas

January 3, 1949

A DEVICE for converting the usual infra-red intensity wave-length curves to percent transmission curves which was described earlier[1] has been modified to increase its versatility. The incident energy (I_0) and transmitted energy (I) curves are run in a conventional manner on an infra-red spectrometer except that they are superimposed on the same chart. This chart is then placed in another instrument and the curves traced simultaneously by hand with two pointers placed on a single track. One of the pointers selects a voltage E proportional to I and applies it to the other pointer which impresses it across a resistance R proportional to I_0. The current i flowing in the resistor is equal to the quotient of E/R and is thus directly proportional to I/I_0 or the percent transmission.

The infra-red equipment consists of a Perkin-Elmer Model 12-C Infra-Red Spectrometer equipped with a chopped beam detecting system and a Perkin-Elmer Breaker Type D.C. Amplifier.[2] The output of the amplifier is impressed on a suitable filter circuit and then fed to a Brown Elektronik strip chart recorder. The electrical circuit of the computer is illustrated in Fig. 1. All of the electrical components were mounted on a Brown Elektronik recorder chassis that had been stripped of everything except the chart drive motor and associated mechanism. The two resistance cards, specially wound by General Radio so that the total length occupied by the windings was equal to the 0–100 distance on the chart paper, were mounted in the place originally occupied by the Brown slidewires. An additional Brown carriage for carrying the sliding contacts was placed on the carriage track, and contacts were mounted on both carriages. Since each contact had two elements, one of these was cut off so that each carriage and its contact touched only one resistance card. A pointer was mounted on each carriage and aligned with the point of contact between the resistance card and the sliding contact. In addition, two more sliding contacts, one for each card, were mechanically coupled together and mounted on a special carriage at the zero end of the resistance cards. These contacts allow compensation for difference in zero levels. A shorting switch S_2 was also mounted across the input to the recorder to allow the fiducial marks appearing on the original curve to be transferred to the percent transmission curve. This switch was mounted under an accelerator pedal to allow it to be operated by foot. A variable shunting resistor R_3 across the recorder input allows the sensitivity of the recording system to be adjusted to compensate for the changes in battery voltage and, in effect, is a standardizing knob. The chart drive motor on the computer and the recorder were connected to a common switch to allow the computer and recorder charts to be started and stopped simultaneously.



R₁ = 300,000 OHMS, I₀ Scale
Output to Recorder
R₃ = 250 OHMS Shunting Resistance for Range Adjustment
Mechanically Linked Contacts for Zero Adjustment
Sliding Contacts To Follow I₀ and I Curves
R₂ = 1300 OHMS, I Scale
S₁ Battery Switch
22½ Volts

FIG. 1. Circuit diagram of Percent Transmission Computer.

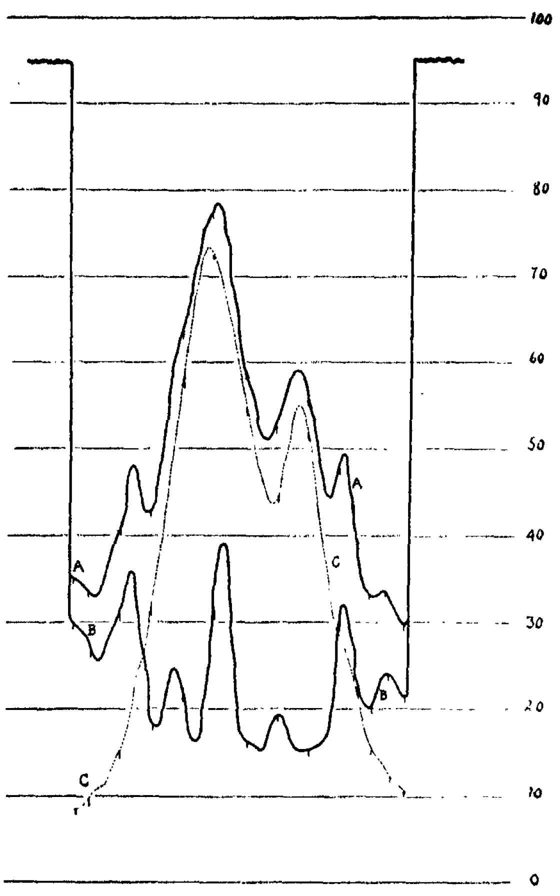


FIG. 2. Curve A: cell filled with sample; curve B: cell filled with reference standard; curve C: percent transmission (curve A×100/curve B) traced by the computer.

To use the instrument, a record of the wave-length intensity curve for the filled sample cell is made in the usual manner. Then the chart is turned back to the starting point and a record is made of the reference. This is very readily done with the Perkin-Elmer Model 12-C Infra-Red Spectrometer since the chopped beam detecting system eliminates practically all zero drift. The chart is then removed from the original recording system, placed in the computer, and aligned for the proper starting position. The zero contacts are then adjusted to the proper zero level. When the start switch is thrown, both charts begin moving simultaneously and at the same speed. The superimposed charts are traced by hand, and whenever a fiducial marker passes under the tracing pen, the marking switch is pressed to place a mark on the percent transmission curve. Figure 2 illustrates the type of results obtained from this instrument. Curve A is the intensity wave-length curve for the 6.70 to 7.00 micron region for a sample cell filled with

0.182 volume percent *trans*-1,3-dimethylcyclohexane in carbon tetrachloride, and curve B is the corresponding curve for the same sample cell filled with carbon tetrachloride. Curve C is the ratio of A to B as determined by the Percent Transmission Computer.

Tests obtained on this computer show that it has an inherent accuracy and reproducibility of ±0.1 percent transmission on the average with a maximum deviation of approximately 0.3 percent. Tests under actual operating conditions give results that are on the average within ±0.7 percent of the actual value, with the maximum deviation occurring when both the incident and transmitted energy curves have steep slopes, such as those occurring in the regions where water vapor absorbs strongly.

The Use of Anodized Aluminum in the Construction of Calorimeter Heaters

George W. Murphy
Department of Chemistry, University of Wisconsin, Madison, Wisconsin

February 9, 1949

AMONG the desirable features of electrical heaters for introducing measured amounts of energy into calorimeters are those of low heat lag and low heat capacity. For routine work, durability is also an important asset. Where a liquid of negligible electrical conductivity is to be heated, bare resistance wire satisfies the first two requirements admirably; however, in aqueous solutions of electrolytes, which are appreciably conducting, bare resistance wire in contact with the solution cannot ordinarily be used. Furthermore, any attempts to insulate the wire inevitably increase the heat lag and the heat capacity. It is the purpose of this paper to describe a technique for preparing insulated heaters with very low heat lag and heat capacity and high durability.

Anodically prepared layers of aluminum oxide on aluminum have been employed for many years for corrosion protection and for other purposes.[1] These layers are extremely tenacious and durable, and for our purposes, have the important property of being electrically insulating. The thickness of the coating can be controlled within wide limits. Thus if a suitable aluminum heater core is anodized, resistance wire wound on this core will be insulated from it; heat conductivity between the wire and the core should not be seriously impaired because of the thinness of the coating. A casing can be soldered to the core to protect the resistance wire from the solution.

A heater which has been so prepared and used for routine work in the undergraduate physical chemistry laboratory will be described in a forthcoming book.[2] Several variations in design of this heater have been prepared by the author and his associates, and the wide application suggested has prompted this publication of constructional details.

The sequence of operations for preparing a heater is shown in Fig. 1. The heater illustrated is tubular in form so that a stirring propellor can be inserted to improve circulation of the liquid. Pure aluminum is best for anodizing, but the customary alloys will give satisfactory service for this application. Threads are machined on the core for a calculated length of resistance wire. Rounded grooves should be milled between the thread terminals and the outlet holes for the wire, and all sharp corners over which the wire might pass are carefully removed. If this is not done, subsequent breakdown of the coating is likely. The usual anodizing process increases the dimensions very slightly; therefore, the casing should be a free fit around the core before anodizing.

The part to be anodized is degreased in an organic solvent, pickled in 1-molar sodium hydroxide solution until hydrogen is copiously evolved, rinsed thoroughly, and placed in the anodizing bath. The electrolyte in the anodizing bath is 5 percent by volume H_2SO_4.[3] The temperature should not rise much above that of the room for best results. For this purpose tap water may be circulated through a copper cooling tube, which also serves as cathode. A motor stirrer should be provided. A current density of about 0.2 amp./sq. in. yields a satisfactory coating in about 30 minutes. Thicker coatings can be obtained with higher current densities and longer times. After anodizing, the part is rinsed and "sealed" by immersion in boiling water for about 20 minutes. This operation seals the pores by formation of a hydrated oxide.

When both parts have been anodized, the surfaces are tested for short circuits, and if the tests are satisfactory, resistance wire (preferably of Advance or manganin) is wound on. The small outlet hole at one end is reamed to expose the bare metal, since one end of the wire is to be grounded to the case. The casing is now slipped on and soldered to the core with aluminum solder.[4] The oxide coating must, of course, be filed or ground away at the points to be soldered. The grounded end of the resistance wire is soldered to the case.[5] A heavy copper wire lead may be soft soldered to the other end of the resistance wire. No flux should be allowed to flow into the outlet hole of the heater. The lead wire may then be insulated by a tube of Lucite which is sealed to the heater by Lucite cement, or by such other means as may be dictated by the particular problem. The other end can be a strip of aluminum grounded to the case. Additional leads for potentiometer connections can be provided if desired.

The heaters described above were designed for a low voltage (6 volts) and low power dissipation (6 watts). There is nothing in the construction, however, to indicate that these units cannot be used for much higher voltages and power dissipation. Professor Paul Bender and his associates of this De-

partment have constructed heaters which operate satisfactorily from a 110-volt power supply and will handle at least 250 watts.[6] These units were totally enclosed in a brass shell and the lead wires were carefully insulated and enclosed in brass tubes.

Rough tests of these units for heat lag have yielded no quantitative data, since the results seem to be influenced as much by the stirring arrangement and thermometer inertia as by the lag of the heater itself.

The heater described above is suitable for use in aqueous solutions which are neither strongly acid nor strongly basic. For acid or basic solutions the heater could be sheathed with gold or other non-corrodable material. It might also be mentioned that tantalum is known to form anodic layers similar in characteristics to those on aluminum. A heater made with a tantalum core would be able to withstand strong acids; furthermore, tantalum might make possible high temperature applications beyond the melting point of aluminum.

The author in collaboration with Mr. W. R. Rowe has also prepared a low heat lag resistance element for temperature control by winding Hytemco wire on an anodized aluminum form. This has given satisfactory service for a year at control temperatures in the neighborhood of 250°C.

The author wishes to thank Mr. Lloyd Lincoln of the departmental shop for his skillful assistance in the machine and soldering work on a number of these heaters. He is indebted to Mr. Harry A. Schopler for preparing sketches on which Fig. 1 was based.

[2] Daniels, Mathews, Williams, and staff, *Experimental Physical Chemistry* (McGraw-Hill Book Company, Inc., New York, 1949), fourth edition.

[3] Many variations in electrolyte have been employed (see reference 1). The concentration is not critical.

[4] Aladdin Rod, a solder made by the Aladdin Rod and Flux Manufacturing Company, is satisfactory. The manufacturer's instructions for using this solder should be carefully followed.

[5] If the aluminum core is tinned with aluminum solder at this point, soft solder may be used between the resistance wire and the core. Aluminum solder will not in general wet the resistance wire.

[6] These heaters will be described in more detail in forthcoming publications by Bender and associates.

Method for Preparing Capillary Tube Samples for X-Ray Diffraction Powder Analysis*

Paul J. Hagelston and Harris W. Dunn
Carbide and Carbon Chemicals Corporation, Y-12 Plant, Oak Ridge, Tennessee

February 1, 1949

FILLING of capillary tubes with powder samples for x-ray diffraction work is usually accomplished by thrusting the capillary into a quantity of powdered sample material, each thrust forcing some of the powder into the tube until the required amount is enclosed therein. The tube is then end-sealed.

Under the following increasingly common conditions, the usual method is not at all satisfactory.

1. Handling of hygroscopic materials in a dry box is difficult since it necessitates wearing cumbersome gloves extending through the ports while manipulating small tubes. Too, the likelihood of moisture pick-up is a danger during the period of removal of the sample for sealing.
2. Contamination by dirt and dust from air, vessels, and hands is an ever-present possibility even with stable samples.
3. Samples extremely limited in quantity, such as enriched isotopes, make capillary filling virtually impossible.

Gibons and Bicek[1] have recently outlined a method for filling capillaries which requires the use of a vacuum set-up. The points of great caution they cite as necessary in their method are believed to be non-existent through use of the following technique. In addition, the limiting conditions numbered above are virtually eliminated.

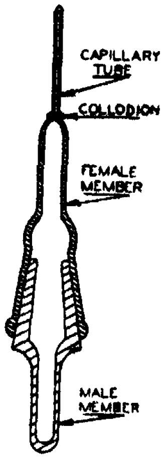

FIG. 1. Capillary filling jig final assembly.

Figure 1 shows a capillary filling jig, consisting of an amended 10/30 pyrex ground joint whose male member is closed at the tubular end. The female member has a small hole in its tubular end into which is placed the open end of a capillary tube whose other end is sealed. The capillary is held in position by application of collodion or other suitable thick fluid to its junction at the tip of the female member.

To assemble this filling jig, a difficult and unsatisfactory job when done by hand, an assembly jig is used, one head of which is shown in Fig. 2. The sealed end of the capillary is stuck in a plastic-clay-filled hole on the bottom of the lower knurled knob on the screw column of the assembly head, and the amended 10/30 ground joint assembly placed in position by inserting the tubular end of the male member in the base hole provided. The capillary is positioned directly above the female member tip hole through use of the rotational, horizontal, and vertical adjustments provided. The lower knob, which is attached to but free to rotate upon the vertical screw shaft, is held while the screw shaft is rotated downward, bringing the capillary the desired distance into the tip of the female member. Collodion or other material is applied, allowed to dry, and the lower knob again held while the shaft is retracted.

To fill the then assembled jig, the ground joint is separated and the sample material placed in the female member. The male member is refitted and a fine-cut file drawn across the assembly, the resultant vibration forcing the material into the capillary. When the latter is filled to within about one-quarter inch of the collodion joint, it is sealed-off by a hot pin-point flame.

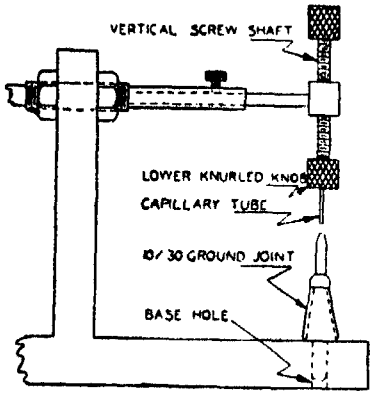

FIG. 2. Assembly jig head.

With hygroscopic materials, the component parts of the jig are allowed to dry in the dry box, the material placed in the female member, and the male and female parts refitted. The assembly may then be removed from the dry box and the capillary filled and sealed-off as above. Throughout the procedure, parts can be kept clean and very little possibility of contamination presents itself.

When dealing with materials of extremely limited quantities, it is necessary to assemble the filling jig so the junction of the capillary to the tip of the female member is essentially a butt joint.

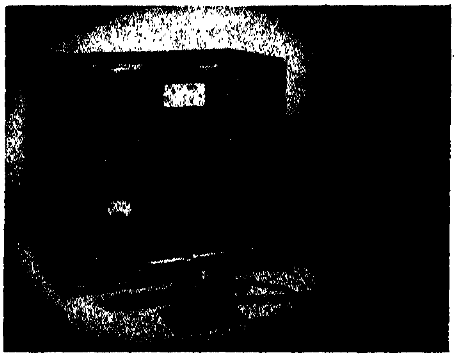
Nucleometer

The Mark 9, Model 3, RCL Nucleometer-Scaler Type is a complete instrument for counting alpha-, beta-, or gamma-radiations with extreme precision and reliability. It consists of the counter tube, high voltage supply for the counter tube, amplifier, pulse equalizer, scaling circuit, a supply of gas and a regulator. With reasonable precautions the reproductibility of the RCL Nucleometer-Scaler Type will be within statistics.



The counter tube through which the hydrocarbon gas flows, operates in the proportional region as differentiated from the Geiger region. This results in the following advantages:

a. Low resolution loss at all counting rates—less than 2 percent at 100,000 counts per minute.
b. Exceedingly flat and long plateau.
c. With an airlock to introduce samples directly into the counter, the tolerance to air is several orders of magnitude greater for a given accuracy than a Geiger counter tube, permitting shorter flushing time.
d. The chemical breakdown of the gas, forming undesirable deposits on the inside surface of the counter, is approximately in the ratio of the voltage pulses from Geiger and proportional counter tubes, being on the order of 1000 times less obnoxious for the proportional counter tube than for the Geiger counter tube.

The counter tube is available in either an internal sample or external sample type. With the internal sample type, the radioactive sample is placed in a "well" and slid directly into the counter volume giving 50 percent geometry and no window absorption. This counter tube is used for counting samples with soft radiation and when sensitivity is of utmost importance. The external sample type has a thin window and is furnished with standard Lucite mount. It is used where variations in geometry are desired, as well as when absorption measurements are required. Since both counter tubes operate slightly above atmospheric pressure all consequent leakage problems are eliminated.

The counter tube is operated at 4200 volts from a regulated supply with a stabilizing factor greater than 200. The voltage may be varied from 2200v to 5000v permitting determination of the counter tube characteristic curve.

Since the counter tube operates in the proportional region an amplifier is used between the counter and scaler. In order to advantageously use the fast characteristics of the counter a fast linear amplifier is employed. Use of the proportional counting region requires that the pulsed amplitudes be equalized before scaling.

The scaler is of the time tested Higinbotham type and contains a scale of 512 in order that one may count at the high rates permitted by the low resolution loss of the counter, with alternate selection of scales of 64, 128, and 256. It is complete with panel mounted Standard Electric Timer and Wizard Recorder.

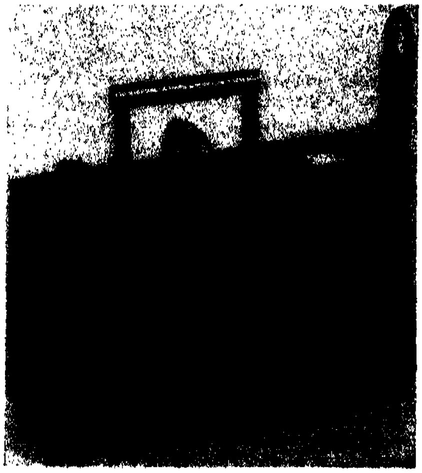
The gas is specially purified methane and is furnished through a two-stage regulator, which informs the operator of delivered pressure as well as an indication of gas remaining in the tank.—RADIATION COUNTER LABORATORIES, INC., *1844 West 21st Street, Chicago 8, Illinois.*

Radiation Meter

Radiation Meter, model number RM-1 is a portable survey meter which has the following features:

1. Continuously variable high voltage supply from 400 to 1500 volts, permitting the use of end-window as well as cylindrical type G-M tubes. High voltage is obtained from inexpensive 67.5-volt batteries.

2. A meter range covering three ranges of activity: 5000, 50,000, and 500,000 counts/minute. At the upper range, more than four times tolerance dosage of x- or gamma-radiation can be measured. Intensities considerably above tolerance levels for the various alpha- or beta-emitting radioactive isotopes can also be readily determined.



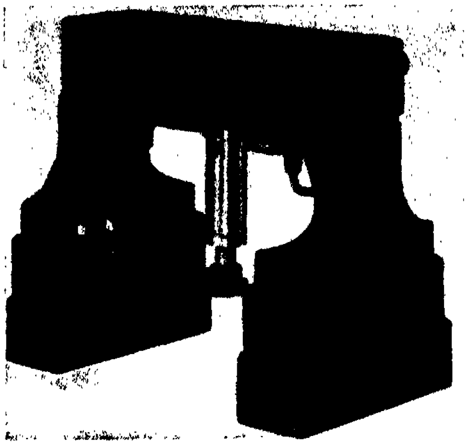
3. Meter accuracy of better than 2 percent, full scale. This permits use of the instrument as an inexpensive count rate meter for quantitative assay, besides its regular application for health monitoring and contamination detection.

4. The instrument is of rugged construction. It can be used in all kinds of weather. It is supplied with earphones. It is particularly suitable for prospectors for radioactive ores.—THE NUCLEONIC CORPORATION OF AMERICA, *497 Union Street, Brooklyn 31, New York.*

Alpha-Particle Counter

The outstanding feature of the Model D45 detector is its ability to count alpha-particles in the presence of high beta-activity with 50 percent geometry and low coincidence losses.

When this detector is used with a high gain linear amplifier and a "fast" scaler, it is possible to count alpha-particles in the presence of a beta-activity of 5×10^9 disintegrations per minute. Measurements of this type are particularly useful in chemical, physical, and biological research.



The counter chamber of Model D45 has a very highly polished cylindrical cathode. The anode is 0.002" diameter tungsten wire mounted between glass insulators. Construction is designed to permit easy decontamination both inside and outside. The sample holder, mounted on a stainless steel sample changer, is designed for standard one-inch diameter samples, with provisions for raising the sample up into the counting volume for improved geometry. Flow of methane gas through the chamber is controlled by means of valves and an attached bubbler. Connection of a coaxial cable is made to the center wire via a well insulated connector on rear of the cover.—NUCLEAR INSTRUMENT AND CHEMICAL CORPORATION, *223 West Erie Street, Chicago 10, Illinois.*

Wide-Range Power Supply

A new wide-range power supply apparatus featuring a continuously-variable voltage output from 500 to 50,000 volts with a maximum current output of 1 milliampere has been announced by the General Electric Company.

Designed for laboratory applications where a variable voltage at low current is required, the new wide-range power supply can be used in electron diffraction studies, mass spectroscopy studies, research on high intensity screens for cathode-ray studies, electron microscopy, and projection television experiments.

The high voltage is attained through the use of a radio-frequency oscillator, power amplifier, r-f transformer, and a ladder-type voltage tripler circuit. Use of the r-f source, about 40 kc, makes possible reduction of the output ripple to a low value by simple filtering means. This minimizes the equipment's weight (350 lb.) and size (23×84×20 in.).

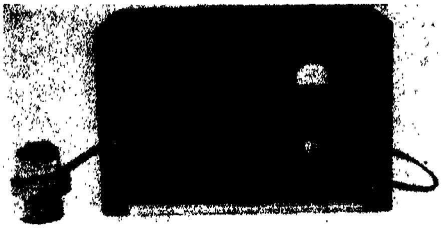
The wide-range power supply has been designed with exceptional stability as to output voltage, ripple, and load regulation. Output power, supplied through a 15-ft. x-ray cable, is not affected by variations in line voltage or frequency. Full compensation is made for ambient temperature changes, and precision regulation is attained through the use of two regulating loops in cascade.

A switch on the control panel provides for the selection of two ranges: 500 to 5000 volts and 5000 to 50,000 volts. Output voltage may be turned on or off by easily accessible, momentary push buttons. A gravity-operated grounding device shorts the output terminals when the high voltage is turned off. The output voltage and output current may be read on two panel-type meters at the top of the equipment. Controls are provided to turn the supply on or off, to adjust the voltage, and to adjust the plate current in the oscillator tubes.

Power requirements are 100–130 volt r.m.s., 60 cycles, with commercial stability. Full load power consumption is approximately 1000 watts. Ripple is between 0.006 percent and 0.04 percent, depending upon output voltage and load. Drift is less than 20 parts per million per minute on the low voltage range and less than 100 parts per million per minute on the high voltage range.—SPECIAL PRODUCTS DIVISION, *General Electric Company, Schenectady 5, New York.*

Ultrasonic Generator

A new type "CL" (clinical-laboratory) ultrasonic generator has recently been developed by Ultrasonic Engineering Company. The principal feature of the new equipment is the special convertible "transducer" for transmitting the high frequency vibrations to the skin of the patient, or to the specimen of tissue or other material under treatment. The transducer is connected to the generating unit by a coaxial cable carrying low voltage (less than 100 volts) high frequency current.



The base of the transducer comprises a transparent Lucite tube, surrounded by a ring containing the primary winding of the step-up Tesla coil, from which a handle projects, with the connecting cable leading through it.

Inside the tube is the secondary winding of the step-up coil. The crystal is mounted above the secondary coil upon Nylon rods, between Bakelite and glass disks. The tube is closed by a cap containing a Bakelite diaphragm 1/100 inch thick, mechanically connected with the vibrating crystal by oil which fills the entire assembly.

This diaphragm, placed against the skin of the patient under treatment, effectively transmits the ultrasonic vibrations generated by the crystal, which is one and one-half inches in diameter and from approximately one-eighth to one-quarter inch thick, depending upon the frequency desired.

A second Lucite tube is provided, which may be screwed to the top of the base assembly and filled with oil, into which a test tube or other vessel containing either solid or liquid material to be treated may be immersed. Through this feature of convertibility, the equipment is readily adapted to most requirements of clincial or laboratory work.

The generating unit, operated by standard 115-volt, 60-cycle current, uses full-wave rectification with adequate filtering. The self-excited oscillator is coupled to the crystal circuit, and is frequency-controlled by it. Thus the frequency of the oscillator is prevented from drifting out of phase with the natural period of the crystal, assuring constant and maximum energy delivery. Power control is adjustable, and is metered in the crystal circuit.

Standard frequency of the generator is 450 kc, with alternate crystal and coil available for quick conversion to 900 kc. Other frequencies are available upon special order.

A series of larger models have been developed for industrial laboratory and production work and will soon be available. Particularly interesting is a model designed for continuous-flow processing of liquids in manufacturing applications.

The new "CL" Ultrasonic Generator is designed to provide the clinic, laboratory, or physician with compact, flexible, inexpensive equipment for experimental research or treatment work.—Ultrasonic Engineering Company, *Dept. 33, Main Street and Eighth Avenue, Maywood, Illinois.*

Sound Measurement

Model GA-1002A sound pressure measurement equipment is a newly designed instrument incorporating important structural refinements resulting from the experience acquired during manufacture and use of its predecessor. Major improvements include a specially isolated socket tip which effectively separates the microphone clamping structure from the preamplifier extension tube. This isolation eliminates mechanical resonances that might otherwise result in the extreme high frequency range due to standing waves which could be set up in the preamplifier extension tube under certain conditions of use. The M-101 standard microphone, which is part of the equipment, has been re-designed to provide more accurate polar symmetry of the mechanical structure, resulting in exact acoustic symmetry about the normal axis of the microphone even at frequencies above 20 kc.

Sound pressures from less than 1 dyne/cm^2 to 20,000 dynes/cm^2 (160-db level) may be directly measured, and a times-ten multiplier is available for extending the upper range to 200,000 dynes/cm^2 (180-db level). A built-in calibrating circuit permits setting the system gain so that exactly 1 millivolt/dyne/cm^2 is delivered across the 10,000-ohm output circuit.

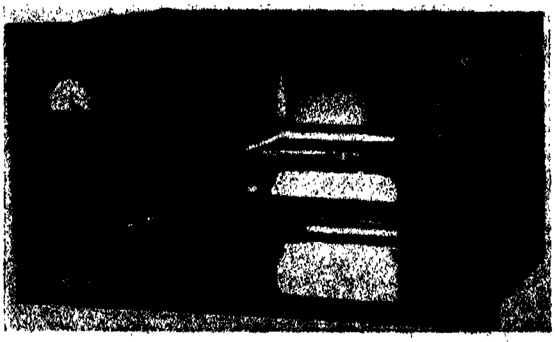
The acoustic impedance of the standard microphone is virtually infinite so that accurate sound pressure measurements may be made even in very high impedance environments such as inside small enclosures at the higher frequencies. Complete lack of phase distortion permits exact reproduction of sound pressure transients over the complete audio frequency spectrum.—Massa Laboratories, Inc., *Cleveland, Ohio.*

Graphic Recorder

Model FRA, a direct ink-recording instrument, automatically plots a curve of any slowly or rapidly changing measurable quantity that can be converted into a d.c. or a.c. voltage. The measuring ranges can be selected and recorded either on a logarithmic or linear scale.

This recorder may be applied to the fields of acoustics, electroacoustics, noise and vibration, loudness, strain and pressure, and field strength.

This instrument is available in 56 double chart speed combinations from 45 inches per minute to ½ inch per hour and for recording frequency ranges from 2 to 200,000 c.p.s.

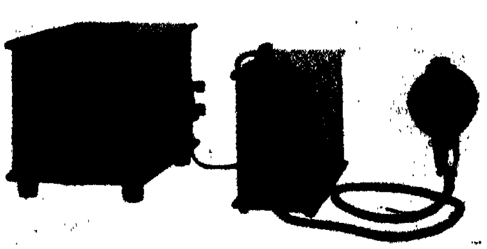


It is completely cased for portable field use or laboratory rack mounting in 10½″ rack space, incorporates built-in cali*bration control, and is unaffected by line voltage changes.*—Sound Apparatus Company, *Stirling, New Jersey.*

Electron Multiplier Photometer

The Farrand Electron Multiplier Photometer has been designed for general purpose measurement of very low light intensities. Photo-multiplier tubes affording high sensitivities are used as detectors and obviate the need for additional amplifiers.

The main features of this photometer are: Selective wide range of sensitivity, linear response, measurements in the ultraviolet and visible region, dark current balance control, constant voltage, stable battery power supply, interchangeable photo-multiplier tubes, flexible utility, compactness, and simplicity of operation.



By choice of a photo-multiplier having optimum characteristics in the ultraviolet or visible region of the spectrum, the use of the photometer is readily extended to numerous and broad applications concerned with photometry.

The photometer is comprised of three units: (1) detector, (2) power supply and controls, (3) galvanometer. This arrangement makes it convenient to use directly or to attach the photometer to various instruments.

A detailed description of the Farrand Electron Multiplier Photometer is contained in Bulletin 804.—Farrand Optical Company, Inc., *4401 Bronx Boulevard, New York 66, New York.*

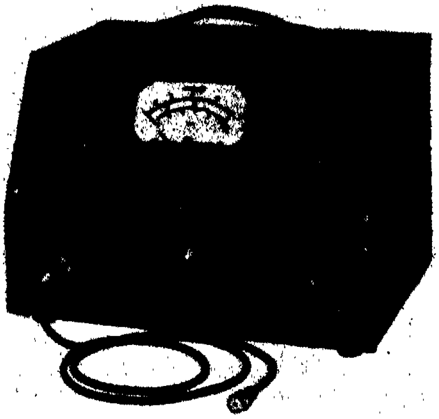
Microwave Power Meter

The Hewlett Packard Company announces a new microwave power meter. The new instrument is known as the −hp−430A Microwave Power Meter, and is designed automatically to indicate power developed in a standard barreter. Power level is read directly on a 4″ square meter face. No calculation or knob-twisting is necessary once range selection and zero set are made. The −hp−430A is automatically self-balancing, and may be used over any frequency, depending on the associated barreter and mount.

This instrument consists of an a.c. bridge, one arm of which is a barreter. The bridge is in balance with zero r-f power in the barreter. As r-f power is applied to the barreter, an equivalent a.c. (audio) power is automatically removed; thus the bridge remains in balance. A vacuum tube voltmeter reads the change in audio power level. This meter, calibrated in milliwatts, gives a direct indication of the r-f power in the barreter.

The indicating meter is calibrated in dbm in addition to the linear milliwatt calibration. The 5 power ranges are selected on a convenient front panel switch.

From a technical standpoint, the new −hp−430A covers a power range of from 0.02 milliwatt to 10 milliwatts. Ranges are related in 5 db steps, and continuous readings are available from −20 dbm to +10 dbm (0 dbm equals 0.001 watt). This power range may be extended by the use of attenuators or directional couplers. Accuracy of the meter is within 5 percent of full scale readings.

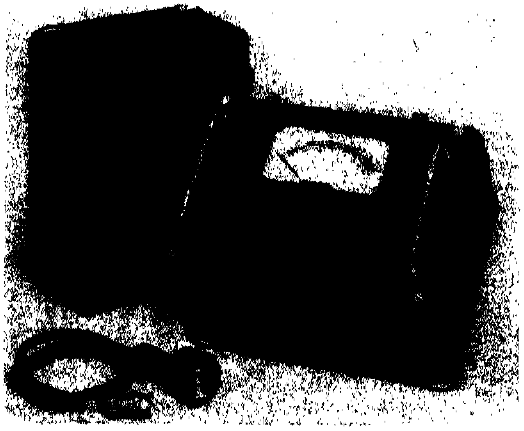


This power meter measures 12″ wide by 9″ high, and is 9″ deep and is powered by any 115 volt, 60 c.p.s., a.c. source.—Hewlett Packard Company, *395 Page Mill Road, Palo Alto, California.*

Coatingage

The "Coatingage" is an instrument for measuring the thickness of non-magnetic coatings on iron or steel. Measurements are made rapidly, without damage to the coating, and the thickness is indicated directly on the meter of the instrument. Two concentric scales cover a range of 0.0001″–0.50″. The instrument's lightweight and self-contained battery power supply permit its use in the field as well as in the laboratory or on the production line.

The "Coatingage" head contains a coil, connected in a bridge circuit. Coating thickness is measured by the effect of changes in the reluctance of the magnetic circuit. When the coil is in direct contact with the base metal the reluctance is low and the self-inductance of the coil is high. The bridge is then balanced for zero thickness. An increase in the gap between the coil and the base metal unbalances the bridge, and causes current to flow through the indicating microammeter.



The instrument is housed in a luggage-type carrying case, 8″ high, 9″ wide, and 6″ deep, weighing 10 lb. Power is furnished by two 67½-volt batteries and one 1½-volt battery, contained in the instrument. Thickness readings are within 10 percent of the actual thickness.—Branson Instruments, Inc., *436 Fairfield Avenue, Stamford, Connecticut.*

Manufacturers' Literature

Sonic Energy—4-page brochure discusses potentialities of sonic energy for laboratory and production applications.—ULTRASONIC CORPORATION, *61 Rogers Street, Cambridge 42, Massachusetts.*

Electronic Counters—4-page catalog is a brief guide to the company's line of high speed electronic counters, scalers, counter chronographs, and special electronic frequency measuring and computing equipment. A discussion of the electronic counting principle, methods of count detection, and typical applications are included.—POTTER INSTRUMENT COMPANY, INC., *136-56 Roosevelt Avenue, Flushing, New York.*

Alarms—Bulletin 300 describes various types and applications of Panalarms, sound and visual alarms which indicate failure or abnormal conditions when actuated by a remote switch, thermostat, float switch, or other switch.—PANALARM PRODUCTS, INC., *7216 North Clark Street, Chicago 26, Illinois.*

Universal Tester—Bulletin M, 4 pages, describes a multilow range universal tester. An 8-inch dial indicator is calibrated in 4 scales, up to 100 pounds.—W. C. DILLON AND COMPANY, INC., *5410 West Harrison Street, Chicago 44, Illinois.*

Manometer—Publication No. TP-30-A describes recent improvements in new models of the W and T Precision Dial Manometer.—WALLACE AND TIERNAN PRODUCTS, INC., *Belleville 9, New Jersey.*

Self-Lubricating Bushings—A 7-page pamphlet describes the uses and properties of Graphalloy self-lubricating bushings. These contain no oil, and are particularly useful in inaccessible equipment; at temperatures where oil solidifies or volatilizes; for current-carrying bearings; for submerged bearings, etc.—GRAPHITE METALLIZING CORPORATION, *1050 Nepperhan Avenue, Yonkers 3, New York.*

Standardization—Pamphlet contains a series of papers on the subject "What Good Are Standards?" which were presented at the 1948 annual meeting of the American Standards Association. These papers include discussions of various problems, such as the legality of standardization, the standardization work of the Munitions Board, and the functions of standardization in such company operations as purchasing, manufacturing, and marketing. Available for $1.00 from AMERICAN STANDARDS ASSOCIATION, INC., *70 East 45 Street, New York 17, New York.*

Hydraulic Cylinders—Catalog Section No. 103, a 20-page illustrated booklet, describes all standard hydraulic cylinders, with complete diagrams and information. Engineering data in the new catalog includes displacements and theoretical forces for cylinders.—GEROTOR MAY CORPORATION, *Baltimore 3, Maryland.*

Metals—24-page booklet, PM 13, is a brief survey of the manufacturer's metals, alloys, and chemicals and their uses. Booklet available in English, French, and Spanish editions.—MUREX LIMITED, *Rainham, Essex, England.*

High Speed Motion and Still Photography—129-page illustrated booklet (reprints of papers presented at 1948 Convention) describes various high speed cameras as well as techniques used by governmental and industrial agencies. Specific topics include electrical flash photography and a new high speed stroboscope, lamps for high speed photography, motion picture equipment for very high speed photography, methods of analyzing high speed photographs and the uses of high speed photography in the armed forces, automotive and other industries and research. $1.50.—SOCIETY OF MOTION PICTURE ENGINEERS, *342 Madison Avenue, New York 17, New York.*

Socket-Turret—A single-page illustrated bulletin describes various types of new and unique terminal structures on which the circuit components associated with a vacuum tube may be neatly connected directly at the socket.—VECTOR ELECTRONIC COMPANY, *738 East Third Street, Los Angeles 13, California.*

Explosilite—Bulletin No. DT-4 describes the M.S.A. Explosilite, a simple and dependable automatic means of warning when dangerous atmospheres contaminated by natural gas or petroleum vapors occur. This device continuously samples the air of a working place, flashing an alternate bright and dim red signal light when flammable gas concentrations reach a predetermined danger point.—MINE SAFETY APPLIANCES COMPANY, *Braddock, Thomas and Meade Streets, Pittsburgh 8, Pennsylvania.*

pH Equipment—Circular 1176A describes pH meters, pH electrodes, flow, and immersion type assemblies, and miscellaneous accessories.—CENTRAL SCIENTIFIC COMPANY, *1700 Irving Park Road, Chicago 13, Illinois.*

Edgewise Panel Instruments—A 4-page brochure "Electrical Measurements" is devoted to edgewise panel instruments, explaining their desirability for accuracy and a description of various instruments which are available in the edgewise panel case.—SENSITIVE RESEARCH INSTRUMENT CORPORATION, *9-11 Elm Avenue, Mount Vernon, New York.*

Vacuum Tube Voltmeter—Bulletin GEC-461 describes Type AA-1, vacuum tube voltmeter, with a calibrated range of 0.001 volt to 300 volts at all frequencies from 10 cycles to 1.5 megacycles. This voltmeter is graduated in decibels, covering a range of −52 to +52 db from a reference level of 1 milliwatt at 600 ohms, and contains a 10-position pushbutton switch for selection of any working range instantly.—GENERAL ELECTRIC COMPANY, *Schenectady 5, New York.*

High Vacuum Apparatus—The winter 1949 publication of DPI features an article on the "Measurement of low pressures" and includes other high vacuum techniques of interest.—DISTILLATION PRODUCTS, INC., *Vacuum Equipment Division, Rochester 13, New York.*

CEC Recordings—A 6-page house organ, Vol. 3, No. 1, features a description of a new sampling probe (Type 18863) for the Consolidated Leak Detector, a description of an automatic high vacuum bakeout oven to speed up and greatly improve the cleaning process of vacuum system parts, and other items of interest.—CONSOLIDATED ENGINEERING CORPORATION, *620 North Lake Avenue, Pasadena 4, California.*

UHF Noise Diode—Publication 86-30B describes the Type TT-1 temperature-limited diode used as a noise source in measuring receiver sensitivity for frequencies up to approximately 3000 mc. Having coaxial-line construction, it is readily adaptable to wide-range (untuned) coaxial circuits. A maximum temperature-limited emission of 100 ma enables the measurement of receiver noise factors up to about 20 db. This brochure is fully illustrated with a photograph of the tube, schematics, and characteristic curves.—ECLIPSE-PIONEER DIVISION, BENDIX AVIATION CORPORATION, *Teterboro, New Jersey.*

New Materials

Forest K. Harris: Associate Editor
in Charge of this Section
National Bureau of Standards, Washington, D. C.

Glass

"Glass is an inorganic product of fusion which has been cooled to a rigid condition without crystallizing" (A.S.T.M.). Usually 60 percent or more of sand is fused together with various percentages of two or more oxides of Na, Ca, K, Pb, B, Mg, and Al. About 600 different glasses are made commercially which can be classified into five chemical types of silicate glass.

Soda-Lime glasses have been made for more than 5000 years, and are still used for 90 percent of all glassware. Their raw materials are the least expensive and they are among the easiest to melt and shape. Only within the past 40 years have they been studied scientifically to improve their properties. Silica is used as the glass-forming oxide, Na_2O and K_2O as alkaline fluxing ingredients to lower the fusion temperature, and CaO and MgO as alkaline earth fluxing agents to increase chemical durability. At the present time 70–75 percent of silica is used with seldom more than 17 percent of alkali and 5–15 percent of alkaline earths. Controlled amounts of minor ingredients are used to fit the glasses to different purposes.

Lead glasses were first produced in 1675 and have been extensively used in cut and engraved glassware. Their indices of refraction are high and they are used in compound lenses. They also have higher electrical resistivities than soda-lime glasses. Today they are used for insulators, in some radio tubes, for lenses, prisms, and fine art glass. Lead oxide is a good fluxing agent and in percentages from 20–40 it replaces most or all of the lime and some of the soda or alkali content. Excluding x-ray absorbing and optical glasses, compositions are in the range 53–67 percent SiO_2, 5–10 percent Na_2O, 1–10 percent K_2O, 0–6 percent CaO, and 20–40 percent PbO.

Silica glass (fused quartz or fused silica), 99.8 percent silica, can be made by fusing quartz crystals or sand. The fusing temperature is high (about 3150°F) so that special melting techniques must be used. Also the molten glass is so viscous that it is difficult to make it homogeneous and free from bubbles. It is difficult to shape and its use has been restricted to small and simple forms. It has been used for the envelopes of ultraviolet light sources, for chemical laboratory ware, combustion tubing, thermocouple sheaths, furnace windows, etc. First commercial production was about 1910.

Borosilicate glasses (1910) are of a type in which the melting point of the silica is lowered by the addition of boric oxide (B_2O_3) and aluminia (Al_2O_3) with only the smallest possible amounts of alkali. They have high intrinsic resistance to corrosion and to thermal shock but are difficult to manufacture and work. Thermal expansion coefficients may be as low as 25×10^{-7}/°C, whereas soda-lime and lead glasses have coefficients around 90×10^{-7}/°C. Pyrex laboratory and oven glassware are of this type. Present day compositions of commercial borosilicate glasses are in the range 73–82 percent SiO_2, 3–10 percent Na_2O, 0.4–1 percent K_2O, 0–1 percent CaO, 0–10 percent PbO, 5–20 percent B_2O_3, and 2–3 percent Al_2O_3.

Ninety-six percent silica glasses, developed in 1939, employ a revolutionary process in manufacture. An article is formed from conventional borosilicate glass and a heat treatment causes the glass to separate into two intermingled phases. One phase contains nearly all the alkalies and can be leached out by hot acids to leave a sponge-like glass containing 96 percent silica and 3+ percent of B_2O_3. The pore diameters average 20A in size. The leached glass is so refractory that subsequent heating can close the pores completely without any change in the shape of the article even though there is a linear shrinkage of about 14 percent. Thus the difficulties of working a glass of high silica content are circumvented and the resulting 96 percent silica glass is practically as ideal as fused quartz. Also large and intricately shaped objects can be made. "Vicor" brand glassware is of this type and has such uses as range burner plates, crucibles, laboratory ware, germicidal lamps, thermocouple protection tubes, induction furnace linings, and electrical insulation. Such glass can be used at a red heat and plunged into ice water repeatedly without cracking.

The above material was abstracted from an article in the "Burrell Announcer" written by H. G. Vogt of the Corning Glass Works.—BURRELL TECHNICAL SUPPLY COMPANY, *1942 Fifth Avenue, Pittsburgh 19, Pennsylvania.*

Cellulose Gum

Considerable new information on the physical and chemical properties of *Hercules CMC* cellulose gum is contained in a revised technical booklet on this chemical, just released by the manufacturer.

Hercules CMC is a refined, odorless, and tasteless grade of cellulose gum (sodium carboxymethylcellulose). Solutions of this gum can be evaporated to leave flexible films which are unaffected by oils, greases and most organic solvents. Certain salts and acids react with the gum to give films which are relatively insoluble in water. Tensile strength of CMC films ranges from 9600 to 11,600 p.s.i., and their percentage elongation from 1.7 to 4. The film-forming properties are used in the formation of barrier coatings on paper board, where it adds resistance to penetration of oils, waxes, and ink. This property is also utilized in textile sizing and finishing. In addition, it also has marked suspending, thickening, and stabilizing properties. It is used to stabilize oil-in-water emulsions; to control viscosity in resin emulsion paints; as an additive to detergents where its suspending properties help to eliminate the redeposition of dirt; as a thickening agent in latex solutions; and as a binder in the ceramic industry in various glaze applications. The purified food-grade type of this gum is finding use in the food and pharmaceutical industries to control viscosities, stabilize emulsions, as a suspension agent, or as a water-soluble film-former.—HERCULES POWDER COMPANY, *Wilmington, Delaware.*

Plastic Bell Jar

Lucite bell jars, developed by the manufacturer for use in vacuum equipment for precision casting, are now generally available in-seven-in. and ten-in. diameters. They can also be made on quantity order in other specified sizes for evacuation work.—DURABLE FORMED PRODUCTS, INC., *6–8 Greene Street, New York 13, New York.*

Silicone Fiberglas Sleeves

A sleeve employing silicone rubber reinforced with Fiberglas has been developed for flexibly connecting lengths of rigid duct carrying air heated to 550°F. An internal pressure of ten p.s.i. is withstood at this temperature without leakage. The sleeve will also remain flexible at temperatures as low as −75°F. The manufacturer is prepared to supply sleeves in diameters between a fraction of an inch and several feet, with the length and wall thickness appropriate to the application.—CONNECTICUT HARD RUBBER COMPANY, *405–9 East Street, New Haven 9, Connecticut.*

Glass Phenolic Laminate

Grade 170 Laminate is characterized by very low water absorption (0.06 percent) and low power factor. Its tensil and flexural strengths are both very high, 52,000 and 69,000 p.s.i., respectively. Its density is 1.78, and its dielectric strength is 580 v.p.m. It is available in natural color and semi-glass finish with standard NEMA tolerance for grade *G-3*, in thicknesses from 1/32 in. to 2 in., and sizes 36×36 in. and 36×48 in. The manufacturer suggests that the use of this material may eliminate the necessity for fungicides and other special handling required for tropical and high humidity applications.—St. Regis Paper Company, Panelyte Division, *230 Park Avenue, New York 17, New York.*

Insulating Bushings

Compression type lead-through bushings of steatite and Neoprene, designed for use in hermetically sealed transformers and capacitors (including oil-filled types) are now generally available. They are stated to have high resistance to mechanical and thermal shock even at extreme temperatures, and to be free from tracking tendencies. Voltage and current capacities are high for the space occupied.—Lundey Associates, *694 Main Street, Waltham 54, Massachusetts.*

Carbide Milling Cutters

Carbo-Mills form a new series of carbide cutters having 1/8-in. shanks. They are made of solid carbide in a single piece, cutting heads and shanks being integral. There are 12 different shapes in the series, chosen to meet the widest possible range of applications. These mills are suited to the deburring and machining of parts made from materials that are abrasive, tough, or of hardness ranging up to 60-C Rockwell.

The single piece construction simplifies the problem of balance at high speeds, making possible precise work in intricate or exacting operations. The prices are less than for similar mills of two-piece construction; and they can be repeatedly reground to give results comparable to new tools at each regrinding.—Severance Tool Industries, Inc., *710 Iowa Street, Saginaw, Michigan.*

Carbide Blanks

Cylindrical carbide blanks are available in lots of 50 or more in any one of 7 grades of carbide. Lengths range in 1/16-in. steps from 3/16 in. to 1½ in., and diameters in 3/32-in. steps from 3/32 to ½ in. Ground or unground finish may be specified.—Carboloy Company, *11167 East 8 Mile Road, Detroit 32, Michigan.*

Tungsten Powder

Tungsten powder of closely controlled particle size and distribution is now available as a result of newly installed facilities for producing tungsten in powder form for the manufacture of tungsten carbide tools. This material will contain at least 75 percent of individual particles measuring below 5 microns.—Sylvania Electric Products, Inc., *500 Fifth Avenue, New York 18, New York.*

Stainless Steel Clad Sheets

Permaclad is a composite sheet material in which a layer of stainless steel is permanently bonded to a carbon-steel backing plate. The stainless layer forms 20 percent of the total thickness in sheets up to 13 gauge, and 10 percent in heavier gauges. The cost of the material is about half the cost of solid stainless in the same gauge. The bond strength is stated to be equal to that of the component steels. The clad material is metallurgically correct on one side for corrosion-resistant service, and possesses the ductility and other desirable properties of the carbon-steel backing plate. The standard material (type 304 stainless with AISI-1008 backing) can be cold-formed, arc- or spot-welded, soldered, drawn, or stamped without separating the layers and without loss in the corrosion-resistant properties of the stainless steel. Compositions other than the standard may be specified.—Alan Wood Steel Company, *49 Darby Street, Conshohocken, Pennsylvania.*

Phosphor Bronze Wire

By special processing the manufacturer has increased the tensile strength of "Grade-A" phosphor bronze wire by at least 10,000 p.s.i. over established standards, and increased the tensile strength of "Grade-E" to the values covered by standard specifications for "Grade-A." Both types can be had in diameters from 0.0159 in. to 0.182 in., making available to spring makers a better product at no increase in price, according to the manufacturer.—Riverside Metal Company, *Riverside, New Jersey.*

Centrifugal Castings

Cylindrical steel castings, free from defects and of uniform quality, are available in specified alloys. The centrifugal casting process used is licensed on an exclusive basis from Firth-Vickers Stainless Steels, Ltd. Castings up to 42 inches diameter and in lengths up to three feet (depending on diameter) can be supplied. The work is handled in permanent metal molds and the desired heat treatment is applied during the process. The finished casting is machined to remove surface skin and the scale resulting from heat treatment, and examined by x-rays to insure freedom from structural defects. The user employs this blank to machine whatever finished parts are required.—Lebanon Steel Foundry, *First Avenue and Leaman Street, Lebanon, Pennsylvania.*

THE REVIEW OF SCIENTIFIC INSTRUMENTS

Further Improvements in Magnetic Focusing

LARKIN KERWIN AND CLAUDE GEOFFRION
Department of Physics, Laval University, Quebec, Canada
(Received December 20, 1948)

The general theory of magnetic focusing in a plane developed in a previous paper is extended to asymmetric cases. The general asymmetric case being developed, several particular examples are considered, including one which eliminates second-order aberrations, and requires a smaller magnet than the normal design. Methods of minimizing aberrations are discussed.

I. INTRODUCTION

IN a recent paper[1] a theory of magnetic focusing of charged particles in a plane was developed. It is based on an ideal magnetic field of such a boundary shape as to produce perfect focusing, as shown in Fig. 1. Here the field boundary M is symmetrically shaped so that monoenergetic ion beams leaving a source S are deflected so as to focus perfectly at T. The equation of M is a function of the parameters a and R, and is given by:

$$y=x(a-x)/(R^2-x^2)^{\frac{1}{2}}.$$

In the theory was developed a method for calculating the aberration, dispersion, image widths, etc., produced by any approximation to the ideal curve. Among the several practical approximations considered were the normal case—being the line through O tangent to the ideal boundary as shown by N, which is the type of focusing currently in common use—and the inflection case—being the line F tangent to the ideal boundary at its inflection point. The inflection field eliminates second-order aberrations, yet requires a smaller magnet for the same resolving power.

In all of these cases, the discussion was confined to approximations which were symmetrical about the y axis. It is the purpose of this paper to show how further practical improvements may be obtained by using non-symmetrical fields. In designing these, we may use the technique, familiar in optics, of balancing a positive aberration produced by one boundary with a negative aberration produced by the other.

In Fig. 2, M is the ideal field boundary and C is any curve coincident with M at P. Then any ray from S entering the field defined by C at a point other than P will pass through an interval of magnetic field w which will cause it to be aberrated from the focusing point T. We introduce an axis tangent to the ideal curve M and call k the abscissa along the axis. Then if we designate the ordinate of M with respect to k as $f(k)$, and that of C as $F(k)$, we have:

$$w=F(k)-f(k).$$

If, using the magnetic field boundary C on the left, we wish to focus all beams at T, then the point where an extra-P beam leaves the field boundary on the right must not be on M, but a distance w' from it, such that the aberration produced by w' is equal to that produced by w, but of opposite sign. Although not immediately obvious, it may be shown that, to the degree of approximation to be considered, w' must equal $-w$. By finding w' for

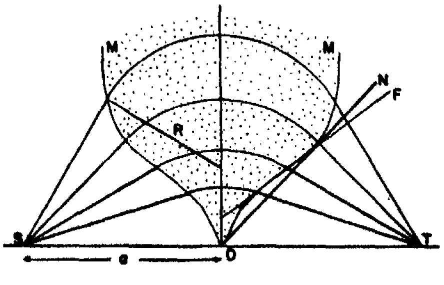

FIG. 1. Ideal magnetic focusing field.

---

[1] Larkin Kerwin, Rev. Sci. Inst. 20, 36 (1949).

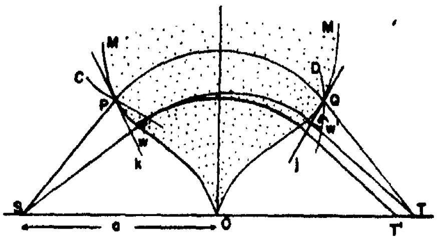

FIG. 2. C is any approximation to the ideal curve M; D is the corresponding approximation which corrects defocusing produced by C.

each ray we establish a curve D, which differs from M by w' and corrects the defocusing effect of C. Placing the equation D equal to $E(j)$ where the j axis is tangent to the ideal boundary at the point Q where the ray through P leaves it, we have:

$$w'=E(j)-f(j).$$

Remembering that $f(k)=f(j)$, we therefore have, as the condition for corrected focusing,

$$F(k)+E(j)=2f(k).$$

Expanding these functions in Taylor series at the points P and Q, neglecting 4th-order terms, and remembering that $f'(k)=0$ and that $\Delta j=\Delta k$ to this degree of approximation, we have

$$\begin{aligned}2[(\Delta k^2/2)f''(k)+(\Delta k^3/6)f'''(k)]\\ =\Delta k[F'(k)+E'(k)]+\Delta k^2/2[(F''(k)+E''(j)]\\ +\Delta k^3/6[F'''(k)+E'''(j)].\end{aligned} \quad (4)$$

Equation (4) enables us to determine the exit boundary shape D which will correct aberrations produced by an entrance boundary shape C. Several practical examples of this asymmetric arrangement will now be considered.

II. NORMAL CASE CORRECTIONS

In the case of the normal approximation, the curve C becomes a straight line tangent to the ideal boundary at P, as shown in Fig. 1. Accordingly, $F(k)=0$, and Eq. (4) simplifies to

$$\begin{aligned}2[(\Delta k^2/2)f''(k)+(\Delta k^3/6)f'''(k)]\\ =\Delta kE'(j)+(\Delta k^2/2)E''(j)+(\Delta k^3/6)E'''(j).\end{aligned}$$

Therefore, since $E'(j)=0$, we see that the curve D must have the same slope as the ideal curve at the point Q, where it coincides. If D is to be approximated by a circle, then we neglect third-order terms, and have

$$(\Delta k^2/2)E''(j)=\Delta k^2f''(k).$$

If we insert the geometric conditions developed in the reference cited[1] we find for the radius of curvature of the circular approximation to D:

$$R_d=R_0(\cot^3\theta)/2,$$

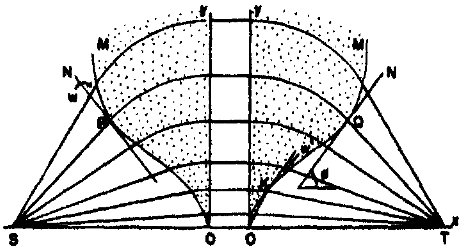

FIG. 3. Aberration produced near P is negative, that produced near K is positive.

where R_0 is the radius of curvature of the ion beam in the magnetic field.[2] A magnetic field bounded by a straight line on one side and an arc of a circle of radius R_d on the other, these boundaries being located according to the theory just discussed, will produce third-order focusing. That is, second-order aberrations will be corrected. Using the same procedure we may verify the case previously suggested,[1] that an entrance field boundary in the shape of a circle of radius $R_0\cot^3\theta$ may be corrected by an exit field boundary in the shape of an arc of a circle of the same radius.

III. INFLECTION CASE CORRECTIONS

In the inflection approximation, the curve C becomes a straight line tangent to the ideal boundary M at its inflection point. Here again $F(k)=0$, and in addition $f''(k)=0$.

Equation (4) therefore simplifies to

$$\begin{aligned}(\Delta k^3/3)f'''(k)=\Delta kE'(j)+(\Delta k^2/2)E''(j)\\ +(\Delta k^3/6)E'''(j).\end{aligned} \quad (5)$$

From this we see that the curve D must have the same slope as the ideal curve M at the inflection point, and further that D must be an inflection curve with the same inflection point as M. If we wish to eliminate second-order aberrations, then we drop third-order terms and D becomes simply a straight line, i.e., the inflection case already discussed.

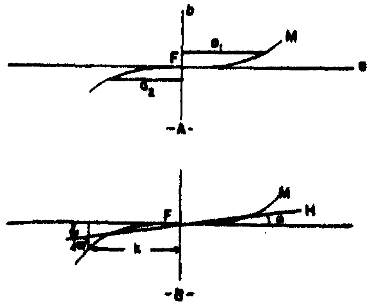

FIG. 4.

---

[2] In a recent paper (Proc. 7th Solvay Congress, Brussels, 1947), Dr. Kenneth T. Bainbridge proposes such a focusing field. We thank Professor Bainbridge for an advance copy of the manuscript.

In the reference cited, it was shown that third-order aberrations may be made to average zero by using entrance and exit boundaries in the shape of arcs of circles tangent at the inflection point and of radius given by

$$R=4\Delta k/f'''(x),$$

where $f(x)$ is given by Eq. (1). Equation (5) points to the fact that we may make the third-order aberrations average zero by curving only one boundary. To effect this it is necessary that

$$E'''(j)=2f'''(k)$$

to the approximation considered. If therefore the exit boundary shape is that of a circle of radius

$$R_{a'}=2\Delta k/f'''(x),$$

then the average of the third-order aberrations over a region $\pm\Delta k$ will be zero.

We note that the radius used depends on the portion of the boundary utilized—i.e., the width of the beam. Also, that as Δk is plus or minus (on one or the other side of the central ion trajectory), the radius reverses sign, i.e., the boundary shape is that of two circles tangent at the inflection point.

IV. ASYMMETRIC IDEAL FIELD

In Fig. 3 we consider the ideal field as consisting of two halves joined along the y axis. The left half deflects the divergent beam from S into a beam parallel to the x axis, while the right side deflects a beam parallel to the x axis into a beam focusing at T. Obviously any section of the left side might be combined with any section of the right side to produce perfect focusing.

Another method of reducing aberrations is therefore based on the observation that the normal or inflection case approximations produce a residual aberration of one sign or the other depending on whether the concave or convex part of the ideal curve is approximated. We may therefore obtain a better correction if we combine the convex part of the boundary P, at the entrance, with the concave section K, at the exit.

In order to correct, say, second-order aberrations in this way, it is necessary that the 2nd-order term component of w at P should equal the second order term component of w' at K. This means that the radius of curvature at P should equal that at K. This enables us to locate the point K, but since the equations involved are very cumbersome, we may use a simpler method of finding K which is illustrated for the normal case.

TABLE I.

θ	R	x_K	y_K	θ'	h
30°	$0.500a$	$0.0890a$	$0.165a$	10.2°	$0.329a$
45°	$0.707a$	$0.193a$	$0.223a$	15.7°	$0.459a$
90°	$1.000a$	$0.628a$	$0.300a$	38.0°	$0.490a$

In Fig. 4A the ideal curve is shown at M, drawn with respect to new axes a and b, through the inflection point F. Then the equation of the ideal curve with respect to these axes may be represented by:

$$b=Aa^3+Ba^4+\cdots,$$

whence:

$$b'=3Aa^2+4Ba^3+\cdots,$$

and

$$b''=6Aa+12Ba^2+\cdots.$$

Therefore the radius of the curve at a_1 is given by:

$$R_1=\frac{(1+9A^2a_1^4)^{\frac{3}{2}}}{6Aa_1+12Ba_1^2}.$$

If we place $a_1=-a_2$, we have:

$$\frac{R_1}{R_2}=\frac{-Aa+2Ba^2}{Aa+2Ba^2}.$$

We see, therefore, that if a is small, or B is small, then $R_1=-R_2$. In the case considered here, 4th-order terms are neglected, i.e., B is small, so that we see that R_1 will equal $-R_2$ when $a_1=-a_2$. In this case, we see that $b_1'=b_2'$. Referring back to Fig. 3, we see then that the ideal curve will have the same radius of curvature at K as at Q when the slope at K equals that at Q. This slope is given by

$$\tan\phi=\frac{a^3\sin^2\theta-2xR^2+x^3}{(a^2\sin^2\theta-x^2)^{\frac{1}{2}}}$$

from which we may easily calculate x_K by numerical methods, and draw through it the line A with slope $\tan\phi$. It is then only necessary to match the central ray through P with the central ray through K, and we have an aplanatic combination, as shown in Fig. 5 for the general case.

From this figure we see that the distance h is still necessary to completely determine the exact

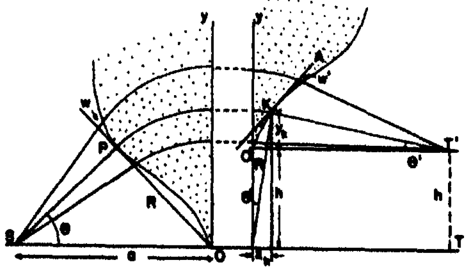

FIG. 5. A combination of negative aberration produced near P and positive aberration produced near K gives an unaberrated image at T'.

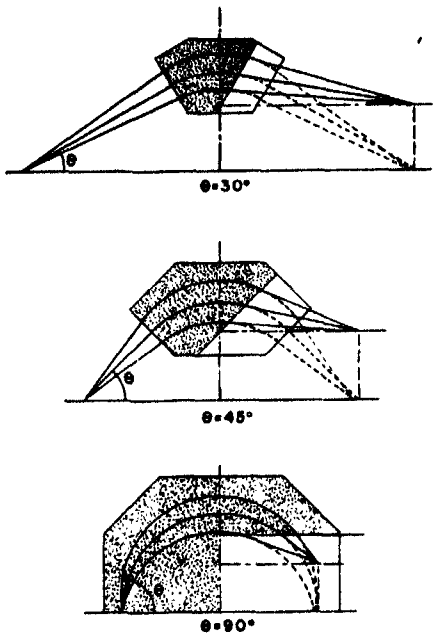

FIG. 6. Comparison of normal focusing and compensated aberration fields.

location of K. This is obtained by putting

$$h=R\cos\theta'-y_K,$$

where y_K is obtained by using Eq. (1), and θ' is determined by

$$x_K=R\sin\theta',$$

where, of course, $R=a\sin\theta$.

These various calculations have been made for a number of instruments, and are given in Table I.

These cases are shown in Fig. 6, with the normal case dotted in for comparison. In addition to the reduced aberration, we see that this field possesses the further practical advantage in being considerably smaller than the normal field, permitting the use of much smaller magnets.

V. MINIMIZING ABERRATIONS

The various approximations to the ideal magnetic field boundary discussed in this theory have this in common: the central ion beam passes through the points of coincidence between the ideal boundary and the approximation and hence is not aberrated, while rays to either side of the central ray are aberrated by an amount which is a function of their distance from the central ray. For all practical purposes, the aberration of an instrument is its maximum aberration, which is provided by the outer rays of the beam. It is possible to reduce the instrument's effective aberration by reducing this maximum aberration, at the expense of aberrating the central rays. In other words, it is possible to minimize the maximum aberration by simple methods, which will be illustrated for the inflection case.

It has been shown[1] that the aberration is proportional to the y component of the displacement of the approximation from the ideal curve. This in turn may be shown to be a function to the w component parallel to the central ion trajectory as it enters the field. In Fig. 4B which shows the inflection approximation F to the ideal curve M we see that the maximum aberration is due to the component w. If instead of F, however, the line H, at an angle β with F, were used as the effective field boundary, then the maximum aberration would be due to w'. The condition for which w' will be a minimum is best found by averaging the squares of the deviations and finding the condition for which the average is a minimum. We thus have:

$$w'^2=1/\Delta k\int_0^{\Delta k}w'^2dk,$$

where

$$w'=1/6f'''(x)\Delta k^3-\Delta k\tan\beta,$$

whence

$$w'^2=\frac{f'''^2(x)\Delta k^6}{252}-\frac{2f'''(x)\Delta k^4}{30}+\frac{\Delta k^2\tan^2}{3}.$$

From this we easily find, as the condition for minimum aberration,

$$\tan\beta=[f'''(x)k^2/10].$$

If the inflection field boundaries are tilted so as to coincide with H, the aberration will therefore be reduced by a factor of about 2.

The Regulation of Temperature in the Application of High Frequency Induction Heating to Thermodynamic Measurements*

RUDOLPH SPEISER, GEORGE W. ZIEGLER, JR., AND HERRICK L. JOHNSTON
The Cryogenic Laboratory and The Department of Chemistry, The Ohio State University, Columbus, Ohio

(Received May 20, 1948)

An apparatus to regulate the elevated temperatures produced by high frequency induction heating is described. The regulation is achieved by varying the inductance in series with the work coil in such a way as to hold the current through the work coil constant. Except for a *negligible* error due to a small percentage change in frequency, the energy transferred to the work (in applications described in this paper) can be held constant.

INTRODUCTION

A PROGRAM of research on the structure and thermodynamic properties of inorganic solids, liquids, and gases at very high temperatures is underway in this Laboratory. This program includes: vapor pressure measurements,[1] calorimetry,[2] and structure studies by x-ray diffraction.[3]

The use of high frequency induction heating has been developed as the principal source of energy to carry out the aims of this research because this method of heating is particularly well suited in the temperature range 1000°–3000°K. Employed as generators are two 3-phase, 15-kilowatt, General Electric electronic heaters which operate at a frequency of 500 kilocycles. The power output of these units is varied by changing the plate voltage. For this purpose, the manufacturer has supplied only six voltage taps on the primary of the high voltage transformer in the power supply for the oscillator, thus making available only six different outputs for a given experimental set-up. However, two requirements are necessary for satisfactory application of these generators to high temperature research: (1) The power output must be continuously adjustable to any value desired within the rated capacity of the generator; (2) the energy supplied by the generator must be regulated in such a manner that the temperature of the object being heated is maintained constant with the necessary precision.

The problem of designing a suitable device to satisfy these requirements is greatly simplified by the fact that the methods[1–4] employed in determining the vapor pressure, heat capacity, and high temperature crystal structure of a substance, lead only to a negligible change in its mass and emissivity. Also, the efficiency of heating is not critical because the mass of the object being heated is seldom greater than 50 grams and the power cost in research of this type is insignificant.

It was found that by placing a variable inductance (hereafter called a variometer) in series with the work coil (see Fig. 1a), the current flowing through the work coil, hence the energy, could be varied over limits wide enough to satisfy experimental requirements. In addition, fluctuations in the r-f current in the work coil due to fluctuations in the line voltage (which lead to temperature fluctuations) could be reduced to negligible proportions by *small* changes in the inductance of the variometer.

APPARATUS

A variometer was designed to have a maximum inductance of 35 percent of the total inductance in the tank circuit of the oscillator. The variometer is made of two helices of 13 turns each and of different diameters. The helices are connected in series with opposing windings and are arranged, one within the other, so that the smaller helix can be moved along the common axis with reference to the larger, stationary helix. A diagram of the variometer is

shown in Fig. 2. The coils are made of ¼-in. o.d. copper tubing through which cooling water is circulated and are wound on low loss plastic frames. The upper, movable coil is rigidly supported by a plastic arm attached to a counter-weighted brass carriage. The carriage is driven up or down through a gear train and rack and pinion (reduction ratio 6030:1) by a small d.c. motor whose sense of rotation depends upon the polarity of the d.c. signal applied to the armature. The speed of the motor can be varied from 100 revolutions per minute to 3000 revolutions per minute by varying the voltage across the armature of the motor.[5] Limit switches prevent the moving coil from traveling too far up or down. The entire assembly is mounted upon a micarta base 1½-in. thick. To prevent heating by r-f radiation, all parts of the variometer to the right of the dotted line are made of low loss plastics. The variometer parts to the left of the dotted line are made of brass.

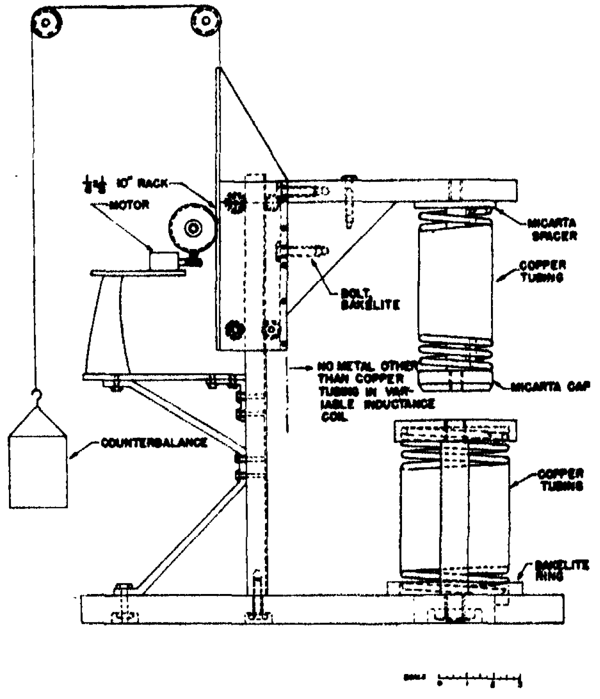

FIG. 2.

The range of the variometer was checked by heating an ⅜-in. iron washer, 1¼-in. diameter, in a work coil of 5 turns, made of ¼-in. copper tubing, 2½-in. diameter and 2½-in. long; the data obtained are given in Table I. These data show that there is a satisfactory overlapping of the available power at each plate voltage setting in the oscillator. Thus a continuous range of output energies are available instead of the six fixed values built into the set.

If the variometer is connected as a transformer, as illustrated in Fig. 1c, temperatures from as low as a few degrees above room temperature up to the highest temperature obtainable with the variometer connected as shown in Fig. 1a, are available without changing the coupling of the work coil to the load. Hence, a continuous range of temperatures from about room temperature to about 3000°K is available through the use of the variometer. The ability to reach lower temperatures through the use of the variometer is especially important in case of the high temperature x-ray work since the need for another type of camera (perhaps resistance heated) to bridge the gap from room temperature to 900°C is thus eliminated.

REGULATION OF TEMPERATURES

Fluctuations in the line voltage lead to small fluctuations of the r-f current flowing through the work coil. These lead in turn to temperature

[5] At present, a Delco motor, 27.5 v. d.c., taken from a Sperry Automatic Pilot is being used. The field of this little motor is a permanent magnet.

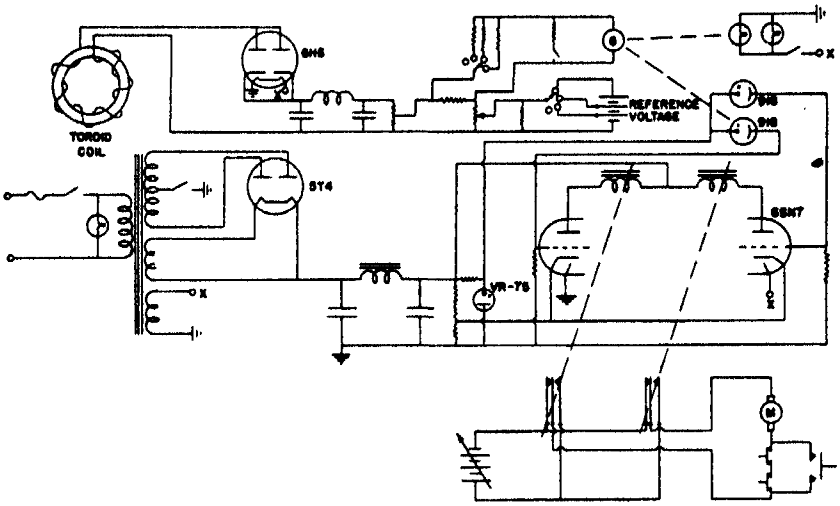

FIG. 3.

fluctuations of the sample being heated. However, small changes in the variometer inductance can be made to counter these deviations so that the temperature is held constant. This can be accomplished manually or automatically. In manual operation the temperature is frequently observed with a pyrometer and the inductance of the motor-driven variometer is adjusted so as to maintain the temperature constant. Temperature control with a precision of 0.2 percent is accomplished in this manner.

A servo-mechanism to maintain constant current in the work coil is shown diagrammatically in Fig. 3. In the Appendix it is shown that, except for a small term that is of negligible magnitude, the power is held constant** when small changes are made in the variometer inductance to compensate for supply line voltage fluctuations. The slight error is due to the small changes in frequency that occur when the variometer inductance is changed.

A toroid is mounted on a straight portion of one lead from the oscillator so that the plane of the toroid is perpendicular to the lead, which is coaxial with the toroid axis. The toroid signal is rectified, filtered, and balanced against a standard reference potential corresponding to the desired temperature. The difference or error signal is impressed upon a galvanometer, *G*, and a light beam reflected from the galvanometer mirror activates one of two photo-cells, the photo-cell being activated depending upon the direction of unbalance. This d.c. signal is amplified so as to actuate a relay which in turn applies a d.c. voltage to the motor *M*. The motor, in rotating, changes the inductance of the variometer in such a way as to oppose the current change in the work coil.

The effectiveness of this method in holding the temperature constant can be judged from the data listed in Table II. The voltage given in the third column is the primary voltage of the transformer used in the high voltage power supply for the oscillator. The temperature regulation is as good as the precision of the optical pyrometer, i.e., 0.1 percent.

APPENDIX

The induction heating circuit shown in Fig. 1a can be represented by the equivalent circuit[6] shown in Fig. 1b. Except for inclusion of the variometer inductance, L_v, the relationship between the generator voltage, V_p, the primary current, I_p, the resistance of the work being heated, R_s, its inductance, L_s, and the mutual inductance between the work and work coil, M, is given by Eq. (9.03) of reference 6:

$$V_p=\left[R_p+j\omega(L_v+L_s)+\frac{(\omega M)^2}{R_s+j\omega L_s}\right]I_p. \tag{1}$$

The power consumed by the work is

$$P=I_p^2\Delta R, \tag{2}$$

where $\Delta R=[(\omega M)^2R_s]/[R_s^2+(\omega L_s)^2]$.

Fluctuation of the line voltage leads to a change in the generator voltage, V_p, and consequently in I_p as shown by Eq. (3).

$$dV_p=\left[R_p+j\omega(L_v+L_s)+\frac{(\omega M)^2}{R_s+j\omega L_s}\right]dI_p. \tag{3}$$

If the variometer inductance, L_v, is varied, then due to the consequent change in frequency, $\omega(\omega=2\pi f)$, R_p and R_s are changed ($R\propto f^{\frac{1}{2}}$), and from Eq. (1),

$$\left[R_p+j\omega(L_v+L_p)+\frac{(\omega M)^2}{R_s+j\omega L_s}\right]\frac{dI_p}{dL_v}+I_p\frac{d[R_p+j\omega(L_v+L_p)+(\omega M)^2/(R_s+j\omega L_s)]}{dL_v}=0. \tag{4}$$

** It can be readily shown that at high temperatures if the power flowing into the work is held constant, the temperature will be held constant too, with rather high precision if the characteristics of the work being heated do not change. This is true as long as the difference is great enough between the temperature of the work and the environment. Under these conditions, the steady state temperature of the work is insensitive to fluctuations of the environment temperature.

[6] Brown, Hoyler, and Bierwith. *Theory and Application o Radio-Frequency Heating* (D. Van Nostrand Company, New York, 1947), Chapter 9.

However, during regulation, L_v is automatically adjusted so that dI_p in Eq. (4) is made equal and opposite to dI_p in Eq. (1). This variation in L_v, in order to keep I_p constant, causes a variation of the frequency so that P in Eq. (2) is not held quite constant and there is a change,

$$dP = I_p^2 d(\Delta R), \qquad (5)$$

which will be shown to be negligible.

Substituting the value of dI_p in Eq. (4) into Eq. (3), $d(\Delta R)$ can be obtained,

$$d(\Delta R) = \pm\frac{2\omega M^2 R_s^3}{(R_s^2+\omega^2 L_s^2)^2}d\omega \pm \frac{\omega^2 M^2(\omega^2 L^2 - R_s^2)}{(R_s^2+\omega^2 L_s^2)^2}dR_s. \qquad (6)$$

If $\omega L_s/R_s$ is set equal to Q, then Eq. (6) can be written as

$$d(\Delta R) = \pm\frac{2M^2}{L_s}\frac{Q}{(1+Q^2)^2}d\omega \pm \frac{M^2}{L_s^2}\frac{Q^2(Q^2-1)}{(1+Q^2)^2}dR_s. \qquad (7)$$

But the fractional error in power control will be

$$dP/P = d(\Delta R)/\Delta R \qquad (8)$$

and

$$\frac{d(\Delta R)}{\Delta R} = \pm\frac{Q^2-1}{Q^2+1}\frac{dR_s}{R_s} \pm \frac{2}{Q^2+1}\frac{d\omega}{\omega}. \qquad (9)$$

It can be readily shown that $d(\Delta R)/\Delta R$*** is a negligibly small quantity. The Q of the secondary circuit is much larger than unity for the frequency range (~0.5 Mc) employed.[6] Thus the magnitude of the factors involving Q in Eq. (9) are less than unity. The maximum change in the frequency, as a result of changes in L_v to compensate for line voltage fluctuations in order to keep the current I_p constant, is approximately 1000 cycles per second. Now the resistance, R_s, varies as the square root of the frequency (reference 6, p. 93), hence, $dR_s/R_s \sim 0.001$; the value of the second term in Eq. (9) is $2/Q^2+1\times 0.002$, and assuming $Q=5$, $dP/P \sim \pm 0.0012$. The fluctuation in temperature as a result of this fluctuation in power is $dT/T = dP/4P \approx \pm 0.0003$. Thus, as is evident from Table II, the servo-mechanism described in this paper can be expected to regulate the temperature to 0.1 percent or better as long as the characteristics of the sample being heated do not change.

*** The result given in Eq. (9) could also have been directly derived from Eq. (2), but at a loss, perhaps, in the clarity of presentation of the working theory of the regulator.

THE REVIEW OF SCIENTIFIC INSTRUMENTS VOLUME 20, NUMBER 6 JUNE, 1949

Instrumentation for Nuclear Studies with Externally Focused Deuteron Beam from Ten-Mev Cyclotron*

B. R. CURTIS,** J. L. FOWLER, AND L. ROSEN
Los Alamos Scientific Laboratory, P. O. Box 1663, Los Alamos, N. M.

(Received February 9, 1949)

A beam of ten-Mev deuterons of about ½ μa has been focused on an area ½ in. in diameter at the center of a 2-ft. diameter reaction chamber 15-ft. away from the cyclotron. In the center of the reaction chamber a gas target is supported with side ports so constructed that nuclear reaction products from the gas can be counted by a proportional counter mounted at the periphery of the chamber. The counter can be rotated through a Wilson seal to make any angle with the beam in the horizontal plane. At the exit of the reaction chamber a Faraday cup is supported. This can be removed to allow the beam to pass between the poles of an analyzing magnet for energy measurements. Tests with charged particle detectors such as a proportional counter or photographic plates show the background to be sufficiently low to allow good resolution of the products from the *d-d* reactions. Using the *d-d* reaction as a neutron source, background neutrons above 12 Mev are only about ten percent. However, the background neutrons above one Mev amount to about 25 times the neutrons from the *d-d* reactions.

I. INTRODUCTION

THE high neutron and gamma-ray background in the immediate vicinity of cyclotrons makes many experiments impossible. In order to avoid this difficulty the beam from the Los Alamos cyclotron has been brought out and focused at the center of a reaction chamber 15 feet from the cyclotron and so located that the three foot water and paraffin shield lies between the reaction chamber and the cyclotron. Figure 1 shows a diagramatic layout of the apparatus. The deflected beam enters a wedge shaped focus magnet about six feet from the beam exit port of the cyclotron.[1] From there the beam, diaphragmed to about ±½ deg., passes into the center of a two-foot diameter reaction chamber. The target is mounted in the center of this chamber. In most of the experiments done to date, gas targets have been used. These are constructed with a beam entrance and exit port and a side port for particle counting. A proportional counter is mounted in the reaction chamber on a movable arm through a Wilson seal in the base of the chamber. The counter can be rotated to make any desired angle with the beam so that it can count the reaction products produced by the beam.

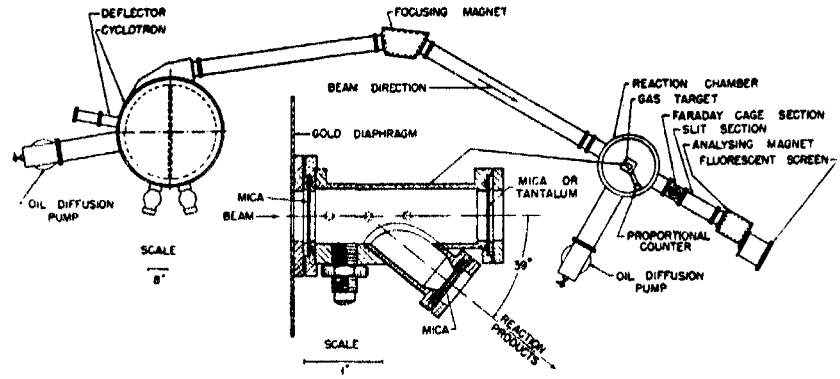

FIG. 1. Diagram of apparatus with enlargement of gas target.

On emerging from the reaction chamber the beam enters a Faraday cage section. From time to time the energy of the beam is determined by lifting the Faraday cup out of its path and allowing it to pass through slits and then between the poles of an analyzing magnet. A simultaneous measurement of the deflection of the beam and the magnetic field gives the deuteron energy.

II. FOCUS MAGNET AND FOCUSING BEAM

The focus magnet used in these experiments was designed and constructed by Feynman, Lavatelli, and Sutton.[1] It consists of a focusing wedge which deflects the deuteron beam through 32 deg. on a radius of curvature of 46 cm. The magnet was designed to provide horizontal and vertical focusing at a first order focal distance 300 cm from the wedge. The field of the focus magnet is held constant during an experiment by electronic controls.[2]

In order to determine the best focal distance and arrangement of the focusing magnet with respect to the reaction chamber, a television camera was used for continuous observation of the focused spot of deuterons as observed on a willemite (zinc orthosilicate) screen placed at the end of a telescoping exit tube.

The beam is defined by the opening of the focus magnet chamber to an area five in. wide by ½ in. high. After focusing, and under optimum operating conditions, a beam of six μa of ten-Mev deuterons can be obtained over an area ¼ in. wide by ⅜ in. high.

Since the target is located at the focus point of the magnet, the beam converges as it enters the scattering chamber and diverges as it leaves. In order to confine the beam to a known direction, a slit 1⅛ in. wide by 11/16 in. high is placed between the focus magnet and the scattering chamber, and a gold diaphragm with a ¼ in. hole is placed at the entry port of the gas target. The beam is thus defined to ±0.63 deg. in the horizontal and ±0.53 deg. in the vertical direction. Under these conditions about ⅓ μa of beam can be obtained through the ¼-in. hole.

To determine the exact direction of the beam as it passes through the gas target chamber, a small aperture (⅛ in. diameter) Faraday cup is mounted on the proportional counter. This is moved through the beam and the current picked up by the cup monitored by a d.c. amplifier and a meter. Thus, the angular spread of the beam can be measured and its angular direction in passing through the scattering chamber determined. A sample curve of the angular spread is shown in Fig. 2. This is the spread expected from the geometry of the experiment. Rutherford scattering due to the front window of the gas target did not appreciably increase the angular spread, since only about 2.5 percent of the beam is scattered more than one degree.

III. THE REACTION CHAMBER ASSEMBLY

Figure 3 is a side view assembly drawing of the reaction chamber and proportional counter. The reaction chamber proper, pump out leads and side ports are of welded steel construction. The lid of the chamber is a 1½ in. thick safety glass plate which rests on two ¼-in. by ¼-in. rubber gaskets which are countersunk in ⅛-in. deep grooves in a ring around the edge of the chamber. At one time a one-in. thick plate glass lid was used and it held under atmospheric pressure. However, the heat

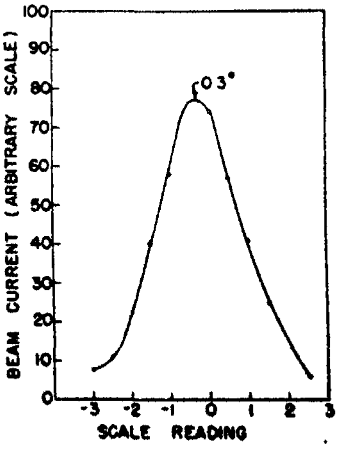

FIG. 2. Spread of beam after passing through gas target. One scale division corresponds to 1/32-in. Beam is limited by a ⅛-in. hole at entrance of gas target 7⅛ in. in front of the position where spread is measured.

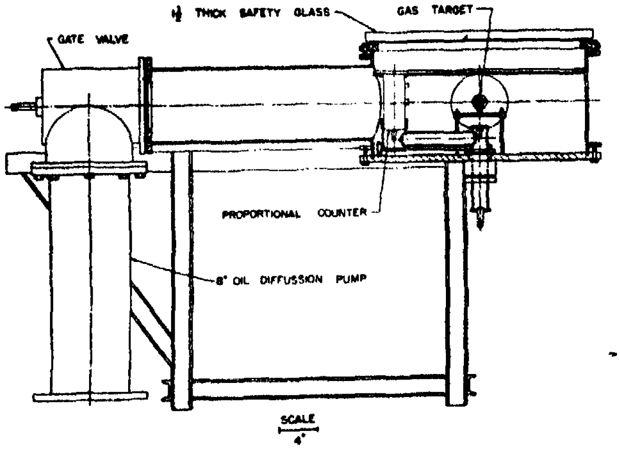

FIG. 3. Assembly drawing of reaction chamber.

from a photo-floodlight left over it produced enough strain to cause it to shatter under atmospheric pressure.

The bottom of the chamber is a ¾-in. brass plate which has a ¼-in. gasket groove to make a vacuum seal to the chamber. In the center of the bottom plate is a Wilson seal through which the proportional counter can be rotated at the desired angle to the beam in the horizontal plane. The lead to the counter passes through the center of its supporting arm. The counter is so mounted that it can be adjusted in height relative to the base plate. The high voltage connections and preamplifiers which can be seen in Fig. 4 are supported at the end of a two-in. tube which passes through the Wilson seal. Mounted within the reaction chamber at about the top of the proportional counter is a ring accurately graduated in degrees from 0–360 deg.

Included in Fig. 1 is a drawing of a typical gas target which is supported on a mount above the base plate so that it can be lined up with the geometrical center of the reaction chamber. The windows over the ports are mica of thickness from one to three mg/cm². The target is so constructed that the proportional counter can only see the beam where it is bombarding the target gas, and hence the charged particle background due to bombardment of windows, etc., is eliminated. Similar targets have been constructed in which the side ports make angle of 20 deg. and 30 deg. with the beam axis. These targets are water cooled.

Figure 4 is a photograph of the reaction chamber, showing the beam entrance tube, Faraday cage section and analyzing magnet.

IV. FARADAY CAGE

In order to determine absolute deuteron cross sections, one has to accurately measure the number of deuterons in the bombarding beam. For this purpose a nine-in. long Faraday cage 1¾ in. in diameter is supported in the six-in. tube at the exit of the scattering chamber (Fig. 1). The Faraday cage is supported by a rod through a Wilson seal so that it can be removed from the path of the beam when a measurement of beam energy is made. The Wilson seal, and therefore the Faraday cage, was insulated by Lucite from ground. Permanent bar magnets arranged on the outside of the vacuum system produce a small magnetic field perpendicular to the direction of the beam in the vicinity of the back of the Faraday cage in order to prevent secondary electrons from escaping from the cage.

The deuteron current collected by the Faraday cage is measured by an electronic current integrator,[3] the Faraday cage being held at a negative potential to prevent secondary electrons produced by the beam in its path from reaching the Faraday cage section. Tests were made on the current as a function of the negative potential where the beam was monitored by the He³ particles produced in a gas target and counted by the proportional counter. Within the accuracy of this measurement the He³ counts per current integrator count were independent of this bias between −40 to −120 volts.

During an experiment in which the deuteron current must be known accurately, the current integrator is calibrated (at approximately four-hour intervals) under as nearly as possible the same conditions as it is used. The Faraday cup is connected to ground through a very high resistance. The negative potential at which the cup is held causes a current to flow through the current integrator and this current is measured either with a calibrated galvanometer or with a standard resistance and type "*K*" potentiometer. With the current constant a timed run is taken with the current integrator. This procedure is repeated with different values of resistance and hence different values of current until one has a calibration curve over the current range expected in the experiment. For most

[3] H. T. Gittings, Los Alamos Report LADC-520.

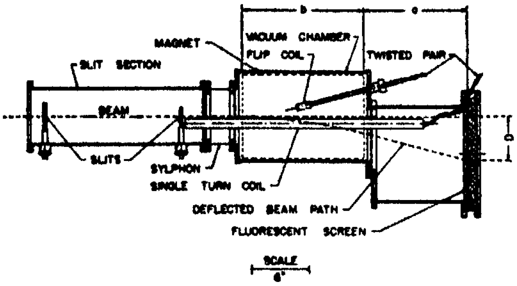

FIG. 5. Slit system and analyzing magnet for energy measurements.

experiments the deuteron current is from 0.1–1.0 μa. With the cyclotron turned on and the beam prevented from reaching the cup, radiation produces a leakage current of about 3×10^{-4} μa.

V. ENERGY MEASUREMENT

The energy of the beam of deuterons is measured by a magnetic deflection method following the general procedure described by Creutz and Wilson.[4] This involves measurement of the deflection of the deuteron beam and the simultaneous measurement of the magnetic field causing this deflection.

The experimental arrangement is shown in Fig. 5. It consists of a magnet with rectangular pole pieces (28.5×25.0 cm), a fluorescent screen for observation of the deuterons, and a single turn rectangular flux coil for measurement of the field. An adjustable slit section is provided between the gas target and the analyzing magnet to define the beam to a line about one mm wide.

The energy of the deuteron beam is given approximately by the following formula, as derived from the equations of motion by Creutz and Wilson.[4]

$$W=\frac{e^2A^2}{2M_0c^2}\left(1-\frac{W}{2M_0c^2}\right)\times\left[1+\left\{\frac{a+b/2(1-e^2A^2/8M_0c^2W)}{D}\right\}^2\right], \quad (1)$$

where, W is the energy of the deuteron beam in ergs, D is the deflection as measured on the fluorescent screen, c is the velocity of light, e is the charge on the deuteron, M_0 the rest mass of the deuteron, and a and b are dimensions of the apparatus as shown in Fig. 5.

The quantity A in the above equation is equal to $\int Hdx$ where H is the change in magnetic field produced by breaking the magnetizing current and dx is measured along the initial direction of the deuteron beam. The value of A is determined by use of the single turn coil, of width W, which extends through the magnetic field from a zero field region on one side of the magnet to a zero field region on the other. The coil was constructed by placing a copper ribbon $\frac{1}{16}$ in. high by 0.001 in. thick around a form of Lucite 25 in. long by 1 in. wide, carefully machined so that the width was uniform to ±0.002 in. The ends of this coil are brought out with a twisted pair to reduce the effect of stray fields and connected to the secondary of a mutual inductance M. The total flux as measured with the coil is equal to $W\int Hdx$ which is equal to $M\Delta I$ where ΔI is the current through the primary of M necessary to balance out the emf developed by the change in flux through the coil. The current ΔI is measured with a potentiometer bridge and standard resistance.

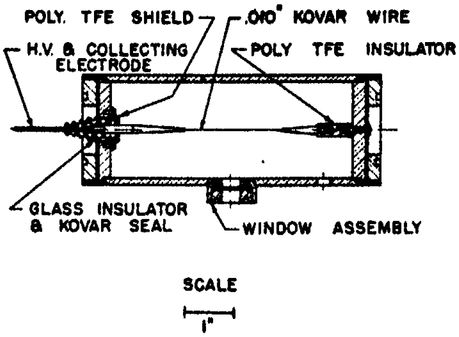

FIG. 6. Sectional view of proportional counter.

Since in this method only single deflection was measured rather than reversing the magnetic field, as in the method of Creutz and Wilson, a small correction was necessary for the residual field of the magnet. This was obtained by using a small flip

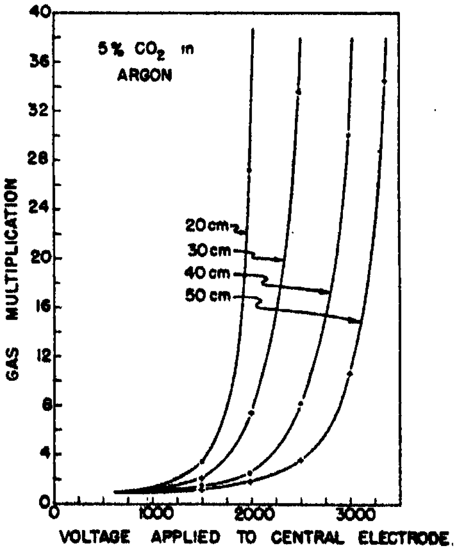

FIG. 7. Gas amplification for proportional counter as function of voltage on central electrode and pressure of gas in cm of Hg in counter.

[4] E. C. Creutz and R. R. Wilson, Rev. Sci. Inst. 17, 385 (1946).

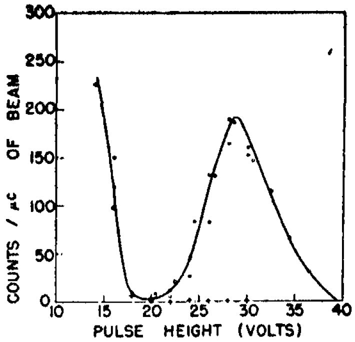

FIG. 8. Distribution of pulses from proportional counter due to He^3 particles which come off from the $D(d,n)He^3$ reaction at 22.7 deg. to deuteron beam.

coil, which was calibrated against the single turn coil so that the residual field could be measured and the correction applied. Since the residual field causes compensating correction in both D and H, the final correction to the energy is small. The use of single deflection requires this correction, but no galvanometer correction is necessary since the galvanometer drift over the time for the field to come to zero is negligible.

The mutual inductance used in these experiments was calibrated by Leeds and Northrup to 0.5 percent accuracy. It was compared with two other inductances, also calibrated by Leeds and Northrup, and found to agree within 0.2 percent.

The width of the undeflected deuteron beam is approximately one mm wide. When deflected, the width increased about 0.5 mm, indicating an inhomogeneity of energy of approximately one percent. The position of the beam could be read to 0.5 mm in 160 mm.

The geometrical constants a, b, and w could be measured to better than 0.5 percent.

Since the energy is proportional to A^2/D^2 the expected accuracy is of the order of two percent.

Several tests were made using aluminum absorbers to take out most of the energy of the deuteron beam and then varying the gas pressure in the target chamber to give a range-absorption curve for the beam. The results of this method showed essential agreement with the magnetic deflection method and indicated that no larger error existed, i.e., a shorted pick up coil, etc.

VI. PROPORTIONAL COUNTER

Figure 6 shows the proportional counter used to determine the absolute intensities of the charged particles resulting from deuteron reactions. The central electrode was made of 10-mil Kovar wire and served both as the high voltage and collection electrode, the signal being taken off through a 5000 volt 0.0001-μf mica condenser. The body of the counter was turned from brass to a wall thickness of $\frac{1}{16}$ in. In order to eliminate background which might result from an (n, alpha) or an (n, p) reaction in the glass insulator a shield of Poly TFE was placed around this insulator. All parts of the counter were furthermore decontaminated in 1–1 HNO_3 before assembly. The counter was found to operate well when filled with argon at pressures ranging from 20 cm to 70 cm Hg and at voltages ranging from 500–2000 volts. (This is the only pressure and voltage region tried to date.) The rise time of the pulses is approximately 1.1 μs when a gas amplification of about ten is utilized.

Figure 7 is a family of gas amplification curves for this counter. Plutonium alpha-particles from a $\frac{1}{10}$ mg/cm^2 foil were used to obtain these curves, both the foil and the counter being mounted in a vacuum system. The argon in the proportional counter was contained by a 1.4 mg/cm^2 mica window. In a similar manner the resolution of the proportional counter was determined by obtaining the energy distribution of the alphas from the above mentioned plutonium foil. The width at half-maximum of the energy distribution curves was found to be 3.5 percent.

A number of background difficulties were experienced when the counter was first tried. The background experienced can be discussed under three categories: gamma-ray background, background due to voltage breakdowns, and particle background. The gamma-ray background was sufficiently reduced by encasing the counter in two in. of lead, except for a $\frac{3}{8}$-in. opening in front of the window. Spurious counts caused by voltage breakdowns inside the counter were essentially eliminated by applying an over-voltage to the counter and permitting it to break down for about five minutes.

Charged particle background was successfully eliminated by the simple device of making certain that the counter could not see the deuteron beam at points where it came into contact with mica windows or diaphragming slits.

Even after eliminating the above sources of background a disturbing amount still remained due to high energy neutron bombardment of the walls of the counter and of the gas in the counter. This could only be eliminated by reducing the neutron background. By use of detectors sensitive to neutrons of energy one Mev and over, it was found possible to eliminate effectively all neutron background of over one Mev coming from the cyclotron tank proper by shielding with water and paraffin as heretofore mentioned.

A considerable number of neutrons of energy greater than one Mev were, however, produced by deuteron bombardment of the diaphragming slits and target windows. This background could not be shielded from the counter by hydrogen containing materials due to geometrical considerations. However, this background was also considerably reduced by utilizing gold diaphragms to define the beam. It was found, for example, that gold gives only about 0.3 the neutron background of brass.

It was also found that a 0.0003-in. tantalum target window produced 0.4 the neutron background of a two mg/cm^2 mica window.

Even after the above mentioned modifications were incorporated into the set-up, the neutron background of energy greater than one Mev was approximately 25 times the neutron flux obtained from the d-d reaction at a point 45 cm from the target. This was the case when a target six cm long containing D^2 at a pressure of 58 cm Hg was used, the beam being diaphragmed by a $\frac{1}{4}$-in. diaphragm in front of the target as illustrated in Fig. 1.

However, when all the above devices were employed for reducing background, the proportional counter gave consistant and apparently precise results. Figure 8, for example, gives the energy distribution of the He^3 particles obtained from the $D+D\rightarrow He^3+n$ reaction using the above counter at 22.7 deg. with respect to the incident deuteron beam. The points shown by crosses were obtained when $H_2{}^1$ was substituted for the $D_2{}^2$ in the target.

VII. CONCLUSIONS

The apparatus described in this paper allows one to do a considerable number of experiments with cyclotrons which otherwise would be impossible due to background. The equipment, of course, is particularly adaptable to the study of scattering and of charged particle reactions. Preliminary results on the differential cross section of the $D(d,n)He^3$ reaction have already been reported.[5] This experiment has been repeated with better resolution and the revised results will be given in a forthcoming paper. By substituting photographic detectors for the proportional counter a number of experiments involving the charged particles from the *d-d* reaction have also been performed.

Experiments which require monoenergetic neutrons are also made possible using this apparatus. With one atmosphere of deuterium gas in a target as shown in Fig. 1, the background neutrons (above 12 Mev) are only about ten percent of neutrons from the $D(d,n)He^3$ reaction. Thus, in this neutron energy region one can perform standard neutron experiments. For instance, the activation of the ten-minute Cu^{62} by the $Cu^{63}(n,2n)Cu^{62}$ reaction has been done as a function of neutron energy for energies from 11–13 Mev. This work will soon be published.

Although the neutron background between one and 12 Mev is rather formidable (Section VI) one can, by use of coincidence techniques, perform experiments with monoenergetic neutrons in this energy region. An example is the possibility of doing *n, p* scattering at 8.0 Mev. A triple coincidence proton recoil counter would be supported on the outside of the *d-d* chamber with its hydrogen containing radiator so mounted as to intercept the neutrons which would lie in the horizontal plane passing through the center of the target and which would come off at an angle of 61 deg. to the deuteron beam. When the bombarding deuterons had an energy of ten Mev these neutrons would have an energy of 8.0 Mev. Then one would rotate the proportional counter in the reaction chamber to 38.6 deg. so as to count the He^3 particles associated with the 8.0-Mev neutrons. The neutron cone is, of course, defined by the diaphragm between the He^3 counter and the target. In doing the experiment one would record the coincidences between the He^3 counter and the proton recoil counter. Thus, the real coincidences would give the number of recoils due to the eight-Mev neutrons and the total He^3 counts would give the total number of neutrons passing through the radiator.

We wish to acknowledge the assistance of Mr. John Slye, Mr. Harry Snowden, Mr. Raymond E. Squires, and Mrs. Louise Spence, who helped construct the apparatus and who operated the cyclotron during many of the tests described above. We also wish to thank Mrs. Mary A. Dodds who assembled many of the figures and material used in this report.

THE REVIEW OF SCIENTIFIC INSTRUMENTS VOLUME 20, NUMBER 6 JUNE, 1949

A New Method of Measuring the Stopping Power of Several Materials for Alpha-Particles

F. Emmett Hammer* and Frank E. Hoecker
Department of Physics, University of Kansas, Lawrence, Kansas

The application of an atmospheric pressure alpha-particle detector to the measurement of the relative stopping power of thin films of absorbing material for alpha-particles was investigated. The air-equivalent of absorbing films was measured directly by balancing the counting rates of two detectors in air, and again when an absorbing film is inserted between one of the detectors and its source. Measurements of the air-equivalent and relative stopping powers of films of mica, polystyrene, and aluminum are given. The relative stopping powers determined agree well with previous values. The errors of the method are discussed and an attempt is made to specify the magnitude of the probable error in the result.

INTRODUCTION

DATA published by different observers on the relative stopping powers of heavy substances for alpha-particles differ by as much as 10 percent.[1] More complete and precise data on this subject are desirable as a basis for revision of present theoretical treatments.

The application of a variation of the wire-plate alpha-particle detector, described by Chang and Rosenblum,[2] to the measurement of the relative stopping powers of certain substances has been studied. Data which are in close agreement with the best available values on mica and aluminum, and data on polystyrene (not previously available), are presented. These measurements are in the nature of preliminary tests to determine the applicability of the method of measurement to heavy substances.

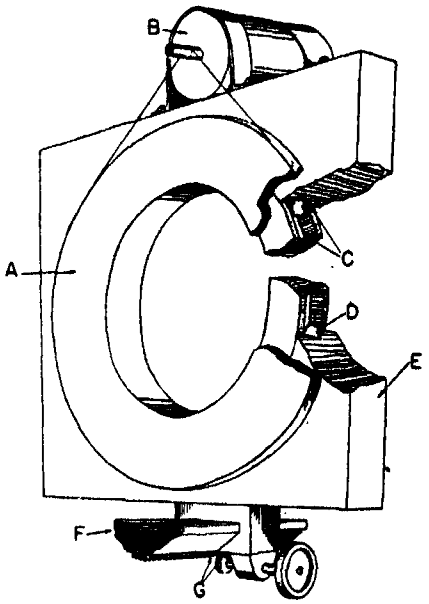

FIG. 1. Film rotating mechanism. *A*—Rotating ring. *B*—Drive motor. *C*—Ball-bearing raceway. *E*—Frame.

APPARATUS AND MEASUREMENT PROCEDURE

The apparatus consists basically of an alpha-particle detector and an associated electronic circuit[3] which counts individual alpha-particles after their passage through chosen thicknesses of absorbing material.

The detector consisted of a circular brass plate 2.5 cm in diameter with a stem threaded through a back plate mounted on a frame of insulating material. An alloy wire approximately 0.07 mm in diameter was stretched across the insulating frame in front of the circular brass plate. The threaded stem permitted adjustment of wire-plate spacing which was maintained at approximately 1 mm. The high voltage negative (2500 to 3000 volts) was connected through a 20-megohm resistor to the brass plate, and the wire connected to ground through a 100,000 ohm resistor. This provided negative pulses to the amplifier on breakdown. A capacity of 250 $\mu\mu f$ was connected between plate and wire to provide a sufficiently large pulse to operate the amplifier.

The alpha-particle sources used were polonium plated on silver.[4]

The films used were aluminum, prepared from various numbers of thin foils, mica,[5] and polystyrene. The polystyrene films were prepared by pouring a solution of polystyrene in amyl acetate of suitable concentration onto a glass plate. Evaporation of the amyl acetate left a thin film of polystyrene which could be removed from the plate. The films were mounted in lucite rings which fitted into the rotating mechanism. (Fig. 1.) Rotation of the films provided a means of averaging out non-uniformities and gave results depending on the average film thickness.

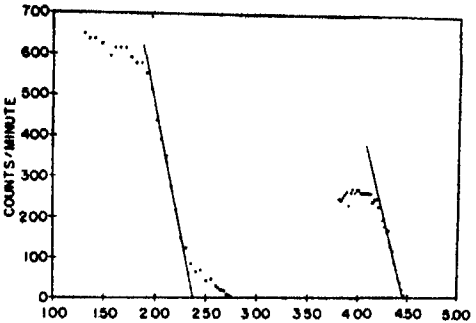

FIG. 3. End-of-range curves for air and mica using narrow source. Left-hand curve is for mica. Slope approximately 1750 counts/min. Right-hand curve is for air. Slope approximately 875 counts/min.

Errors due to variations in voltage, temperature, humidity, and atmospheric pressure on the counting rate of a detector were minimized by using two detectors, one having a fixed and the other a movable source. A dual channel counter amplifier and pulse rate comparator, designed by Kloepper and Hoecker,[5] was used to determine when the counting rate of the two detectors was equalized. A mechanical counter (Cyclotron Specialties Company type 401-A) was also connected to the output of each channel.

The two detectors were adjusted for equal counting rates in air. A film of absorbing material was then inserted between the movable source and its detector and the source position again adjusted for equalized counting rate. The difference between the two positions is the air-equivalent[6] of the absorbing film. Since any determination of a balance position may be in error due to random emission from the sources, the mechanical counters were connected for approximately 4000 counts and the difference in counting rates converted into a position correction by use of the average slope of the end-of-range curves.

The operating point used for equalizing the counting rate was approximately the inflection point of the end-of-range part of the counts-per-minute *versus* distance curve. As seen from Fig. 2, this curve is similar to a number-distance curve. There is a peak, however, toward the end of the range, which indicates that the detector is somewhat sensitive to the ionizing power of the alpha-particles. It will be noticed that the slope of these curves varies greatly with the width of source used, and also that any balance position error will vary inversely as the slope of the curve.

The effect of the geometry of the apparatus upon the counting rate, associated with different film thicknesses, was compensated for by the shape and size of source used. The air-equivalent was corrected to air at 15 degrees C and 760 mm of mercury. The absorbing films were weighed and the relative stopping power determined.[7]

CORRECTIONS FOR GEOMETRY OF THE APPARATUS

The effect of the geometry of the apparatus upon the determination of air-equivalent is divided into two parts. These are the effect of the solid angle subtended by the detector wire and the effect of obliquity of the path of particles through flat sheets of absorbing material.

An extended theoretical and experimental study of the characteristics of this type of detector with respect to geometrical and other types of errors is in preparation. This study indicates that the solid angle effect can be represented approximately by a $1/d$ function where d is the distance between the source and the detector. The result of the solid angle effect is to increase both the slope and the maximum counting rate when an absorbing film is in place. This is shown by Fig. 3.

The effect of flat sheets of absorbing material is to produce a greater reduction in the residual air range for particles traveling obliquely through the material than for particles traveling normally. The normal component of this loss in residual range due to obliquity of path is given by $\Delta R = R_0(\cos\theta_0 - \cos\theta_1)$, where θ_0 is the angle between the path

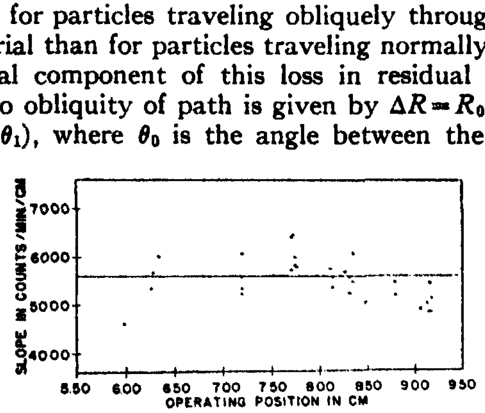

FIG. 4. Values of slopes of end-of-range curves for air and polystyrene films *vs.* operating position. Group of six points at extreme right of figure is for air curves.

---

[6] The air-equivalent of a film is the thickness of air in centimeters to which the film is equivalent for the stopping of alpha-particles.

[7] The relative stopping power of a substance is defined as the weight in mg/cm^2 which is equivalent to 1 cm of air (1.22 mg/cm^2) at 15 degrees C and 760 mm of mercury for the stopping of alpha-particles.

of the particle in air, and the axis of the apparatus, θ_1, is the angle between the particle path through an absorbing film and the axis, and R_0 is the range of the alpha-particles in air. This residual range loss for particles having an oblique path results in a reduction in the slope of the end-of-range curve.

From the above considerations, it was concluded that the solid angle effect and the effect due to obliquity of path through flat sheets of absorbing material could be balanced against each other by a proper choice of size and shape of source. Since the quantitative determination of the above effects is rather difficult theoretically, the conditions for balance were determined experimentally.

A wide source in the form of a portion of a cylinder of 1-cm arc, having a radius of curvature of 0.56 cm and a length of 2.5 cm, was plated with polonium. This was placed with its axis parallel to, and the concave side toward, the detector wire.

Figure 4 shows the values of the slopes (calculated from plots of end-of-range curves) obtained for several polystyrene films plotted against the approximate operating position for each film. It will be observed that these slopes are essentially constant regardless of the distance between the source and the detector. An arbitrary average of 5600 count/min./cm was used in making the corrections to the balance positions.

The curvature of the source might be expected to introduce an error in the determination of the air-equivalent. This point was examined experimentally. The air-equivalents of several films determined from carefully made plots of end-of-range curves using the flat source, Fig. 5, were compared with the air-equivalents of the same films determined from plots of end-of-range curves using a curved source, Fig. 6.

While taking data for these curves, the voltage across the detector was controlled so that the maximum point for each curve was approximately 2000 counts/min. It will be seen that the slope is approximately constant in both cases. Using points on the curves at which the counting rate was 900 counts/min. as reference points, the air-equivalent was determined by measuring the horizontal distance between the reference point on the air curve and that on the film curve. The measurements labeled Fig. 5 and Fig. 6 in Table I show the resultant air-equivalents. It will be seen that there is good agreement between the pairs of values. Four of six pairs agree within 0.01 cm.

From these considerations, it was concluded that any variable effect the curvature of this source had on the shape of the end-of-range curve, was negligible over the part of the curve used for measurement; and that the source curvature introduced no observable variation in the position of the balance point with variation in film thickness.

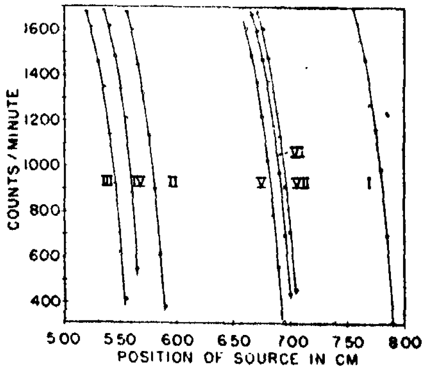

Fig. 5. End-of-range curves for several films using flat source. Curve I is for air, II and VII polystyrene, III aluminum, IV and V mica, and VI Nylon.

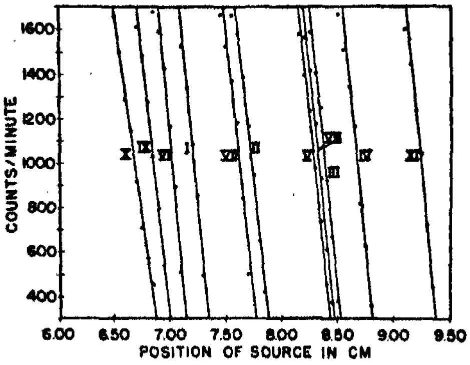

Fig. 6. End-of-range curves for several films using curved source. Curves I to IV inclusive are for polystyrene, V to VII are for mica, VIII for Nylon, IX and X for aluminum, and XI is for air. Curve X is for the non-uniform Al film No. M-2.

DETERMINATION OF PROBABLE ERRORS

Random Errors

Table I shows the air-equivalents of various films measured under the heading of the date on which the measurements were made.

Application of a test described by Simon[8] to the measured air-equivalents of a group of five polystyrene films indicated that the errors were random in nature.

The probable error in the air-equivalent of each of these films varied from ±0.001 cm to ±0.003 cm. Since the number of measurements was rather limited, the probable error specified for the group is that for the films with the largest error.

It should be pointed out that while the probable error in the slope of any one end-of-range curve is quite large, the error in the air-equivalent is small because the variations in slope are caused largely by slow variations in the sensitivity of the detector. When the balance positions for air and for the film being measured are taken in immediate succession, there is usually not much change in the sensitivity of the detector between the readings. Rapid changes may account for the rather unreliable readings for film number seventeen.

The probable error in the weight of any film was estimated from observed variations in the set of weights used. This set was self-calibrated with an estimated probable error in any one weight of ±0.03 mg. The probable error in the weight of any film was estimated as ±0.05 mg.

The probable error in the area of the films was estimated as ±0.025 cm^2 from measurements made on the cutter used to cut film sections for weighing.

The probable error in the relative stopping power was calculated from the propagated errors in the air-equivalent, the weight, and the area.

Assignable Errors

There are certain constant errors which can be assigned. Figure 4 shows that the slopes of the end-of-range curves in air are somewhat less than the average for the polystyrene films. (The group of six points at the right of Fig. 4 is for air curves.) This difference in slope corresponds to an error of 0.012 cm in the air balance position for all measurements.

The average slope of the end-of-range curves for the mica films measured was 7600 counts/min./cm instead of 5600 counts/min./cm for all other films. This slope difference corresponds to a position error for the mica films of 0.043 cm.

TABLE II. Relative stopping powers of various absorbing films (in mg/cm^2 equivalent to 1 cm of air at 15 degrees C and 760 mm Hg for the stopping of alpha-particles).

Material	Film no.	Air-equivalent in cm	Rel. stopping power
Mica	#6	0.994	1.41
	#8	1.199	1.47
	#3	1.550	1.46
	#2	2.102	1.51
	#1	2.175	1.48
	#9	2.895	1.43
		Average	1.46
Polystyrene	#50	0.365	1.02*
	#25	0.791	1.06
	#20	0.971	1.06
	#18	1.224	1.05
	#17	1.375	1.05
	#12.5	1.864	1.06
	#11	2.615	1.10**
		Average	1.06
Aluminum	#1	0.113	1.35*
	#2	0.211	1.50
	#4	0.368	1.53
	#6	0.560	1.56
	#8	0.811	1.59
	#M-1	2.192	1.63
	#M-2	2.367	1.74**

* Errors large due to thinness of films.
** Measurements excluded from calculation of probable error.

Probable Error of the Relative Stopping Power

Table II shows the calculated relative stopping powers for the films measured. The starred measurements were not included in the calculations of probable error. Two of them are for very thin films where the error is consequently quite large. The polystyrene film number eleven is a very thick film and seems definitely out of line with the rest. The film numbered M-2 was a very non-uniform aluminum film. Since no effort was made to allow for the change in slope due to non-uniformity, this measurement was also excluded.

The probable error in the relative stopping power for the mica films was calculated on the basis of the deviations from the average value shown in Table II. It is somewhat larger than the value calculated from the propagated errors in the air-equivalent, weight, and area. Since the sampling of measurements is small, the larger error, ±0.014 is specified.

The probable error in the average value for polystyrene is ±0.003. The probable error in a single determination for a film of average thickness, as calculated from the propagated errors in air-equivalent, weight, and area, is ±0.007. It is believed the polystyrene measurements are sufficiently reliable to justify specifying the smaller error.

If the starred aluminum films are excluded from consideration, there is still a noticeable increase in relative stopping power for the thicker films. This is in accord with the findings of Taylor[9] and others that the relative stopping power increases with decreasing velocity of the alpha-particle. This means that any heavy film is less effective as an absorber near the end of the range than it is near the source.

---

[8] Leslie E. Simon, *Engineers' Manual of Statistical Methods* (John Wiley & Sons, Inc., New York, 1941 edition), pp. 41–51.

Since the alpha-particles from polonium have an initial energy of approximately 5.3 Mev, and all the films measured were placed quite close to the source, the value of relative stopping power specified for aluminum will be that found for film number two and for alpha-particles of approximately 5 Mev. This value is 1.50±0.039. The probable error is that calculated from the propagated errors in air-equivalent, weight, and area.

CONCLUSIONS

The value determined for the relative stopping power of mica (1.46±0.014) compares quite well with previous values.[10] The value for aluminum (1.50±0.039) is in good agreement with a recent value by Rosenblum.[11] No published values for polystyrene are available.

It is believed that this method holds promise of high precision if further investigation of the proper size and shape of source leads to a reduction in the slope deviation of the end-of-range curves for various types of films to be measured.

THE REVIEW OF SCIENTIFIC INSTRUMENTS VOLUME 20, NUMBER 6 JUNE, 1949

A Cloud Chamber of Light Weight for Balloon Flights

R. P. Shutt, A. L. Johnson, and A. M. Thorndike
*Brookhaven National Laboratory, Upton, New York**

(Received February 1, 1949)

Some constructional details of cloud chambers used for balloon flights are described. Details are given on the fabrication of transparent plastic front walls and cylinders for the cloud chambers. A relatively large number of bicycle spokes is used for holding the chamber together, thus distributing material stresses, enabling one to make the aluminum parts of the cloud chamber quite light.

The back and front walls of the cloud chambers are somewhat spherically curved, resulting in considerable reduction of material thicknesses. By the same means a piece of slightly curved metal gauze is sufficient to limit the motion of the rubber diaphragm in the compressed position.

A mechanism used for adjusting expansion ratios can be removed before a balloon flight. Gas and liquid can be inserted through bicycle valves.

The cloud chambers are 12 inches in diameter, 3¼ inches deep, and weigh approximately 6 pounds.

IN the Spring of 1948 several lightweight cloud chambers for balloon flights were constructed, some of which have been in operation during the summer and fall. A few of the constructional details of these cloud chambers will be described in this article.

The weight of the cloud chambers is reduced by the following means. A plastic material is used for the transparent walls of the cloud chamber. Most of the other parts consist of tin-plated aluminum. The plastic front wall of the cloud chamber and the walls limiting the motion of the rubber diaphragm bringing about the expansions are somewhat curved and therefore could be made thin. The remaining parts are also kept thin by distributing material stresses, making use of a relatively large number of bicycle spokes for holding the chamber together, rather than the usual smaller number of heavy bolts. In order to adjust the expansion ratio, a mechanism which is removed before a flight is attached to the cloud chamber. It will be seen that besides saving weight, the latter feature also reduces the amount of compressed air to be carried along for operating the cloud chamber. The resulting cloud chamber is 12 inches in diameter, 3¼ inches deep, and weighs 6.3 pounds. It is felt that by making use of magnesium where possible, and admitting higher material stresses, one might save another one or two pounds in a similar design. Photographs of the cloud chamber are shown in Fig. 1.

Some of the parts of the cloud chamber and, where of interest, their fabrication, will now be described. Reference will be made to the assembly drawing shown in Fig. 2.

The plastic front wall, Part 109 in Fig. 2, ⅛ inch thick and 12¼ inches in diameter, is spherically curved with a radius of 24 inches. A plane flange is retained for clamping it to the remainder of the chamber. Plexiglas** is used as the material. After heating the Plexiglas sheet evenly in an oven to a temperature of 160°C, it is clamped over the top of an open vessel which then is immediately connected to an evacuated tank. Thus, the Plexiglas sheet is drawn into the vessel. When the Plexiglas has reached the desired shape its depth is held constant by regulating the degree of evacuation until it has cooled off. Since in this way the surfaces of the plastic do not come in contact with any other surfaces, the plastic remains quite clear and transparent, and since the wall is only slightly curved and its thickness turns out to be practically constant, no optical distortions are observable, compared to the usual distortions of tracks encountered in any cloud chamber.

---

* Research carried out at Brookhaven National Laboratory under the auspices of the AEC.

The Plexiglas cylinder, Part 110 in Fig. 2, is seamless, 3½ inches deep, with an outside diameter of 12 inches and a wall thickness of approximately ⅛ inch. It is manufactured in the following way. A sheet of Plexiglas, $\frac{3}{16}$ inch thick, again heated to a temperature of 160°C and then clamped over the top of the vessel, in this case is drawn in by evacuating until a cylindrical Neoprene-covered form, 6 inches deep and 11¾ inches in diameter, can be set inside and clamped securely to the top of the vessel. Air is now admitted into the vessel, whereupon the still hot plastic shrinks back tightly over the form. After the plastic has cooled off, the form is removed, and a cylinder of a depth of 3.5 inches is cut out. The remaining sections of the cylinder are useless because they are either too thin or too uneven. The resulting seamless cylinders have a wall thickness tapering from $\frac{3}{16}$ inch at one end to $\frac{3}{32}$ inch at the other and have withstood a force of 5 tons applied along their axes. Optically, the cylinders are comparable to the Pyrex glass cylinders usually used for cloud chambers.

By combining the techniques indicated, the transparent walls of the cloud chamber have also been made in one piece complete with front wall, cylinder, and flange for clamping to the remainder of the assembly. This unit will be used in future designs.

Two short-stemmed bicycle valves, Part 222, passed through holes in the plastic cylinder, serve to admit gas and liquid into the chamber, and to measure the internal pressure, respectively.

A piece of tin-plated brass gauze pressed into spherical shape and soldered to a tin-plated aluminum ring,*** Part 112, determines the position of the rubber diaphragm, Part 218, when the cloud chamber is compressed. The gauze is made of wire 0.013 inch in diameter, and has a mesh of 30×30. Its radius of curvature is again 24 inches. In order to obtain a dark optical background, velvet is sewed to the gauze.

The remainder of the assembly is contained in a flanged aluminum cylinder, Part 108. Through thirty holes in the flange, bicycle spokes, Part 212, are passed to the clamping ring, Part 101, in order to hold the cloud chamber together. Thus the material stresses are distributed so that none of the parts are warped.

The back wall, Part 105, again of spherical curvature of 24 inches radius, and tin plated for soldering, slides in the aluminum cylinder. A seal is provided by an "O-ring" gasket, Part 211. Several ribs, approximately $\frac{1}{16}$ inch high, provide a space between this wall and a layer of aluminum gauze acting as a limit for the movement of the rubber diaphragm when an expansion is made, in order to let the air escape quickly from the back slide of the diaphragm. Three helical surfaces have been milled into the ring supporting the back wall. These surfaces ride on three matching surfaces milled into a ring, Part 106, which in turn rides on a flange extending inward from the back side of the containing aluminum cylinder, Part 108. Upon turning the latter ring the position of the back wall, Part 105, is shifted, in this way changing the expansion ratio of the cloud chamber. Since there is always gas pressure on the back wall, the frictional forces along the helical surfaces are quite large. Adjusting the expansion ratio is therefore facilitated in the following manner. An assembly consisting of an auxiliary cylinder and piston, Parts 116 and 120, sealed with a rubber diaphragm, is attached to the back cylinder, Part 108, by inserting it into a bayonet lock. By means of a bicycle pump, air is now pumped into the auxiliary cylinder, thus pushing the piston against the back wall of the cloud chamber until the internal pressure on the back wall is balanced. The ring, Part 106, can

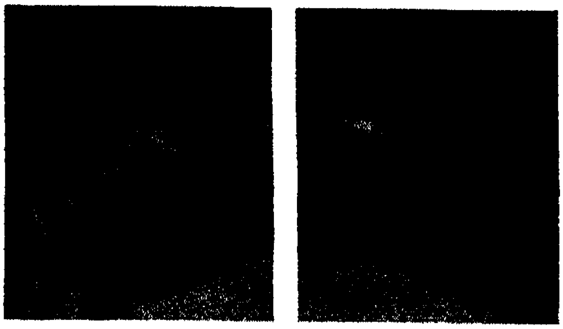

FIG. 1. Photographs of frontside and backside of a cloud chamber designed for balloon flights. The cloud chamber is 12 inches in diameter and 3.5 inches deep. Two lead plates are mounted inside.

** Although Plexiglas and Lucite are assumed to have identical chemical compositions, in the fabricating process described, clear surfaces were obtained more easily with Plexiglas.

*** Aluminum and brass parts were tin-plated by the Sperry Corporation, Lake Success, New York.

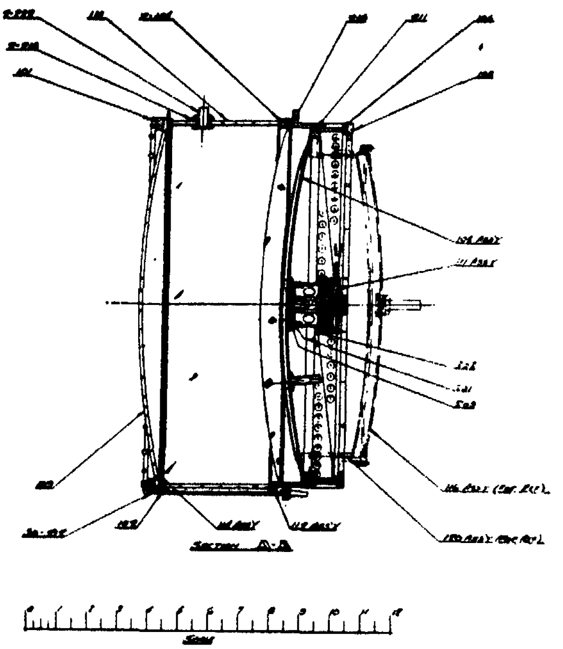

FIG. 2. Assembly drawing of balloon cloud chamber.

now be turned easily in order to change the expansion ratio. Of course, this pressure-equalizing assembly is removed before a balloon flight.

The electromagnetic expansion valve assembly shown, Parts 111, 201, 202, and 209, operates on dry cells with a power consumption of 0.2 watts. With an inductance of 1 henry and a resistance of 200 ohms, it is felt that in connection with suitable control circuits this valve will open fast enough for counter-controlled operation. In order to improve the reliability of operation for many hours without supervision, the design is such that the spring closing the valve after expansion is extended when the valve is opened. It was found that the usually employed compressional springs jam too easily.

Admittedly the construction of a cloud chamber of light weight is accomplished rather simply when, in the compressed position, the movement of the rubber diaphragm is not limited by mechanical means such as the brass wire cloth, Part 112. Since, in this case, only the air pressure behind the diaphragm determines the degree of compression of the cloud chamber, no mechanism is necessary to change the expansion ratio except for some pressure control device. However, in this case the expansion ratio is quite sensitive to small changes in temperature, necessitating compensating apparatus. Therefore, the present design was preferred, employing mechanical stops in both the expanded and compressed position. Pressure-controlled cloud chambers for balloon flights have been described and operated successfully by several authors.[1,2]

A few words may be in order on the use of Plexiglas in cloud chambers. The advantages of Plexiglas are not only its light weight and simplicity of shaping, but also the fact that Plexiglas consists of elements of low atomic number, may be important for many applications. The disadvantage of Plexiglas is its slight swelling and softening when exposed to water or alcohol, both liquids commonly used in cloud chambers. However, several cloud chambers have been in operation for a number of months without any mechanical defects developing due to softening of the cloud chamber walls. At some points where local pressure was applied to the plastic by members supporting lead plates inside the cloud chambers, some crazing was observed. If after some additional time the plastic should soften too much, new plastic parts will be used, since they are easily made in reasonable quantities by the methods described above.

The tracks photographed in these cloud chambers appear to be as good as those obtained in conventional cloud chambers, as far as both their contrast and straightness are concerned. At times there may have been indications that a cloud chamber with plastic walls tends to give general background fog somewhat more readily than one with glass walls, but there are many other factors which may have caused fog in the observed cases. A program to study these questions more carefully is under way. If as a result, glass should turn out to be superior in spite of its relatively high density, glass parts can be substituted for the plastic cylinder and front disk in the present design. For this purpose curved front glass plates and cylinders, approximately $\frac{1}{8}$ inch thick, have been procured.****

ACKNOWLEDGMENT

The authors wish to express their appreciation and gratitude to Mr. K. J. Kristoffersen and to Mrs. S. H. Cornish for developing the described methods for manufacturing the Plexiglass parts of the cloud chambers, and to Mr. S. G. Hasselriis who has been responsible for the manufacture of all of the other parts.

THE REVIEW OF SCIENTIFIC INSTRUMENTS VOLUME 20, NUMBER 6 JUNE, 1949

A Magnetic Field Strength Meter Using the Proton Magnetic Moment

N. J. Hopkins
Radiation Laboratory, McGill University, Montreal, Canada

(Received January 25, 1949)

A simple, portable instrument is described which employs the nuclear absorption method and the known value of the proton magnetic moment to determine magnetic field strength. No known fields and no geometrical calculations are required for calibration. The range covered by the present instrument is approximately 3000 to 19,000 gauss. No upper limit is inherent in the method. Homogeneity is required over a small cylindrical volume. Absolute accuracy of better than ±0.2 percent is obtainable, depending only on precise measurement of frequency. Higher accuracy is possible in comparing fields and in measuring field changes.

INTRODUCTION

It has been suggested in a number of places that either the nuclear absorption method[1] or the nuclear induction method[2] might be used both as a means of stabilizing a magnetic field and as an accurate measure of field strength. Packard[3] has used the induction method for automatic control of the current supplied to a magnet. The instrument described herein used the absorption method for measuring fields.

The basis of operation may be reviewed briefly as follows. A proton sample (distilled water contained in a glass cell) is mounted within a small coil which is inserted in the magnetic field to be measured, with the axis of the coil at right angles to the direction of the field. R-f oscillations are set up in this coil at a frequency determined by the setting of a tuning capacitor. When this frequency coincides with the Larmor precessional frequency of the protons, transitions occur which result in an absorption of energy from the r-f field. With a suitable detector circuit this energy drop appears as a V-shaped dip in a horizontal C.R.O. trace. Also necessary to bring about this display are auxiliary "wobbling" coils which carry the unknown magnetic field back and forth at 60 c.p.s. through its resonant value.

In making a measurement the tuning capacitor is varied until the resonant dip appears on the C.R.O. screen. The field strength is then determined from the well-known equation for the precessional frequency which in this case reduces to

$$H=(234.8_7\pm0.2_9)\times10^{-6}f,$$

where H is the magnetic field strength in gauss; and f is the Larmor frequency in c.p.s. (The proton magnetic moment used is the corrected value quoted by Bloch, Nicodemus and Staub.[4])

No difficulty is experienced in locating the resonance signal and no manipulative skill is required in the operation of the instrument. The apparatus is very simple and a similar instrument could be built quickly in any laboratory.

Four interchangeable sample coils are used to provide coverage of a range from 3000 to 18,900 gauss.

DESCRIPTION OF THE APPARATUS

The sample coil and tuning capacitor are incorporated in a probe together with a 6AK5 regenerative detector and the wobbling coils. The probe is a rectangular box with dimensions dictated by the size of the frequency-linear tuning capacitor, its dial and the space required for mounting the 6AK5, the r-f chokes and the regenerative control potentiometer. It is important that no magnetic materials be used in the probe.

The dial used is calibrated from 0 to 100 over 270°, diameter $2\frac{3}{4}$ inches. It is driven by a friction vernier. To avoid realignment difficulty in the event of tube failure, the capacitor is mounted rigidly on the end plate of the probe with one plug-in type connection to the 54-$\mu\mu$f condenser and with its other connection to a chassis ground.

From this part of the probe a brass tube, diameter $\frac{3}{4}$ inches, length 6 inches extends with an axial lead. This forms a low loss line to the sample coil which plugs into terminals at the tip. Soldered to the tip is a copper shield can which also supports the wobbling coils. These are wound in bakelite forms and each consists of 140 turns of No. 24 cotton covered wire, inside diameter $\frac{3}{4}$ inch, outside diameter $1\frac{1}{2}$ inches, length of winding $\frac{1}{4}$ inch. They are separated by a distance of 1 inch center-to-center and the outside thickness of the whole is $1\frac{9}{16}$ inches. (See Fig. 1.)

Wobbling amplitude amounts to 55 gauss peak-to-peak given by variac range of 0 to 43 volts. The amplitude may be varied down to zero, although it is normally used at maximum. As constructed the instrument can measure magnets with gap widths larger than $1\frac{9}{16}$ inches for pole diameters up to 13 inches and with gap widths greater than

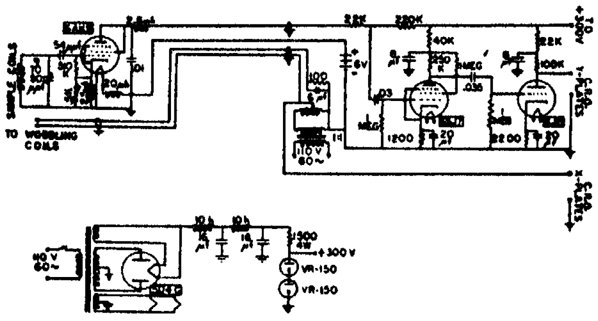

FIG. 1. Circuit diagram; magnetic field strength meter.

3½ inches for larger diameters. The minimum gap width could be reduced without difficulty to ¾ inch if the wobbling coils were removed and others wound on the pole pieces of a particular magnet being measured.

Four sample coils are used having 3, 9, 14, and 25 turns, respectively. The water sample in each is enclosed in a thin-walled glass cylinder inside length 1.2 cm, inside diameter 0.5 cm. These are quickly and satisfactorily made by using glyptal cement to seal each end of suitable lengths of glass tubing.

The remainder of the apparatus is mounted on a single chassis and consists of a standard two-stage audio amplifier, plate and filament power supply and the 60 c.p.s. wobbling voltage supply.

OPERATION

For ordinary measurements calibration curves are useful. They allow rapid translation of the dial reading into the field strength and can give accuracies of ±0.3 percent with the dial described above. They may be plotted easily, using the following procedure.

The regeneration control is advanced until oscillations are just maintained. (This point is easily determined by the behavior of the C.R.O. trace when it is reached.) A standard variable-frequency source is loosely coupled with the sample coil and varied to obtain a zero-beat note on the oscilloscope screen, indicating that the two frequencies are the same. In this way the frequency and hence the field strength corresponding to any dial setting may be determined.

Slight errors may be introduced in taking the dial reading and through change in oscillation frequency with regeneration control setting. These may be eliminated for the most accurate work by making use of the above procedure for each field measurement, the dial setting and regeneration control setting being left unchanged when the resonance dip has been located. In this way the accuracy can be made practically the $\pm 0.1_2$ percent upper limit dictated by the possible error in the numerical constant of the equation given above.

Best sensitivity in measurement will be attained when the regeneration is just sufficient to maintain oscillations. However, this adjustment is not critical.

The horizontal width of the C.R.O. trace is just the wobbling amplitude in gauss. Thus to use the instrument for exploring a field the resonance dip can be located and adjusted to mid-screen with the sample at the center of the field. As the sample is moved away from the center, the field change will be indicated by the change in position of the resonance dip. This type of measurement will be most effective if the wobbling amplitude is variable and its value is known for different settings of the varying control. The method of determining the amplitude is to read the frequency change which moves the resonance dip from one side of the screen to the other.

It is to be noted that the accuracy limitation imposed on absolute measurements does not apply in the case of field changes as discussed in the preceding paragraph. Nor does it apply when the instrument is used for comparing fields since this involves only ratios of frequencies.

The width of the resonance dip is an indicator of homogeneity, allowing use of the instrument for locating the most homogeneous point in a field or for establishing the boundaries of the region in which a field is uniform.

CONCLUSIONS

The operation of the instrument was tested in fields from 1883 to 16,214 gauss, the upper range being in the McGill University cyclotron and the lower range in a laboratory magnet.

The 6AK5 operated normally in the fields available for test and it seems probable that the range of the instrument could be extended considerably higher with no constructional changes beyond winding coils to oscillate at higher frequencies.

The lower limit was set at 3000 gauss since below this the signal became difficult to locate. It was still recognizable down to 1900 gauss.

Radial fall-off in the cyclotron field is approximately 15 gauss per inch, so that inhomogeneity of at least this amount is tolerated with clearly defined signals.

In view of the simplicity of the apparatus, the accuracy obtainable and the ease of operation, the method appears to have advantages over others used for the same purpose.

The author wishes to thank D. A. Anderson for suggesting this work and for much valuable advice, particularly in the design of the probe circuit.

A 22-Inch Wilson Cloud Chamber in a Magnetic Field of 21,700 Gauss

WILSON M. POWELL
Radiation Laboratory, Department of Physics, University of California, Berkeley, California

(Received March 22, 1949)

A Wilson cloud chamber 22 inches in diameter in a magnet producing a magnetic field of 21,700 gauss at the center of the chamber is described. The magnet is pulsed in synchronism with the 184-inch Berkeley cyclotron and can be operated with a steady field of 10,000 gauss. The use of the instrument for identifying light atoms is discussed briefly.

INTRODUCTION

THE 184-inch cyclotron has recently undergone a conversion so that it accelerates protons up to an energy of 350 Mev. A large cloud chamber with magnet for use with the cyclotron has been designed so that particles with $h\rho$ up to 3×10^6 gauss cm will produce cloud chamber tracks of measurable curvatures. In order to accomplish this, the cloud chamber must be in a high magnetic field and a long section of the particle's path must be observable. This magnet produces a field of 22,000 gauss and the cloud chamber has a useful diameter of 19.5 inches. The track of a 350 Mev proton crossing the diameter of the chamber would have a sagitta of 2.3 cm and thus a very accurate curvature measurement can be made.

THE MAGNET

The magnet, Fig. 1, consists of a pair of coils, two poles, and an iron yoke. The coils were made of bare copper strap, 1 inch by $\frac{1}{4}$ inch in cross section, wound in eight pancakes of 75 turns each and insulated between turns with two layers of glass tape 7 mils thick. The pancakes were separated by wooden spacers $\frac{5}{16}$ inch thick and $\frac{3}{4}$ inch wide, so arranged as to direct the cooling oil back and forth across the pancakes as shown in Fig. 2. These wooden spacers were attached to wooden rings which insulated the pancakes from the $\frac{1}{4}$ inch thick iron tank that contained them. The inner wooden rings were $\frac{1}{2}$ inch thick so that the inside diameter of the pancakes was only $1\frac{5}{8}$ inches greater than the $19\frac{1}{2}$-inch inside diameter of the coil tank. The pancakes were dropped into the iron tank, the re-entrant lid dropped on top of them, and great pressure applied to the lid as it was welded down. This was done to prevent the motion of the pancakes inside the coil tank.

The bottom pole fills the cylindrical space bounded by the inside of the coil tank. The upper pole has a conical hole which allows the camera to see a circular region having a diameter of 50 cm.

The current for the magnet is supplied by a navy pulse generator with a five-ton flywheel. It is energized by a 150 hp motor and pulsed once a minute. In order to build the current up rapidly, the circuit to the magnet is interrupted by opening a contactor while the current in the generator field windings is rising to its maximum value. Then the contactor is closed after the terminals of the generator have reached full voltage. During a pulse the speed of the generator and flywheel is reduced by 10 percent. Figure 3 shows how the field at the center of the gap rises with time reaching a peak value in about 2.1 seconds and remaining constant for 0.2 second. At a time 2.3 seconds after closing the contactor, the generator field winding circuit is opened and the current to the magnet drops from 1000 amperes to about 30 amperes in the conductor in 7 seconds. Shortly after this, the contactor is opened, the field windings energized and the generator is ready for another pulse.

The two coils are connected in series, the current passing through each coil in four parallel paths. When the magnet is pulsed as described above, the maximum current is 4000 amperes and the power 800 kilowatts; this produces a field of 21,700 gauss at the center of the gap. The field is constant over the 0.2-second period of steady current; during this time, the cyclotron is pulsed and the cloud chamber expanded. The magnet can also be operated with a steady field of 10,000 gauss; this requires 1300 amperes and 85 kilowatts. Figure 4 shows the magnetization curve measured at the center of the magnet and Fig. 5, the shape of the field at 10,000 and 21,700 gauss.

The coils of the magnet are cooled by oil which circulates through an oil-water heat exchanger (see Fig. 6) mounted on the frame supporting the magnet. During the pulsed operation the temperature of the cooling oil rises to 45°C after several hours. In order to protect the cloud chamber from the heat radiated by the coils, water-cooled, stainless steel pads line all the surfaces of the magnet that are exposed to the cloud chamber. See heat shields, Fig. 1. The temperature of the water circulated through these pads is maintained at 19.3°C. Heavy foam rubber pads protect the chamber from the outside and a small fan circulates the air around the chamber to keep it at a uniform temperature.

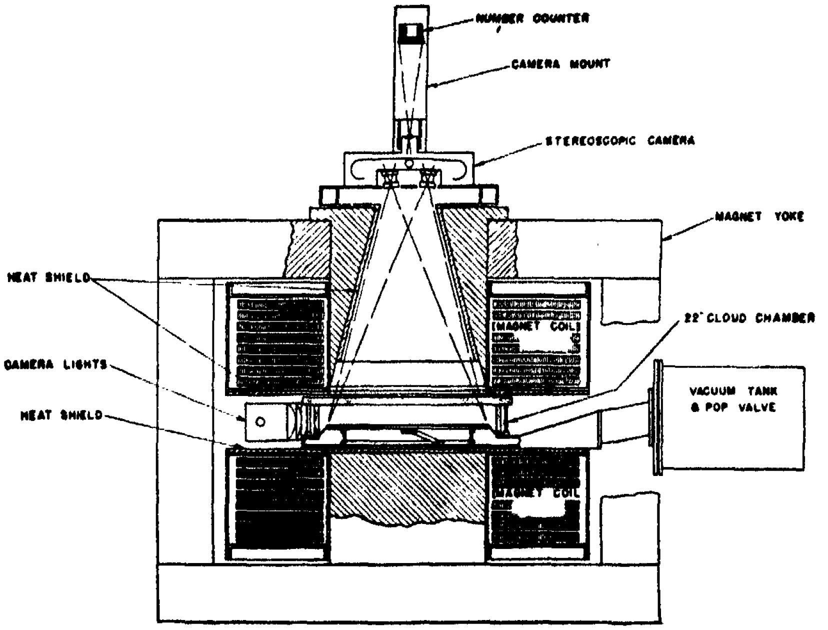

FIG. 1. The cloud-chamber magnet showing the location of the cloud chamber, the camera, and the lights.

THE CLOUD CHAMBER

The cloud chamber, Fig. 7, is built on a duraluminum manifold, circular except for a neck that extends out beyond the magnet coils and to which the expansion valves may be connected. The upper part of the cloud chamber consists of a 22-inch Lucite cylinder, 3½ inches high, and with a ¾-inch wall topped by a one-inch thick Tufflex disk which is attached to the manifold through a dural clamping ring. In order to keep the height of the cloud chamber at a minimum, both the top glass and the clamping ring are bevelled at an angle of 30° to the perpendicular so that the top surface of the clamping ring is level with that of the top glass.

The diaphragm consists of a ⅜-inch Lucite disk, 20½ inches in diameter, with $\frac{1}{16}$-inch gum rubber glued to its top surface. The rubber has a diameter of about 23½ inches so that it extends beyond the edge of the Lucite and makes the seal between the manifold and the bottom of the Lucite cylinder. There is a pantagraph connecting the Lucite disk to the bottom of the manifold; its purpose is to guide the disk during the expansion so that it moves parallel to the cylinder walls. The motion of the

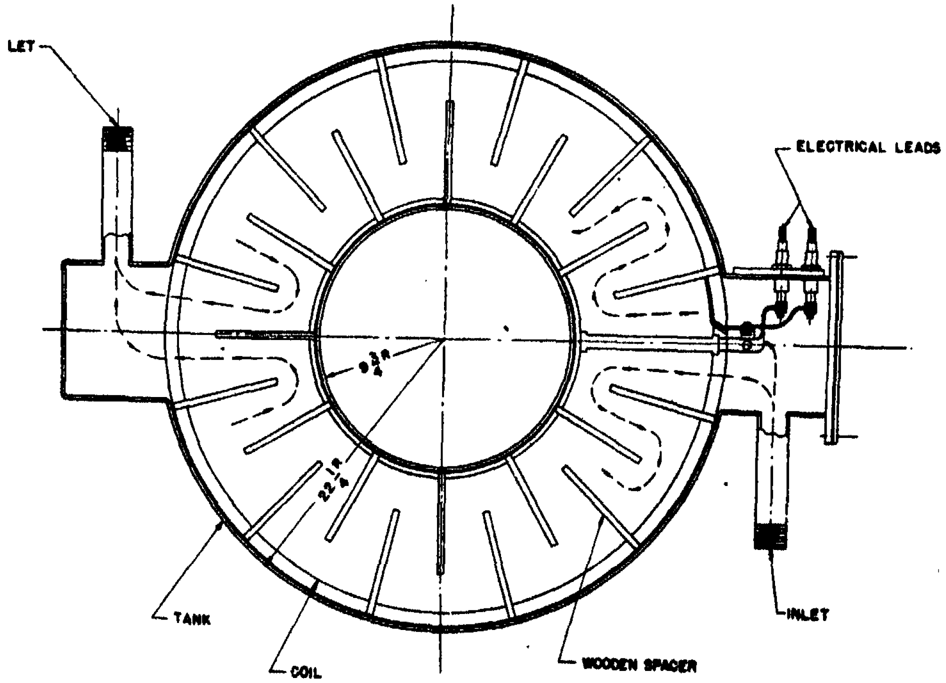

FIG. 2. Plan view of a magnet coil, showing the flow of the cooling oil.

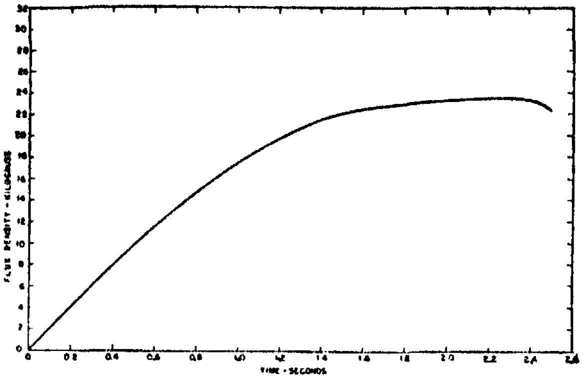

FIG. 3. The rise of the magnetic field at the center of the cloud chamber as a function of time.

disk is stopped by ⅜-inch neoprene pads which cover the bottom of the manifold except for three air channels, each three inches wide.

Several problems arose owing to the eddy currents that are induced in metal parts of the chamber when the field is rising and falling. The forces that were produced were large enough to move the whole chamber. For this reason a hole 19½ inches in diameter was cut in the bottom of the manifold and the duraluminum replaced by a ½-inch thick iron disk. When the chamber is in place, this disk becomes part of the lower pole and serves to increase the field at the center of the chamber as well as to prevent any violent motions of the chamber since it is attracted to the lower pole when the field comes on. The clamping ring that holds the top glass to the chamber has been broken and clamped together with a layer of paper insulation at the break. In addition, the studs that go between the clamping ring and the manifold have been insulated from the clamping ring by paper washers.

The clearing field voltage is applied across two grids of wires. The high voltage is connected to a set of parallel wires spaced ¼ inch apart and supported by a Lucite hoop just below the top glass, while the ground connection is made to a corresponding set under a layer of black velvet that is glued to the top surface of the diaphragm. It is not sufficient simply to ground the manifold since the rubber diaphragm is an insulator. Two aquadag rings were painted near the top and bottom edges of the Lucite cylinder and connected to ground to prevent the surfaces from charging up.

THE OPTICAL SYSTEM

The cloud chamber is illuminated through the Lucite walls of the cylinder by a pair of General Electric FT. 422 flash tubes. Each tube is wrapped in aluminum foil except for a strip $\frac{3}{16}$ inch wide going the length of the tube. The foil was held on by winding 5-mil tungsten wire in a spiral with half inch spacing around the tube; this wire and the aluminum foil acted as the tickler electrode. Although the width of the light source is reduced, the intrinsic brilliance increases so that the intensity of the illumination reaching the lens is reduced by only 20 percent. This lens is cylindrical, 18 inches long and 2¼ inches wide; it provides a beam of light approximately two inches wide at the center of the chamber. Because of the aberration appearing when rays pass obliquely through the cylindrical lenses, it was necessary to place baffles covered with black velvet between the lens and the source in vertical planes perpendicular to both. These louvres were spaced every two inches starting three inches from the center of the lens. The Lucite surfaces of the cloud chamber cylinder scattered light onto the black velvet in an intensity amounting to about 2 percent of the intensity at the center of the chamber. The resulting background made it necessary to use the Eastman Orthochromatic Linagraph film instead of Super XX. This film is at least twice as sensitive

to the light from the flash tubes and has much greater contrast.

460 μf at 1600 volts were discharged through each flash tube. The combination of the resulting surge of current and the magnetic field produces forces large enough to break the tube. This difficulty has been overcome by bringing the ground lead back along the tube and binding it tightly so that it produces a force on the tube in the opposite direction. Wherever possible, the two leads coming to the tube are twisted.

The stereoscopic camera uses a pair of Leitz Summar, F2, 50-mm lenses separated by 4.5 inches. The camera is located about 25 inches above the center of the cloud chamber with each lens toed in toward the other so that the optic axis of each makes an angle of 5° with the perpendicular to the cloud chamber. The film gate is tipped at an angle of 0.34 degree from the perpendicular to the optic axis in the proper direction to keep all parts of the chamber in the best possible focus when the camera is placed directly above the center of the chamber. A third lens in the back of the camera permits a counter and an ammeter showing the magnet current to be photographed at the instant when the cyclotron is pulsed. This is accomplished by discharging a condenser through a flash light bulb illuminating counter and meter at the proper time.

TIMING

Two sets of cam driven switches control the timing of the cloud chamber. The slow timer with seven cams driven continuously by a variable speed motor performs the following operations: (1) rings a warning bell ten seconds before an expansion, (2) turns on the magnet, (3) resets the clearing field, (4) resets the generator circuit, (5) operates a valve to make the cloud chamber expand slowly as many times as desired. The cams are made adjustable by clamping onto them the desired number of dogs which operate microswitches. The maximum time for one revolution is four minutes, the shortest 1.5 minutes. By doubling the number of dogs the cycle can be repeated twice in one revolution.

The second set of cams controls the more rapid sequence and is called the fast timer, Fig. 8. A small synchronous motor running continuously is coupled to the cam shaft by means of a solenoid operated clutch. The cam shaft makes one revolution in half a second. Only five of the seven cams are used. Dogs are attached to the cam wheels at suitable intervals as in the slow timer, and each microswitch is mounted on a wheel which can be rotated by means of a worm gear from the front panel. The microswitch wheels are coaxial with the cam shaft but do not rotate with it. Scales marked in hundredths of a second intervals are pasted to the

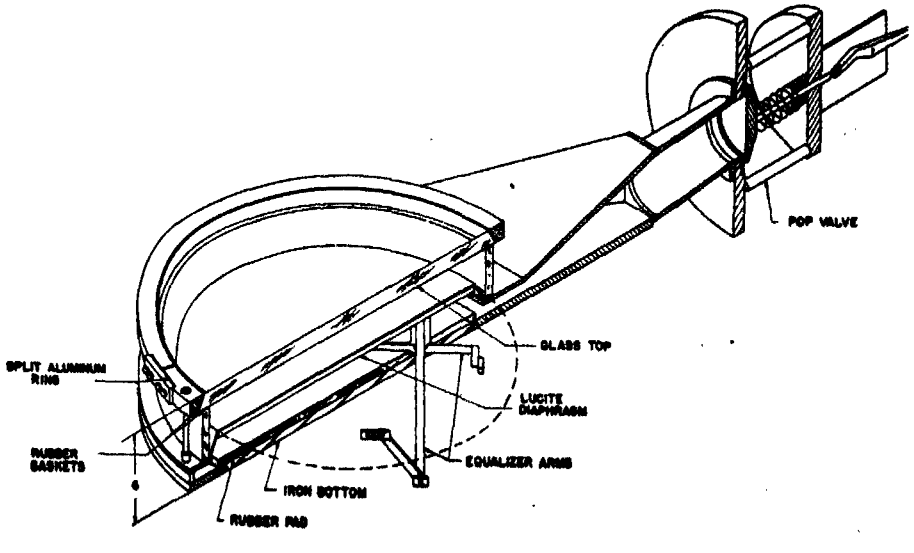

FIG. 7. Cross section of the Wilson cloud chamber.

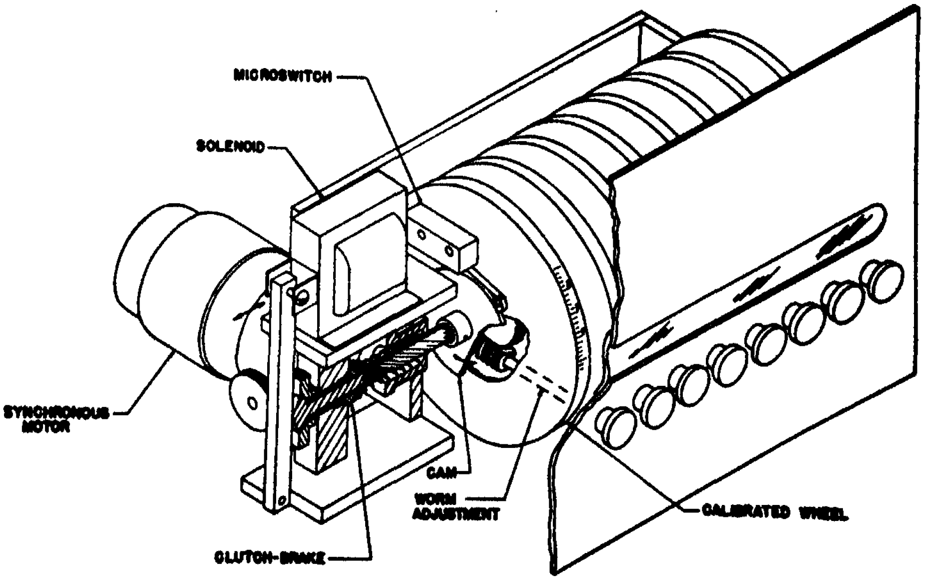

FIG. 8. The fast timer.

edges of the wheels so that their phasing may be read on the front panel and adjusted by means of the worm gear. Cam 1 turns off the clearing field, cam 2 expands the chamber, cam 3 turns on the rf oscillator on the cyclotron, cam 4 pulses the ion source in the cyclotron, and cam 5 flashes the lights. Cam 6 interrupts the current going to the magnetic clutch so that the cam shaft stops rotating. The timing sequence is as follows when operating with 100 cm pressure of helium when the chamber is expanded and using water vapor. The time of starting of the cam shaft will be called zero. The clearing field is turned off 0.12 second later, the chamber expanded at 0.16 second, the rf turned on at 0.18 second, the arc pulsed at 0.21 second, the lights flashed at 0.23 to 0.24 seconds. For gases of higher molecular cross section, greater time must be allowed between the arc pulse and the lights. Higher gas pressures increase this time also. If the arc is pulsed 0.02 second earlier, then about half the time the tracks appear slightly broadened because the ions have diffused before the chamber has reached the appropriate supersaturation to start forming drops. There is a jitter of 0.01 second in the time interval between the expansion of the chamber and the pulsing of the arc. This arises from the fact that the beam from the cyclotron comes out in pulses 0.01 second apart arbitrarily phased with the timing of the cloud chamber. Good pictures can be obtained with both arc and light excitation 0.02 second later, but the longer time makes the tracks less straight in the pictures taken without magnetic field.

TRACK ENDINGS

This cloud chamber and magnet may be used not only to make accurate curvature measurements on the tracks of fast particles but also to identify the slow particles that result from the disintegrations of nuclei. Figure 9 has been prepared to demonstrate how the lightest nuclear fragments may be identified near the end of their range. The lighter particles have a longer range for the same curvature and, hence, curl up more in the magnetic field. It is necessary to use hydrogen or helium gas at 100 cm of mercury or less with water vapor if a distinction between tritons and alpha particles is to be made. Even under these conditions about 20 percent of the tritons will show curvatures identical with those for an alpha particle over the last 20 cm of the track. Protons, alpha particles, and deuterons can be distinguished with little ambiguity in this range.

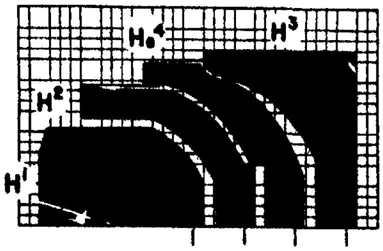

FIG. 9. Track endings in a field of 21,700 gauss with 100 cm. Hg pressure of helium and water vapor at 19.3°C. Last 22 cm all tracks perpendicular to base line.

ACKNOWLEDGMENTS

The major portion of the engineering of the magnet and cloud chamber was done by Paul Hernandez. Walter Hartsough, Dr. Evans Hayward, and Keith Brueckner were responsible for much of the work necessary for successful operation of the chamber, and Marguerite Hayward for the photography. This work was performed under the auspices of the Atomic Energy Commission.

THE REVIEW OF SCIENTIFIC INSTRUMENTS VOLUME 20, NUMBER 6 JUNE, 1949

Magnet Coils

L. G. Coonrod, W. E. Cecconi, C. Gedraitis, K. R. Harper, and R. M. Lewis
Laboratory for Nuclear Science and Engineering, Massachusetts Institute of Technology, Cambridge, Massachusetts

(Received March 3, 1949)

Methods of winding magnet coils using copper tape as the current-carrying element are described. Difficulties with unsatisfactory arrangements are pointed out. One satisfactory system is described in detail, providing an efficient design for magnet winding to yield relatively high copper cross section while permitting the removal of heat at a high rate.

During the past three years a number of magnet coils and Helmholtz coils for the production of magnetic fields from 1700 to 17,000 gauss have been constructed by us for the Laboratory for Nuclear Science and Engineering. These coils have been built to designs of and for use by Professor George E. Valley, Professor Robert Williams, Dr. Robert Thompson, and Dr. William Preston, all now or formerly of this Laboratory. In the construction of these coils several features have been found to contribute to the over-all performance.

Magnet coils should be designed to provide a large value of gauss-cm^3 in the air gap per watt of exciting power. This is especially true for electromagnets to be used with portable power supplies. This can best be achieved by realizing a high ratio of copper cross section to total winding space. Another necessary objective is to provide a design with low thermal gradients from copper to cooling medium so that maximum temperature utilization of the materials is achieved. In the effort to satisfy these requirements a decision was made to use copper strip. This has been followed in all the magnets described herein. Copper strip is usually obtained in 350-foot lengths. It is often desirable to use 2500-foot lengths in coil winding. We have found that lapped joints (tape overlapped approximately 8 to 10 inches), soft-soldered with gas torch, to be the most satisfactory joint. Silver soldering was not satisfactory. The strip must be wound under back tension of several hundred pounds. This is provided by a friction detent, spring-loaded (see Fig. 3). When wound under tension, we have realized actual build-up equal to 112 percent of calculated [no. of turns × (thickness of copper + thickness of insulation) × 1.12 = actual build-up].

In using copper strip on a bobbin such as is shown in Fig. 1(A), the heat developed within the conductor as I^2R loss is readily transferred to the edges of the copper strip by conduction. If the insulating gap to the spool-head is kept small and is thoroughly filled with solid dielectric and varnish, the temperature drop across the gap can be held to low limits. By suitable selection of spool-head thickness with appropriate spacing of cooling tubes, it is possible to limit the temperature drop here to low values. Cooling tubes, for magnets with low power consumption, may be used only on the periphery (Fig. 1(A)), or for larger power consumption, a set of tubes may be added in the position shown dotted in Fig. 1(A). In mounting copper tubing in such position, we flatten the tubing slightly before applying it to the spool-head. It is attached to the spool-head with soft solder, gas-heated, to obtain a low resistance thermal bond. If several bobbins, or pies, are to be stacked or wound as multiple units, the spool-heads may have a recess routed out as shown in the right-hand and center section of Fig. 1(B). The copper tube is then soldered into this groove, leaving no interfering protuberances.

In a typical example[1] six pies, wound on two triple bobbins (similar to Fig. 1(B) and having spool-heads ½ inch thick and approximately 39-inch outside diameter, dissipate 50 kw into 30 gallons per minute of water with a 30°C average temperature rise of copper above water inlet temperature. With the mica and fiberglass construction it would undoubtedly be safe to operate these coils at 100 kw input.

The inner end of the conductor, in all the coils discussed here in, is brought out radially as shown in Fig. 2. The conductor tape is given a 90° lateral bend by folding at 45°. An additional 90° fold brings the end out vertically. The bobbin core is flattened as shown in Fig. 2(A) to accommodate the extra thickness here. A recess is provided in the spool-head to permit this radial lead to clear the normal winding. The radial lead is half-lapped with fiberglass tape and is sandwiched with mica as shown in Fig. 2(B). To prevent slipping during early stages of winding, the inner end is secured by two textolite pins inserted in the bobbin core; these are long enough to penetrate the double thickness of conductor near the 45° fold. (See Fig. 2(B).) This method of attaching and bringing out the inner end of the winding has been entirely trouble-free. The inner end and outer end of the winding are normally terminated on a rectangular textolite block located at some convenient point on the circumference to permit attaching heavy current leads. Naturally the radial groove for the inner lead is designed to point toward this block. The details of attachment have varied from job to job.

---

[1] G. E. Valley and J. A. Vitale, "A counter controlled high pressure cloud chamber," Rev. Sci. Inst. 20, 411 (1949).

Originally 0.004 inch electrical Kraft paper wound in alternate layers was tried for interlayer insulation. It was planned to impregnate the entire assembly under vacuum, as is common in transformer practice. This proved impossible as the varnish penetration was inadequate. The coils so treated were quite unsatisfactory since temperature cycling caused breathing of moisture bearing air, followed by small leakage currents causing electrolysis and rapid deterioration.

The next step, suggested by Dr. Thompson, was spiral wrapping of the copper which was then wound without additional interlayer insulation. See Fig. 3(A). During winding the successive bobbin layers were painted with Ajax Varnish No. 02025. The tight wrapping caused the varnish to squeeze out to the ends of the layers, giving a very tight fill. It should be noted that the spiral tape is butted, not half-lapped, to preserve space-factor. This is not a comfortable expedient as gaps could occur opposite one another to permit leakage. However, the varnish appears to supply adequate fill. A set of coils as described was operated for six weeks in Colorado, in a trailer, at 13,500 feet, and has subsequently been in intermittent use at sea level for four months and still shows insulation resistance better than 10 megohms per pie.[1] Incidentally, any coil showing less than 1 megohm may be expected to give trouble ultimately. Some of our more recent coils show insulation resistance of 3 to 4×10^8 ohms. The spiral wrapping was applied by a Segur Taping Machine, Model 1-109A, modified to take tape width and winding pitch to meet our requirements. This required very close speed adjustment to produce an accurately butted spiral wrap.

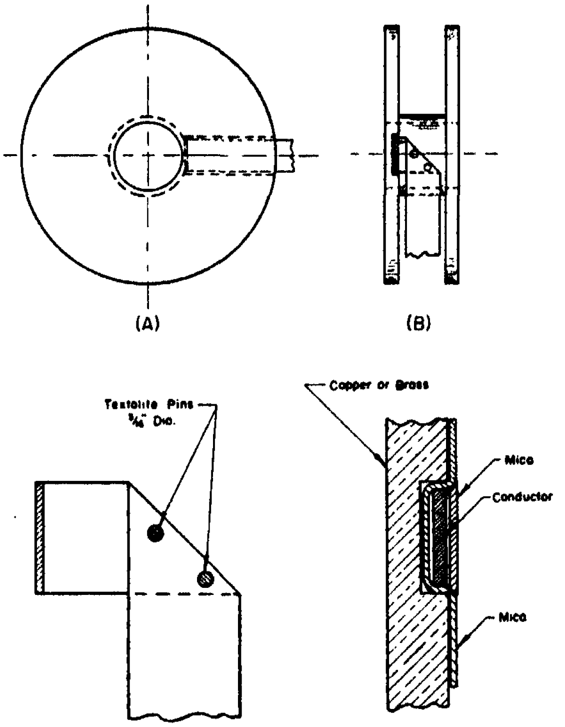

FIG. 2.

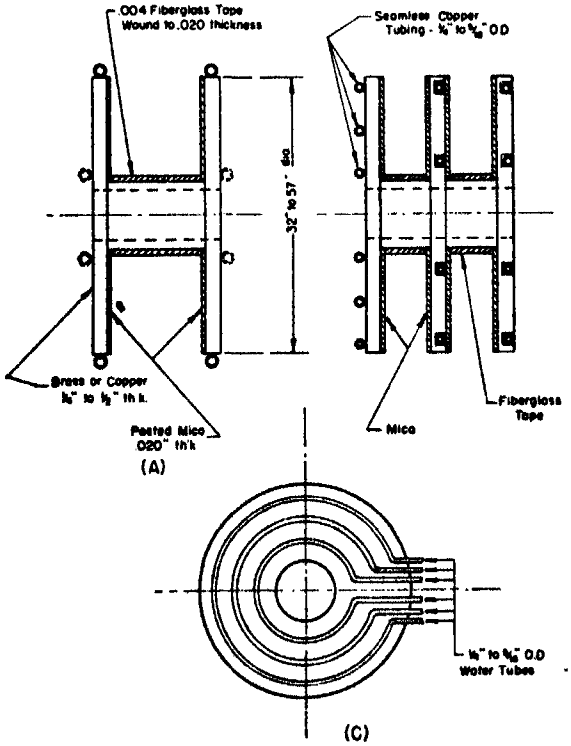

FIG. 1.

An improved method of insulation has just been tried. Availability of wider fiberglass tape made this possible. This consists of a strip of tape folded laterally about the copper tape (see Fig. 3(B)) so that a continuous seam ("*S*" in Fig. 3(B)) comes on top. As this always meets a continuous strip of tape on the next layer, leakage paths are long. Winding presented some problems which were successfully met in the following manner (see Fig. 4):

1. The flat tape was induced to fold by rotating brushes. (See "*RB*," Fig. 4.) These did not crease or crack the tape but firmly brought it over.
2. Rubber friction wheels ("*W*"—Fig. 4) brought the tape snugly over the copper. The amount of tension is controllable by the angle of the wheel.
3. Electrical Scotch Tape is applied by a roller ("*T*"—Fig. 4). This holds the "packaged" copper.
4. A grooved roller ("*G*"—Fig. 4) presses the package tight without causing folded creases. The grooves appear to be necessary.
5. After the "packaged" copper is safely bedded on the bobbin, the Scotch Tape is pulled off since it is not needed in a permanent coil; indeed, it is detrimental, wasting in this case

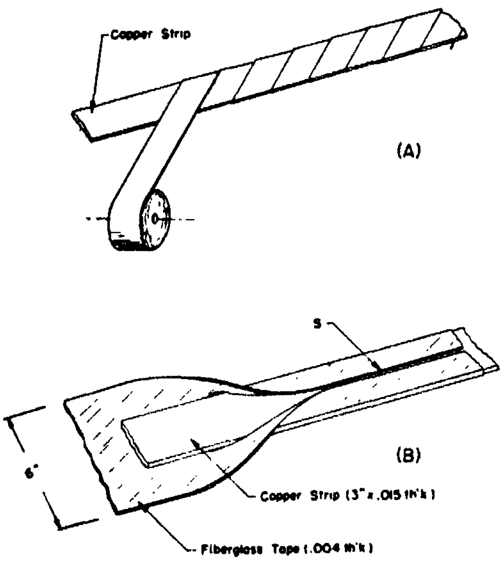

FIG. 3.

1 inch winding space in 300 turns or 12 percent. The tape returns via an idler (Fig. 4) where it is returned to roller "*T*" for reuse.

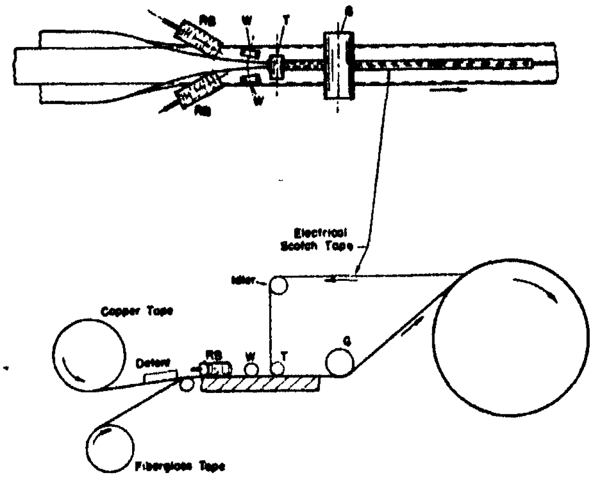

FIG. 4.

Oddly enough the Scotch Tape can be reused for many times. It stretches and from time to time lengths must be cut out. The speed of the rotating brushes is not critical. They can be started in advance of the winding rotation. In our set-up, vacuum cleaner brushes were used, driven by electric hand drills rotating at approximately 1200 r.p.m. One drill was reconnected to provide counter clockwise rotation. The equipment can operate at winding speeds up to approximately 6 r.p.m., being limited by the speed of the operator applying varnish. We expect to mechanize this in the future.

One advantage of the winding last described is that non-circular bobbins can be wound. A shape, roughly pentagonal, gives erratic linear speeds for constant angular velocity of the winding arbor. This would completely prohibit the butted spiral wrap. No difficulty was experienced with the last method in winding such a form.

The construction of the coils described above was in pursuance of research in nuclear physics and cosmic rays supported by the joint AEC–ONR program.

A Counter Controllable High Pressure Cloud Chamber*

G. E. VALLEY AND J. A. VITALE
Physics Department and Laboratory for Nuclear Science and Engineering, Massachusetts Institute of Technology, Cambridge, Massachusetts

(Received March 3, 1949)

A high pressure cloud chamber is described which is so designed as to be as easily counter controlled as an ordinary cloud chamber. The instrument is fitted with a magnet capable of producing a field of approximately 10,000 gauss continuously. It is mounted in a trailer and can be readily transported to mountain sites.

PROPERTIES OF HIGH PRESSURE CLOUD CHAMBERS

A HIGH pressure cloud chamber combines the properties of an ordinary cloud chamber with those of a thick emulsion photographic plate. It can, as a result, yield information which cannot be obtained otherwise.

Compared with an ordinary cloud chamber which operates near atmospheric pressure, a high pressure instrument possesses the following advantages and disadvantages:

(1) The stopping power of the gas is much higher and so is the probability of making a nuclear collision with a gas atom.

(2) The sensitive time is much longer. When random expansions are made for cosmic-ray studies, this is an obvious advantage; when the instrument is counter controlled by cosmic rays, or used with a high voltage accelerator, this ceases to be an advantage and may even be a hindrance because of the background of uninteresting phenomena.

(3) The time required to reach thermal and vapor diffusion equilibria between expansions is much greater. For random expansions this effect is more than outweighed by the increased time of sensitivity. Thus, with 100 atmos. of argon we get forty times as many cosmic-ray tracks per picture, but only twice as many per unit time as compared to an ordinary cloud chamber. If, however, we are interested in observing reactions in the gas, each of these figures must be multiplied by 100 (at 100 atmos.). Thus, we can get 4000 times as much information per picture and so can gather statistics on phenomena so rare that they cannot be observed at all in a one-atmosphere instrument, because of the practical impossibility of scanning the huge number of pictures which would be involved.

(4) Coulomb scattering increases as the square root of the pressure and, under many circumstances, makes any achievable magnetic field give only qualitative information. This is an important effect when argon is used at 100 atmos. or higher. When hydrogen or helium are used, scattering can be reduced to negligible importance by easily obtainable magnetic field strengths. Even when argon is used, it is very useful to have a magnetic field because it enables electrons to be easily distinguished from more interesting particles. This effect is discussed in detail in Appendix I.

(5) Although the time of sensitivity is much increased and a background of tracks is present in every counter-controlled picture, this is considerably ameliorated by another effect. It is well known[1] that, relative to the ion diffusion constant, the ion mobility increases in proportion to the pressure. Moreover, the coefficient of electron attachment is very high, so that both positive and negative ions are heavy. Now, because of the high pressure, it is possible (indeed, necessary) to apply much higher clearing potentials than are commonly used in cloud chambers. One achieves drift velocities, in 100 atmos. of argon, for instance, on the order of several cm/sec. The result is that many tracks, and in particular many counter controlled tracks, are observed to be split into two perfectly sharp and distinct parallel components. By measuring the separation of the positive and negative ion components of different tracks in the same picture, one can determine their relative time of occurrence to at worst ±0.04 sec., which is quite comparable to the resolving time of an ordinary one-atmosphere instrument. In some cases this is not possible because ions of one sign may have drifted outside the illuminated region.

In comparison with photographic plates the high pressure cloud chamber has the following properties:

(1) By choice of pressure and atomic number of the gas, it is possible to determine at least the sign of charge, and often the momentum of particles, by the use of practically obtainable magnetic field strengths (10,000 gauss).

(2) The material in which reactions take place is pure (it requires less than 2 g of alcohol to make tracks in a volume containing 60 moles of argon at 150 atmos., for instance), and can be changed—hydrogen, helium, nitrogen, and argon are practical gases which can be used at present. Oxygen is most dangerous, and krypton and xenon are very expensive. Of the heavy organic gases, only CF_4 remains gaseous at 3000 p.s.i., to our knowledge.

(3) The instrument can be triggered like any other cloud chamber, and there is little question as to whether the tracks seen are germane to the experiment at hand. Moreover, the results do not depend on the time elapsed before the emulsion is developed.

(4) Since the illuminated volume is relatively thick compared to its diameter, it is practicable and useful to take stereoscopic photographs.

(5) A major disadvantage is that ionization density of a track can only be crudely estimated. Neither grain nor droplet counting is possible because the ion density even from a minimal ionizing particle is so high as to produce a completely homogeneous track. Track width however, gives some indication of ion density, so that star fragments are easily distinguished from high velocity particles. The theory of this is given in Appendix II.

CHARACTERISTICS OF THE PARTICULAR INSTRUMENT CONSTRUCTED

The design objective which we set was to achieve the properties listed above within the following limits:

(1) The instrument was to be transportable to a mountain site. This limited its dimensions to fit in a trailer of standard road and railway clearances.

---

* Assisted by the joint program of the ONR and AEC.

[1] L. B. Loeb, *Kinetic Theory of Gases* (McGraw-Hill Book Company, Inc., New York, 1934), Chapter XI.

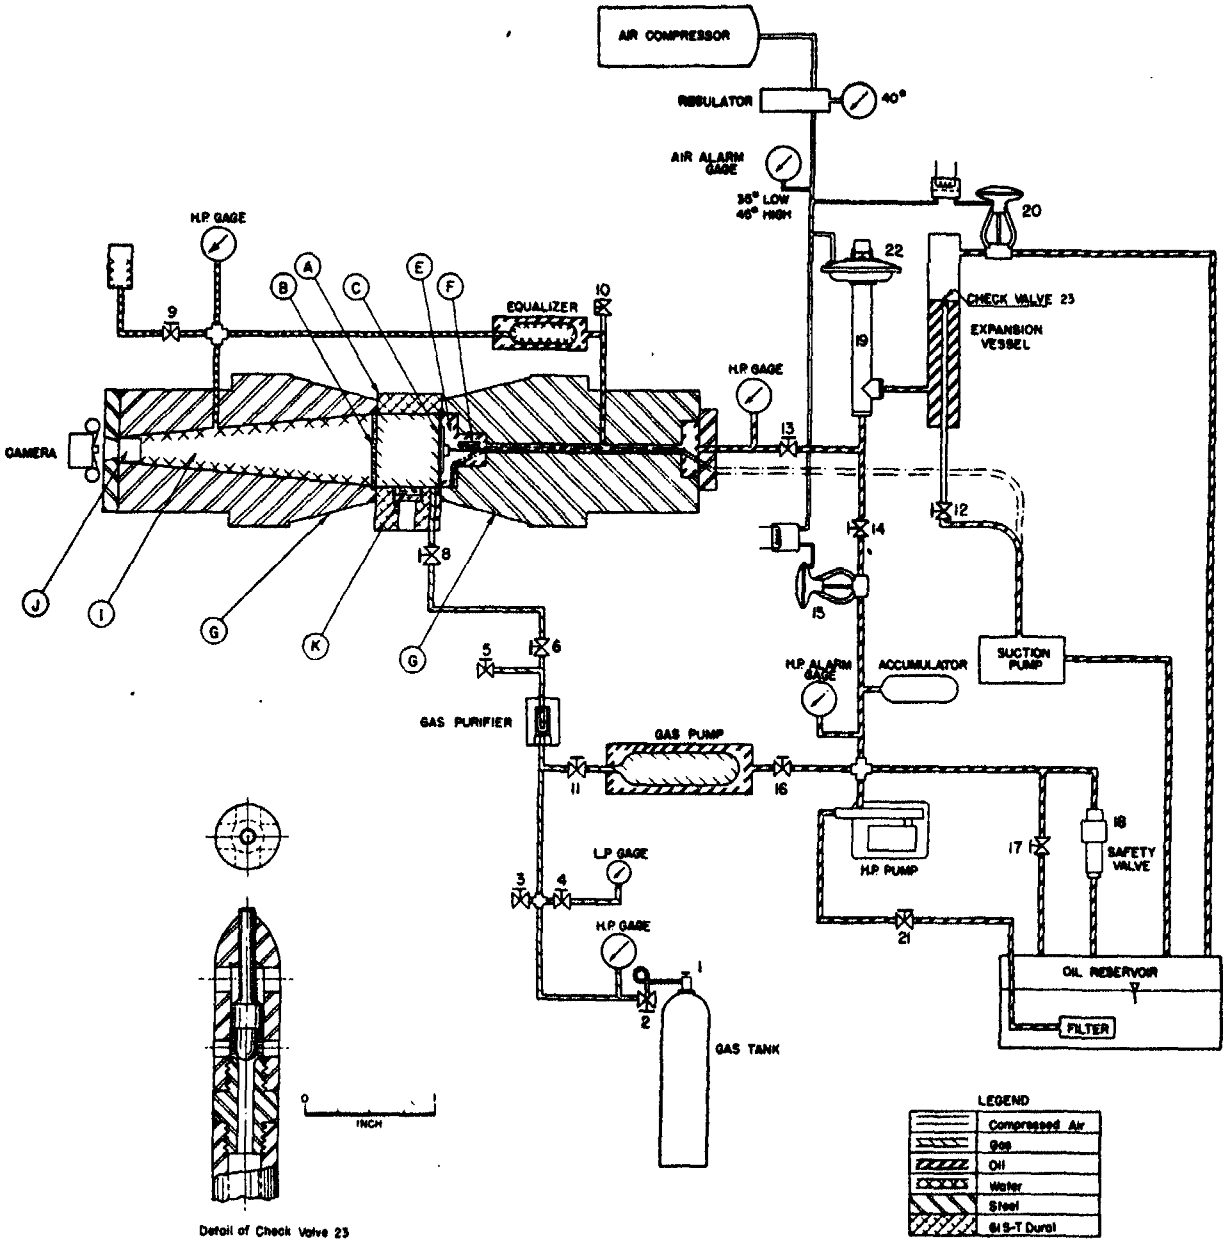

FIG. 1. Schematic of hydraulic system and section in elevation of cloud chamber and magnet without coils.

(2) The fuel required could not exceed what was practical to truck up the mountain.

(3) The instrument was to be capable of rapid assembly and disassembly for repair, with a minimum of physical effort because of the serious loss in effectiveness of personnel at high altitude.

(4) The wall of the cloud chamber was to have the smallest surface density consistant with a contained pressure of 200 atmos.

(5) The configuration of the instrument was to place a minimum of restrictions on the experiments that might be performed with it.

We arrived at a design which yields an illuminated volume 9 in. in diameter and 2½ in. deep, in a magnet which produces 8800 gauss for 43 kw. and which can dissipate 100 kw. given 10°C intake water. The instrument less trailer and generators weighs 8 tons and occupies about 40 percent of the available floor area of a trailer of 25-ton capacity. The surface density of the cloud-chamber wall is 15 g/cm^2 and since the material is of low atomic number, there is little probability of shower production by electrons or photons in the wall. The exterior of the chamber is accessible and almost any arrangement of lights, triggering devices, absorbers, etc. can be used. It requires 90 min. to remove the cloud chamber from the magnet; of this time, 60 min. is required to release the gas and other fluids.

The design evolved is shown in Figs. 1–3. The cloud chamber proper is defined by the machined aluminum alloy cylinder *A*, the circular glass plate *B*, and the rubber diaphragm sealed piston *C*. The piston is caused to move by pumping oil into the chamber *E* until rheostat *F* balances the bridge circuit of which it forms one arm. The piston is caused to move back, thereby expanding the chamber, by releasing a measured quantity of oil from chamber *E* into another vessel. A system of pneumatically operated valves with electrical control allows this cycle to be repeated automatically.

This assembly is made pressure tight by rigidly clamping it between the poles *G* of an electromagnet by means of four studs *H*. The thin glass plate *B* is supported hydrostatically by water in chamber *I* which is automatically kept at the same pressure as the oil in chamber *E*.

Stereoscopic photographs are taken through the thick glass windows *J* and light is admitted to the chamber through window *K*.

THE MAGNET

A general view of the instrument, with magnet coils removed to show the shape of the magnet, appears in Fig. 2. The magnet was cast and machined for us by the Boston Navy Yard.** The material satisfies Navy specification 49-S-1 Class F (carbon 0.3 percent, manganese 0.6 percent, phosphorous 0.05 percent, sulfur 0.05 percent, silicon 0.2–0.3 percent, nickel 0.85–1.00 percent, chromium 0.4 percent).

The pole shape and yoke dimensions were based on previous experience with a smaller magnet.[2] These dimensions were then altered to provide a structure of sufficient strength to withstand a pressure of 3000 p.s.i. on and in each pole.

Each pole is a frustrum of a right circular cone of diameters 13 in. and 18 in. and 10⅞ in. in length. Both poles are hollow.

The cavity *E* is circular in cross section, and is made just large enough to house the piston-bearing, control-rheostat, and the high voltage lead.

The cavity *I* (cf. Fig. 1 and Fig. 3) is defined by the volume of two skewed circular cones of common base. This shape of cavity produces the most rigid structure consistant with the requirement that an unobstructed view of the illuminated volume be obtained from each of the two windows *J*. This cavity was cored and its surfaces were not machined. They were coated with Malacca #810 Neoprene*** compound applied in several successive coats and then cured by an air blast (150°F) for 24 hours. This coating has thus far protected the cavity surface from rusting.

At a pressure of 3000 p.s.i., the force tending to push the poles apart is 260,000 lb. This force is transferred through the magnet yoke to four 2½-in. studs *H* (Fig. 3). The portion of the yoke which is perpendicular to the axis of symmetry is designed to be a beam of uniform strength loaded at the center. It is seen from Fig. 2 that every section of the beam taken parallel to the axis of symmetry is a "T" section. The web of the "T" section is shaped as two parabolas whose vertices are at the end supports. Since the structure was cast, this shape introduced no difficulties of fabrication and yielded a net saving of 1000 lb. as compared with a magnet yoke of uniform cross section, calculated to give the same deflection under pressure.

Type 49-S-1 Class F steel has a tensile strength of 85,000 p.s.i., and a yield point of 53,000 p.s.i. The most highly stressed part of the yoke occurs at the tip of the pole which contains the water column *I*. Here the metal is approximately 1.5 in. thick. Strain gauge measurements over this region at 3000 p.s.i. indicate that the outside surface is stressed to 6750 p.s.i., from which the inner surface is calculated to be stressed to 8700 p.s.i.

The four 2½-in. studs *H* which hold the yoke together are machined from Elastuf Type A-2 alloy machinery-steel. This steel has a tensile strength of 140–160,000 p.s.i. and a yield point of 125–145,000 p.s.i. with 16–20 percent elongation. Each stud is

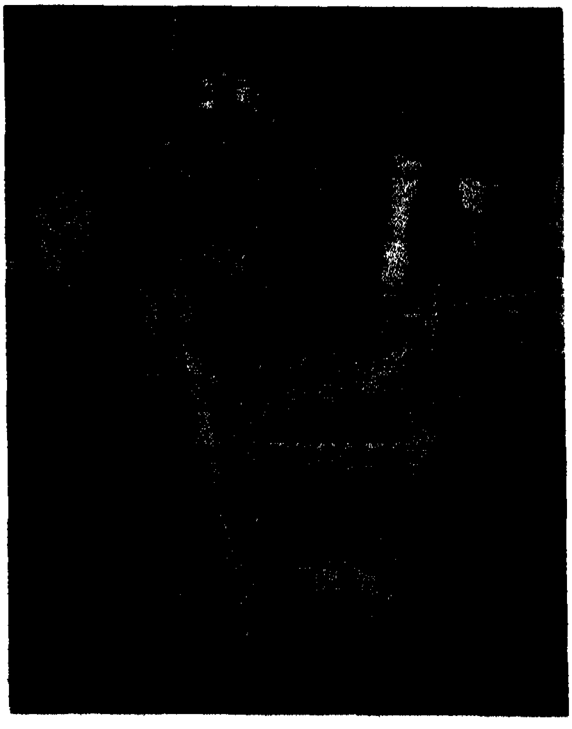

FIG. 2. Photograph of front end of magnet with coils removed.

** We wish to record our indebtedness to Commander F. B. Merkle and his staff at the Boston Navy Yard for their efficient effort in making this magnet.

[2] G. E. Valley, Phys. Rev. 72, 772–83 (1947).

*** Glover Coating Company, Malden, Massachusetts.

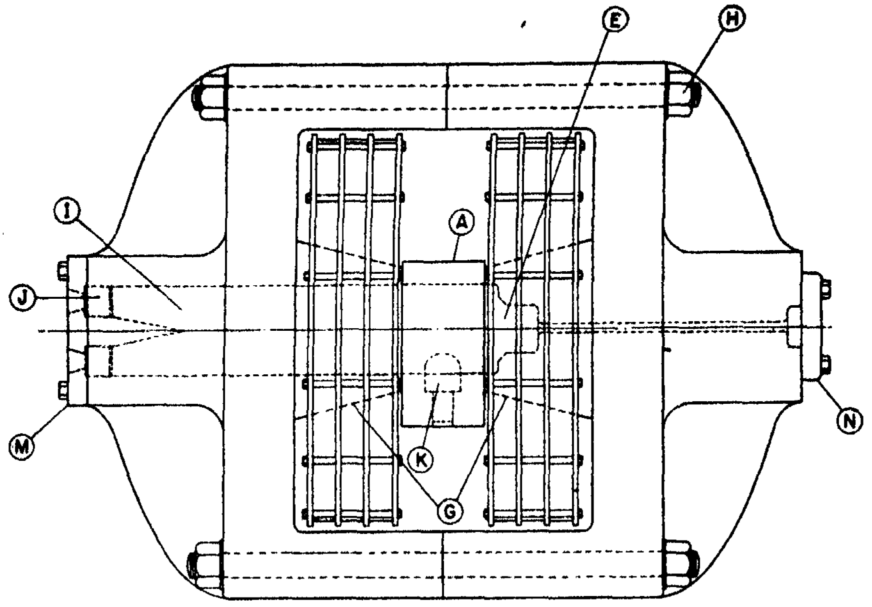

FIG. 3. Plan view of magnet with coils.

loaded to 15,000 p.s.i., and withstands a total of 65,000 lb. when the chamber is pumped up to 3000 p.s.i. Under this condition each stud elongates by 0.020 in. Thus, if the studs are initially unstressed, the magnet poles will separate by 0.020 in. due to this cause alone, upon application of pressure. Prestressing of the studs could of course nullify this effect, however, since the poles separate by an additional 0.005 in. anyway, due to bending of the yoke under pressure, we have not chosen to prestress the studs. Instead, we use a system of gaskets which remain tight for a relative displacement of the poles by more than 0.030 in.

We tried to mount the magnet as far above the trailer floor as was safe in view of the position of the center of gravity of the loaded vehicle. The center line is actually supported 38 in. above the floor, which gives ample room for placing other detecting devices beneath the cloud chamber. The frame supporting the front half of the yoke slides on triangular ways, propelled by means of a screw and wheel (Fig. 2). All parts of the frame in contact with the magnet yoke are made of Type 304 nonmagnetic stainless steel. The yoke is bolted to the frames with push-pull screws so that it can be leveled and aligned to the precision required by the gasket system.

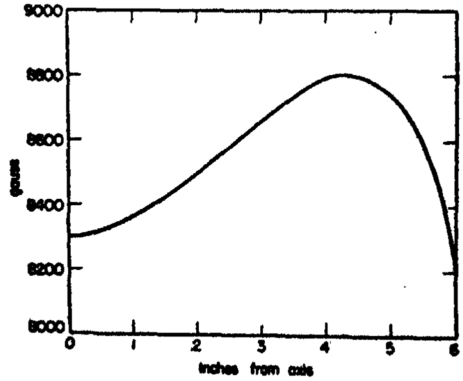

FIG. 4. Axial component of magnetic field along horizontal radius in median plane at 38 kw.

Because of the hollow poles and the comparatively poor magnetic properties of the steel of which the magnet is made, we regard the field distribution (Fig. 4) as being quite satisfactory. Figure 4 shows the axial field component along a horizontal radius; in this direction the cavity *I* is effectively a cylinder. The distribution along a vertical radius differs from that of Fig. 4 by less than 1 percent. This observation indicates that if one is going to put a hole in a magnet pole, there is little gained by using a conical hole rather than a cylindrical one of equal base radius. It will be noted that the maximum difference in axial field component shown in Fig. 4 is 500 gauss in 8500. The field may therefore be said to be uniform to ±3 percent. The method of construction of the coils is described in an accompanying paper.[3]

THE CLOUD CHAMBER PROPER

The cloud chamber is shown in detail in Fig. 5. The chamber wall is essentially a cylinder of 9 in. i.d. and 13.5 in. o.d. and is 8 in. long. As shown in insert *A* of Fig. 5, the wall of this cylinder had to be considerably thickened where the illumination window *K* was to be inserted in order not to weaken the structure. This eccentric configuration itself introduced new problems of stress distribution which we solved by approximate methods.

---

[3] Coonrod, Cecconi, Gedraitus, Harper, and Lewis, Rev. Sci. Inst. 20, 408 (1949).

This configuration gives us a surface density of 15.5 g/cm^2 over half the surface of the cylinder and approximately that value over the surface of the illumination window *K*. Since the cylinder is only clamped between the magnet poles, it can be rotated about the axis of symmetry to place the thin sections in best orientation for a particular experiment. Thus, for anticoincidence triggering, we orient the thin section to the bottom and allow the counter-telescope collimated incident radiation to enter through window *K* after passing through the lamp *L*; whereas, for an experiment to observe the decay of ordinary mesons, we might reverse this orientation.

The choice of the material from which the chamber wall was made depended upon its availability, machineability, corrosion resistance, and upon its density in proportion to its strength. Table I shows wall surface densities for various materials when a safety factor of five is assumed for a 9-in. i.d. cylinder to contain 3000 p.s.i.

TABLE I. Attainable wall surface densities for various materials.

Material	Yield point (p.s.i.)	Wall thickness (cm)	Density (g/cm)	Surface density (g/cm^2)
Stainless steel	60,000	3.4	7.9	27.0
Beryllium copper	95,000	2.0	8.3	16.5
Red brass (hard)	55,000	3.7	8.8	32.4
Aluminum alloy 61S-T	40,000	5.7	2.7	15.5
Magnesium alloy ASTM No. L	26,000	10.7	1.7	18.6

It is seen from Table I that either aluminum alloy 61S-T or beryllium copper might have been chosen. Because of its lower atomic number and greater availability, we chose to make the cloud chamber of aluminum alloy 61S-T. This alloy was chosen instead of other higher strength aluminum forging alloys because of its greater resistance to intergranular stress corrosion when subjected to contin-

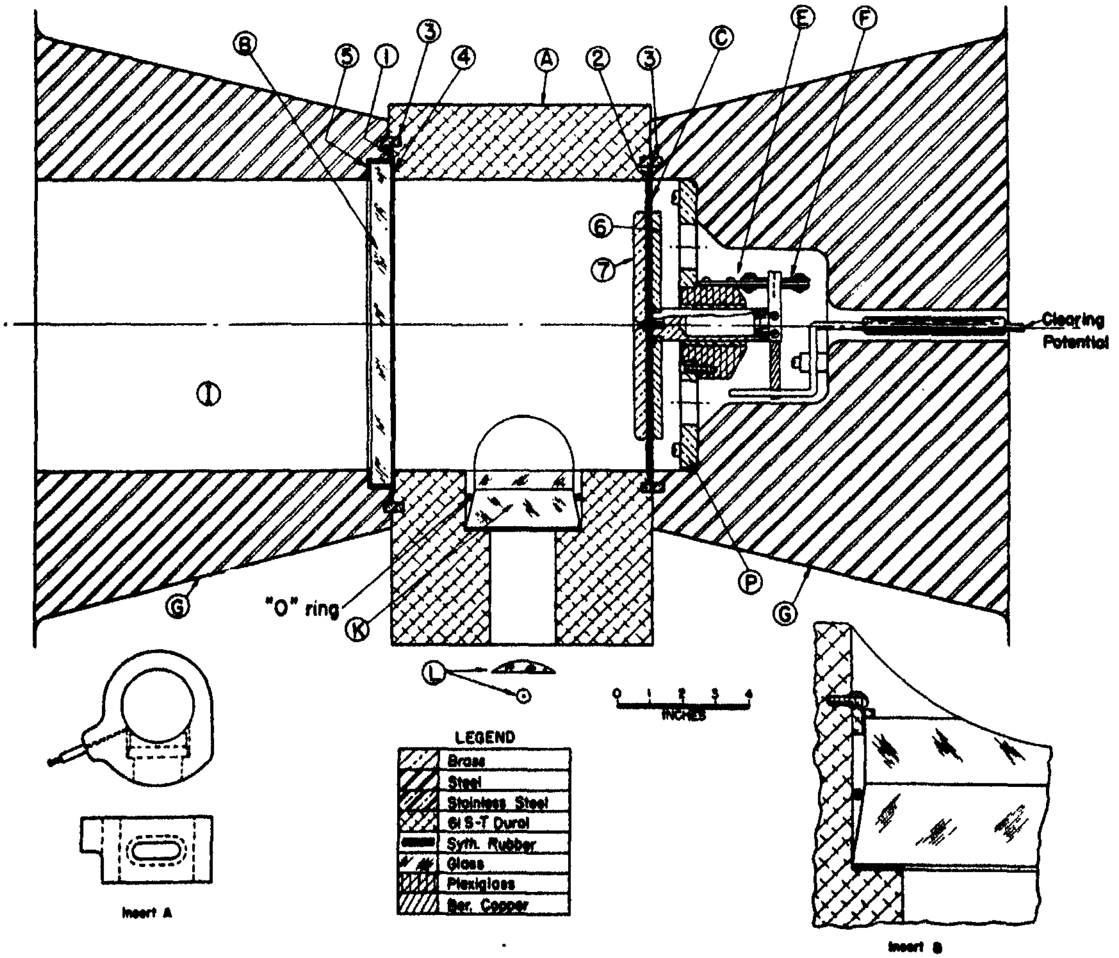

FIG. 5. Detail side elevation section of cloud chamber showing electrical connections; insert *A* shows plan and front elevation of cloud chamber; insert *B* shows pressure seal of window *K*. Inserts *A* and *B* are not to scale.

uous stress in the presence of liquids.[****] The chamber was machined from a forged biscuit 20 in. in diameter and 9 in. thick. In order to protect the aluminum and to prevent undesirable light reflection, the finished chamber was anodized black all over.

A strain rosette cemented to the chamber wall at its thinnest section showed a principal stress of 4000 p.s.i. corresponding to a stress of 6400 p.s.i. on the inner surface, when the contained gas pressure was 3000 p.s.i. It will be noticed from Table I that we calculated safety factors from the yield points rather than from the ultimate strengths of the various materials. This was because any yielding of the material would prevent proper functioning of the pressure seals and would constitute a practical failure. Thus, as far as explosion hazard is concerned, the safety factors are larger than given here and may in some cases change the order of apparent desireability of the various materials.

The glass window *K* is supported by a ¾-in. shoulder as shown in Fig. 5. A rubber-asbestos gasket $\frac{1}{32}$ in. thick is inserted between the glass and the metal in order that the surface of the metal shoulder need not be polished to avoid locally stressing the glass. This gasket is only for mechanical support of the glass, and is not a pressure seal.

The pressure seal is obtained by tapering and polishing the edge of the glass (taper $\frac{3}{16}$ in. in 1¼ in.) and inserting an "O"-ring[4] gasket of ⅛-in. diameter between the glass edge and the polished wall of the cavity into which it fits. This is an application of P. W. Bridgeman's "unsupported area" principle. It is readily seen that the greater the pressure the further into the tapered groove is the O-ring forced, and the tighter is the seal.

The glass is 1¼-in. selected plate prestressed† by the usual heat treatment after being ground and polished to the desired shape.††

Such a 2-in. by 6-in. light of Herculite is expected to fail at an applied pressure of 22,000 p.s.i. which gives us a factor of safety of 7.3 at our maximum working pressure of 3000 p.s.i. Although a safety factor of 10 is usually recommended, we consider this adequate since we can pretest individual pieces of glass to 4500 p.s.i. by filling the entire chamber with water, and also because there is no clamping frame needed to hold the window in position.

Heat-toughened glass has initial compressive stresses on the surface and a tensile stress at its mid-plane. A fully "tempered" plate (4000-μ/in. center tension) has stress of about 9200 p.s.i. at the center. The surface compression has a higher value. A test at 3000 p.s.i. using strain rosettes cemented to the outer surface of the Herculite window showed that the maximum principal stress was 5250 p.s.i. tensile. Thus the window has in use, a residual surface compression in excess of 2000 p.s.i.

It will be observed that whereas the chamber diameter is 9 in., the maximum unobstructed width of the window is only 6 in. It was therefore necessary to insert a plano-concave diverging lens in order to illuminate the entire chamber. This was ground from a piece of plate glass of the same original size of that from which the window *K* was made. It would have been easier to use a plastic for this but we find that Lucite, when exposed to air after a previous exposure to alcohol, develops surface cracks and becomes cloudy for that reason; polystyrene is not subject to this difficulty but is less desireable mechanically. The cylindrical surface has a radius of 4½ in. and so serves also to make the inside of the chamber smooth. This lens simply rests on the Herculite window, being held from falling out by a pair of ¼-in. square brackets screwed to the cavity walls. The resultant illumination is satisfactorily uniform over the entire chamber diameter.

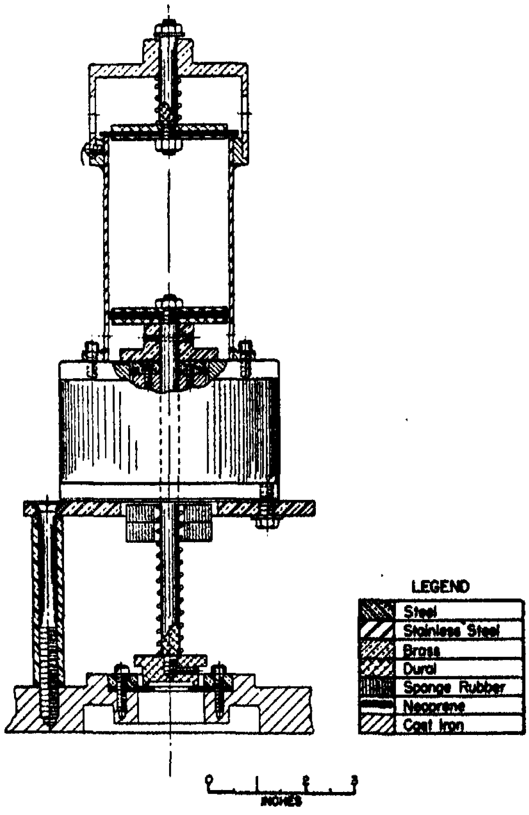

FIG. 6. Assembly drawing of valve 22, air pilot valve for main expansion valve 19.

[****] We are much indebted to Mr. W. G. Dow of the Aluminum Company of America, and to the members of their research laboratory who checked the stress-corrosion behavior of these alloys under stress in an alcohol-saturated atmosphere.

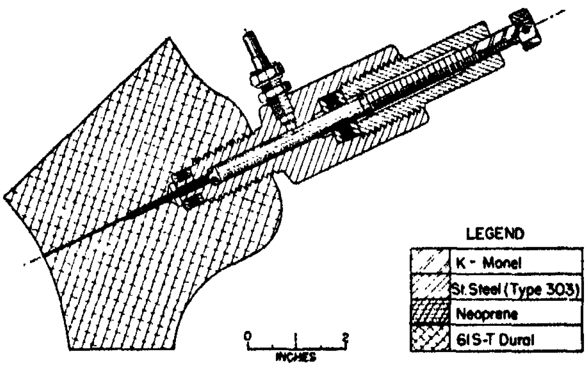

FIG. 7. Section of needle valve 8, shown as mounted in cloud chamber wall.

The crevices required for the sealing gasket are filled with a soft wax. This is made by mixing equal parts of petrolatum and paraffin, blackened with carbon-paper pigment. This material is soft enough to transfer the gas pressure to the O-ring seal at all normal temperatures.

The positions and shapes of the gaskets required to seal the chamber to the magnet poles are shown as Parts 1 and 2 in Fig. 5. Because of the shape of the pole faces between which the cloud chamber was to be mounted and the inevitable deflection of the yoke, ordinary gaskets were unsatisfactory to seal the chamber to the pole faces of the magnet. A satisfactory gasket scheme for this application must (1) be leakproof at 3000 p.s.i. even when the initial or tightening pressure is relaxed due to the yoke deflection; (2) be easily assembled and disassembled; (3) not require too close machining tolerances; and (4) not be very position sensitive.

The gaskets used are cut from $\frac{1}{8}$-in. Neoprene sheet (45 durometer) and are flat. The gasket seat on the chamber is tapered so that when the cylinder is tightly clamped between the poles, the gasket is $\frac{1}{16}$ in. thick at the stainless steel ring (Part 3 in Fig. 5), and $\frac{1}{8}$ in. thick at the inside diameter of the chamber. Gasket (2) being a solid sheet also serves as the moving diaphragm *C* of the cloud chamber and separates the oil in cavity *E* from the gas in the chamber. These gaskets also make use of the unsupported area principle.

A half-size model of this gasket arrangement was built and tested prior to incorporation in the final design. In the model, two flat plates were used for pole faces and the model tested to 6000 p.s.i. with the end plates (poles) moved progressively further apart.[8] This test indicated that the gasket system would remain tight if the magnet poles separated by as much as 0.050 in. under pressure. The measured total separation of the poles of the final instrument was 0.025 in. at 3000 p.s.i., which includes the 0.020-in. bolt elongation and 0.005-in. yoke deflection.

The rings (3) serve to locate the cloud chamber between the poles and also prevent gaskets (1) and (2) from blowing out as the poles separate. These rings slide freely in both the dural cylinder and in the pole faces and enter $\frac{1}{4}$ in. into each. The poles need be moved apart only 1 in. from the closed position shown in order to insert or remove the chamber.

Gasket (4) is a conventional flat gasket made of 80-durometer rubber. Item (5) is not a complete ring gasket but is sectioned to serve as a cushion for preloading gasket (4). The diaphragm gasket (2) was first made of Chemigum and vulcanized to the piston plate (6). The present design makes the clearing field electrode (7) a $\frac{3}{8}$-in. thick brass plate. A tongue and groove clamping ring of $\frac{1}{4}$-in. diameter is cut on the electrode and piston plate. Thus, any diaphragm material can be used and changed at will by simply removing one screw.

A combination of parts like (1) and (3) (Fig. 5) was also used to seal the end plates *M* and *N* (Fig. 3).

The two windows *J* (Figs. 1 and 3), have conventional flat gaskets (80-durometer Neoprene) between the glass and the end plate (*M*). A flanged cup fits over each glass plug and is screwed to the end plate to preload its gasket. When under pressure, the ratio of light area to gasket area is sufficient to ensure a tight seal.

HYDRAULIC SYSTEM

The mode of operation of the hydraulic system for actuating the cloud-chamber piston is essentially

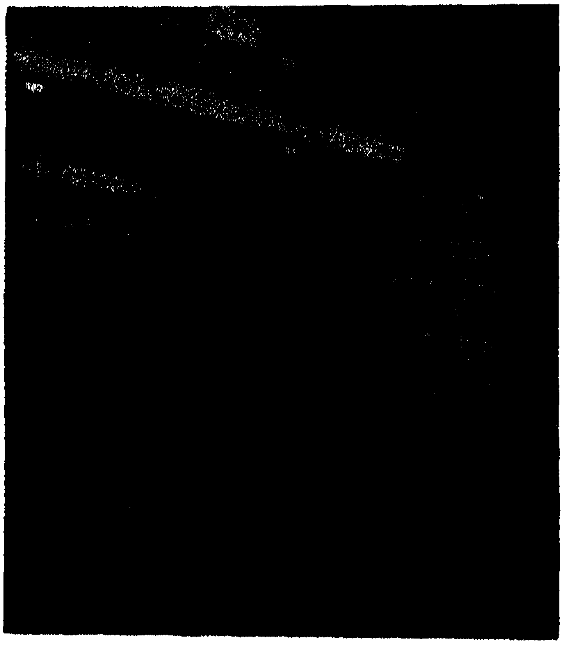

FIG. 8. Photograph of rear of magnet showing hydraulic system and water cooling pipes for magnet.

---

[8] J. A. Vitale, L.N.S.E., Technical Report No. 1, 1947.

that described by Johnson, DeBenedetti, and Shutt.[6] We have made use of commercially available parts wherever possible. These are listed in Table II. The piping diagram is shown in Fig. 1. Figure 8 is a photograph of the rear of the magnet and shows the hydraulic system. The water-oil pressure equalizing system consists of a water-filled Buna-S bag immersed in oil which is contained in a strong steel cylinder. The interior of the bag is connected to water cavity *I*, and the interior of the steel cylinder is connected to oil cavity *E* as shown in Fig. 1. Obviously a change in oil pressure is immediately transmitted to the water and both remain always at the same pressure. Since the piston is free, the oil pressure in turn always equals that of the gas in the cloud chamber. Consequently, the water and gas are also at the same pressure and there is no net force on the glass plate *B*.

The brass piston rod slides in a stainless steel bearing insulated from but supported by a perforated brass disk *P* (Fig. 5).

Prior to an expansion, all valves, except the throttle valve #13 and valve #12, are closed and the expansion vessel is partly filled with oil and partly evacuated. To make an expansion the compressed air, which holds valve 19 closed, is released. This release of air is achieved by means of the permanent magnet Fussell type valve 22,[7,8] shown in detail in Fig. 6. Valve 22 is designed to open valve 19 suddenly. It is held shut by a permanent magnet in order that it shall not open in case of power failure. The dash pot arrangement shown in Fig. 6 is required to prevent valve 22 and therefore valve 19 from reshutting before the piston has finished moving (i.e., before the expansion vessel is completely full of oil). Valve 22 is made to open by means of the system of LePrince-Ringuet as described by Chu and Valley.

After the expansion, the expansion vessel is filled with oil but none escapes through valve 12 because of the check valve 23 on the end of the vertical pipe which is inserted in the expansion vessel. Two seconds after the expansion, the dash pot on valve 22 allows it to close and immediately thereafter valve 19 closes, thus isolating the expansion vessel from the remainder of the system; therefore, the next two operations, of recompressing the cloud chamber and of re-evacuating the expansion vessel, can proceed independently of one another and in any time sequence. We therefore do not provide a timed sequence of operations; instead, we allow the system to recock itself under the control of its interlocking relays alone.

For instance, the high pressure oil pump is actuated, and valve 15 is opened, by any unbalance of the bridge circuit of which rheostat *F* is a component which indicates that the piston has moved in the expanding direction by more than 0.005 in. This is subject only to the condition that the main valve 19 is closed. Thus, while the chamber is standing cocked, any leaked oil is automatically repumped. It should be remarked that we have kept the instrument at 1500 p.s.i. for several weeks at a time and have, during such

periods, never actually observed any gas, water, or oil leakage.

Oil is removed from the expansion vessel by the vacuum pump as soon as the check valve 23 is opened. This occurs as soon as valve 20 opens and allows the pressure in the expansion vessel to fall to zero. The vacuum pump then pumps out the oil in the expansion vessel until its level falls to the port of valve 23; thereafter it removes any residual gas. The evacuated volume of the expansion vessel is obviously the same as the change in volume of the cloud chamber. It can be changed by raising or lowering the tube which holds valves 23 and 12. At present we allow the vacuum pump to operate continuously. The evacuated volume produced in the expansion vessel is satisfactorily reproduceable for expansions made at equally spaced intervals. When expansions are made at irregular intervals controlled by counters, the system of allowing the pump to operate continuously is not completely satisfactory, and we propose in the future to pump the expansion vessel for a fixed interval of time only, after each expansion.

We have found it desirable to interlock the system fairly completely. Valve (#22) cannot be triggered unless valve 20 is closed, nor while the piston controlling bridge is unbalanced nor, after an expansion, until the high pressure oil pump has started to recompress the chamber. Valve 20 in turn cannot be opened unless valve 19 is closed and the air pressure is 40±5 p.s.i. This is required because the main valve 19 will leak if the air pressure is below 30 p.s.i., and valve 22 will spontaneously open if the air pressure is above 55 to 60 p.s.i. In addition, the high pressure oil pump is turned off and an alarm is sounded by a time clock, if it pumps for 10 sec. longer than the average time observed to be required at the expansion ratio in use; and if this fails to stop the pump, its power is cut off by the high pressure alarm gauge at a pressure 500 p.s.i. in excess of operating pressure. All electrical controls failing to stop the pump, safety valve #18 will open at 3500 p.s.i. and bypass the system to the oil reservoir which is at atmospheric pressure. The last two safety devices prevent the entire apparatus from exploding; the previously mentioned devices prevent the more delicate structure of the piston from being broken.

ELECTRONICS

Piston Control Bridge

This circuit (Fig. 9) consists of an ordinary resistance bridge powered by 110 v 60 c from the mains. The unbalance signal is amplified and limited by V_2, and applied to the cathode of the phase sensitive detector V_3. Tube V_3 is rendered phase sensitive by using 60 c 220 v (also derived from the mains) as its plate supply voltage. The grid of V_3 is kept at a fixed bias voltage. Obviously the grid potential of V_3 can be adjusted so that it will conduct only when V_2 drives its cathode negative during the half-cycle when its plate is positive. Since there is a reversal of the phase of the signal from V_2 when the bridge passes through balance, the initial phases can be set so that V_3 conducts only when the bridge is unbalanced in one direction.

Because of the high gain and limiting action of V_2, its output signal is essentially a square wave. Consequently, when V_3 conducts, it functions as a normal half-wave rectifier to drive the relay shown in its plate lead. When a relay is used whose coil resistance is 10,000 ohms, a 1-μfd condenser is a sufficient filter to prevent chattering of the relay contacts.

The bridge is isolated from the mains and from the grid of V_2a in order that one side of the piston rheostat can be grounded. The piston rheostat consists of two pieces of resistance card (as used on General Radio Company Model 301A, 20K potentiometer) mounted side by side. The sliding contact is mounted on the piston shaft by a Bakelite arm, and so is insulated from the high clearing potential which is applied directly to the piston. The sliding contact is made of Paliney #7 contact metal††† (high palladium—low gold alloy).

The bridge is so connected that V_3 conducts (and so activates the high pressure oil pump) when the resistance of the piston rheostat is too low for balance. Thus, if the rheostat breaks, the pump will not run. Tube V_3 is driven by its cathode so that the pump will not run if V_2 burns out. Sufficient gain and output signal voltage is provided by V_2 to drive a Type 6AS7 tube as V_3 (grid biased at −50 v with respect to ground) should it be desirable to drive a heavier load than the small relay shown. When a 6SN7 is used for V_3, its bias can be adjusted over a range of 50 v without noticeable effect on performance; likewise the adjustment of phase control rheostat R_1 is very uncritical.

Tube V_1 is a cathode follower which reads the voltage across the piston rheostat. This tube drives a recording milliameter which records the piston position. It is important to know the piston position at all times since the unbalanced force exerted on it is over 100 tons during expansion, and mechanical stops can obviously not be provided; it is, therefore, necessary to be certain that the piston is pumped sufficiently far forward during the compression cycle, so that it will not exceed its allowable traverse during expansion. The compressed position of the piston depends on the resistance required to balance the bridge; this can be set by adjusting R_2. Although the piston position can be set to ±0.005 in. by this device, such precision is unnecessary because the piston position affects the volume of the cloud chamber before expansion, but does not set the expansion ratio directly, since this is determined by the evacuated volume of the "expansion" chamber. Consequently, an error in the bridge balance affects the expansion ratio only to a second order.

MAIN SEQUENCE CONTROLLER

The only time interval which needs to be precisely controlled is that between the opening signal for the main expansion valve (valve 22 controlling valve 19) and that which fires the lamp.

The circuit (Fig. 10) consists of a slow relaxation

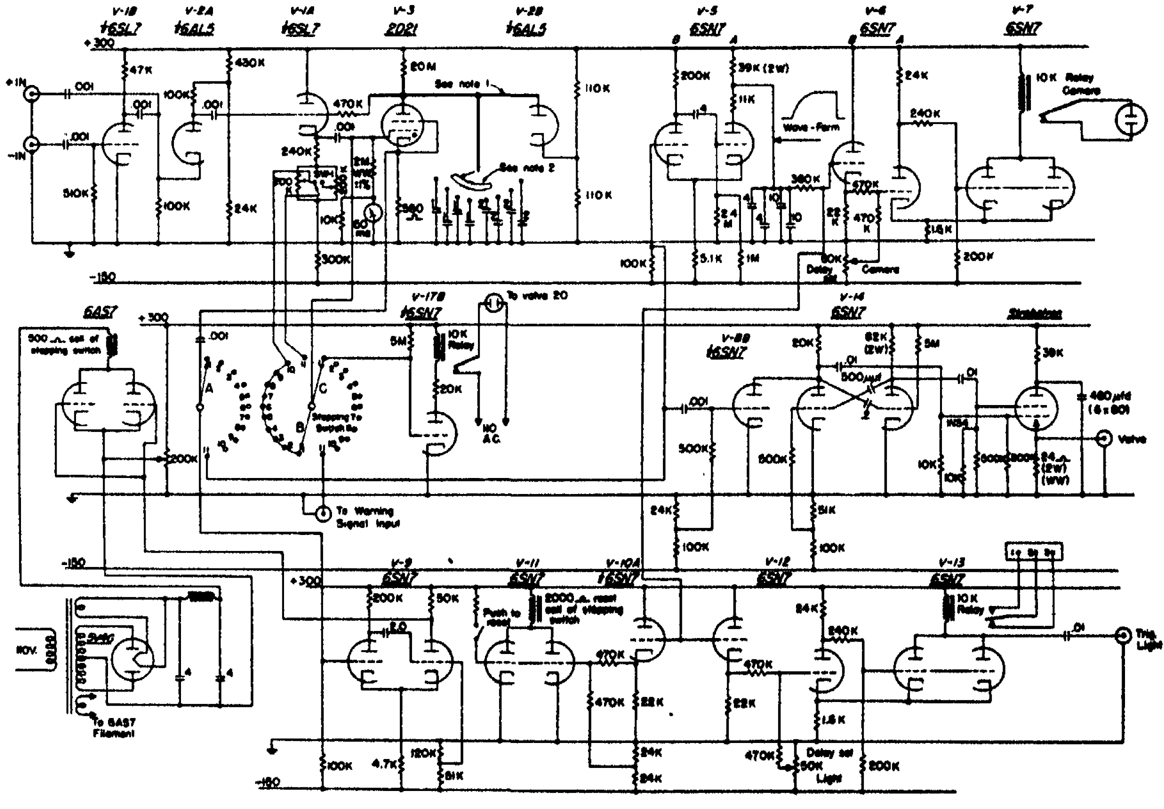

FIG. 10. Schematic wiring diagram of main sequence control circuit. *Notes*: (1) Double lines indicate wires to be insulated for 2000 v. (2) Ceramic switch shorts 1 to 8 contacts when turned.

---

††† From the J. M. Ney Company.

oscillator (V-1A, V-3, and V-2B) which fixes the interval between expansions, and a delay circuit V-5 which controls the interval between inception of an expansion and illumination of the cloud chamber. The remainder of the circuit consists of elements controlled by these two.

The slow relaxation oscillator consists of the thyratron V-3 which is grid controlled by cathode follower V-1A. After the thyratron fires, the condensers connected to its plate recharge through its 20-megohm plate resistor; consequently, the control grid potential of V-3 slowly increases toward the potential at which it will fire again. It is seen that the cathode circuit of V-1A has a split load resistor with two taps, either of which can be selected by a switch SW-1. The voltage obtainable from the left tap can rise to the firing potential of V-3; that from the right tap can rise only to within a few volts of firing potential. With the switch in the right position the thyratron can only be fired if a positive pulse is applied via limiting diode V-2A, and if its plate condenser has had time to charge. Limiting diode V-2B prevents the grid of V-1A from approaching so close to the potential of its plate that a trigger pulse could produce no effect. The relaxation period of V-3 can be selected between 0.3 and 4 min. by choice among several values of plate condenser.

The period of V-3 is multiplied by ten by means of the stepping switch shown.†††† Several features of the circuit are determined by the peculiarities of this switch, which was the only one with a reasonably high coil impedance available to us.

This switch makes one step whenever V-3 fires. A pulse is taken from the cathode of V-3 when it fires and is applied to the grid of V-9A of flip-flop V-9. The signal from V-9 turns on the grid-controlled rectifier 6AS7 which furnishes the 14 watts necessary to actuate the stepping switch. This arrangement requires a separate floating power supply which has not proven unsatisfactory. The alternative would be to put a pilot relay in the plate circuit of V-9B and use this to control the step switch—one still needs 14 watts of d.c., and no reduction of complexity results. Flip-flop V-9 is required because the pulse from V-3 is far too short to actuate the stepping switch. Another method of actuating this switch would be to discharge a large electrolytic condenser through its coil by means of a gas tube. Since the condenser could be recharged slowly, power could be taken from the regulated supply; furthermore, no flip-flop would be required to lengthen the pulse. A condenser of about 100 μfd at 300 v would be required.

The control grid of thyratron V-3 is connected to moving contact B of the stepping switch; this contact can bear successively on any one of eleven fixed contacts; of these the first ten are permanently connected to the higher potential side of SW-1. In consequence, the thyratron fires automatically until arm B, after 9 periods of V-3, finally rests on contact eleven. The position of the moving contact of SW-1 can then determine whether the thyratron fires automatically or not at the end of the tenth period.

When arm A of the stepping switch is at position eleven, the cathode signal of V-3 can, besides triggering V-9, also trigger valve 22, thus expanding the cloud chamber, and can also trigger the delay flip-flop V-5 which controls the flash lamp. Thus, when SW-1 is in the left position the cloud chamber operates automatically (making "random" expansions), and when SW-1 is in the right position the chamber waits until expanded by a Geiger counter pulse arriving via V1-B and V-2A.

Initially, in flip-flop V-5, element V-5A is nonconducting and element V-5B is conducting; this situation is reversed when V-5A receives a positive grid pulse from V-3 via contact A-11 of the stepping switch. The length of time during which V-5B conducts on the time constant of the resistor-condenser combination of the plate circuit of V-5A and the grid circuit of V-5B. This is adjusted to be about 5 sec. The plate of V-5B is made to increase in potential slowly by means of the 28-μfd condenser shown and the output wave form of V-5B is as shown on the diagram. This wave is applied to "pulse-height discriminators" V6, 7 and V12, 13 which control the camera and light, respectively.[9] These devices can be set to function at a particular amplitude of the wave form V-5 and therefore at a particular time after V-3 has fired. The extra width provided for the output wave form V-5 is for the purpose of keeping the camera relay shut long enough to change the film. Although this arrangement allows the time at which the film starts to move to be precisely set, this is a feature of no great value.

The stepping switch is of the type which requires resetting after each cycle; a spring and ratchet combination is built in for this purpose. The pawl is automatically lifted for resetting by a magnet energized by tube V-11 which is turned on by the output signal from V-5 as shown.

After the switch is reset, arm C of the stepping switch applies the grid voltage of V-3 also to the grid of V-17B thereby turning it off. This de-energizes the relay in the plate circuit of V-17B and this causes valve 20 to open. Valve 20 therefore stays open for a full period of V-3.

When arm C is at position eleven, the V-3 grid voltage is applied to frequency modulate an audio oscillator which sounds a warning note whose frequency increases as the instant of expansion is approached. We have found this to be an invaluable device.

---

†††† Stepping switch type Guardian R.E.R.

[9] Cf. Rad. Lab. Tech. Ser., *Cathode Ray Tube Displays* (McGraw-Hill Book Company, Inc., 1948), Vol. 22, p. 234 ff.

The strobatron which energizes the trigger coil of valve 22 is triggered by the biased-off multivibrator *V*-14, whose driver tube *V*-8*B* is triggered directly by the cathode signal from *V*-3 via contact *A*-11 of the stepping switch. A circuit similar to that of *V*-5 could alternatively have been used to trigger the strobatron. It is always desirable to drive both grids of a strobatron with as large voltage pulses as are conveniently obtainable; it is also desirable to mount a small panel light next to the strobatron to keep its cathode illuminated. With these precautions the device is entirely reliable.

OPERATION

The clearing potential which is applied to the piston, is required to be about 4000 v. The surface resistance of the rubber diaphragm is ohmic and depends greatly upon the vapor present in the cloud chamber, but is independent of the gas pressure. When absolute propyl alcohol is used, the resistance is about 20 megohms; any amount of water vapor is harmful and can decrease the surface resistance by as much as an order of magnitude. The current which flows across the rubber membrane produces fog from electrolytic ions; fortunately this fog does not reach the illuminated volume until after the tracks have been photographed. However, it is necessary to allow it to settle out after each expansion if the chamber is to operate for any length of time.

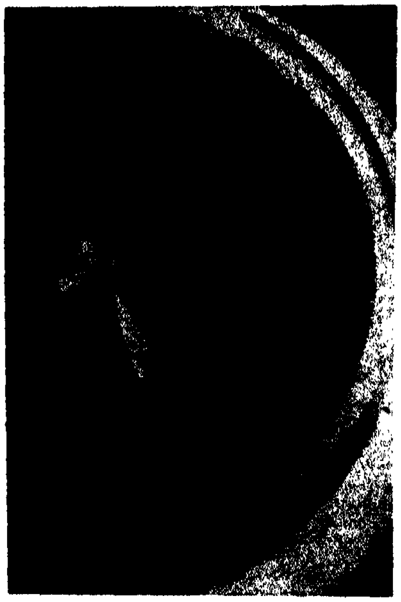

FIG. 11. Cloud-chamber photograph showing sharp negative and positive ion tracks due to a single particle. Range *vs.* scattering measurements indicate that the particle is a proton. The heavy plumes of ionization are caused by corona from the sharp corners of the slot in the head of the screw which holds the clearing field electrode to the piston.

Absolute propyl alcohol is very good as far as this effect is concerned but requires rather a long interval between expansions; absolute ethyl alcohol is faster but has also a higher conductivity. We have obtained best results with a 3:1 mixture of propyl and ethyl alcohols. With either variety of absolute alcohol, the volume expansion ratio at 100 atmos. of argon and with an excess of liquid present, is 1.063. If water is added, the expansion ratio decreases to 1.04,[10] but the performance is considerably worse. At a pressure of 167 atmos. of hydrogen, the expansion ratio for a minimal expansion ratio mixture of alcohol and water is 1.08.

By using the cloud chamber itself as a gas thermometer, we have determined that the time after expansion required to establish thermal equilibrium is 5 to 7 min. The smallest interval between expansions which can be used is 20 min. if the device is to be counter controlled and is to operate reliably for a long time. The extra time is required to establish vapor equilibrium and we are now studying means to reduce this.

We normally operate the chamber unsaturated—i.e., with no excess liquid present. We have operated continuously for as long as 3 weeks on one charge (1.5 cc) of alcohol; the required expansion ratio gradually increases with time as alcohol is absorbed by the rubber membrane. The effect of temperature on required expansion ratio is no greater than for any ordinary one-atmosphere instrument with liquid excess. This procedure does not appreciably decrease conduction across the rubber membrane but has a number of minor advantages.

A photograph taken with this instrument under counter control has already been published.[11] Another is shown in Fig. 11 in which the splitting of the positive and negative ion component can be more clearly seen.

We find that the shortest time after inception of the expansion at which tracks can be photographed is 0.6 sec. This has relatively little to do with the speed of expansion. Actually, we find that the chamber tends to develop a fine general fog if the expansion is too fast. We usually operate with throttle valve 13 nearly closed, a procedure which yields the desired reliability.

The sensitive time is very long; it can be compared to that of an ordinary cloud chamber by observing the average numbers of cosmic-ray tracks which are photographed per expansion. We estimate the sensitive time to be about 5 sec. at 100 atmos. of argon and a clearing field of about 250 v/cm. It is very noticeably longer at 150 atmos. The sensitive condition exists before the expansion and not after it, and is due to the small diffusion and drift velocity. Consequently, it cannot be measured by use of a fast motion picture camera as is often suggested. We have demonstrated that it can be changed by variation of the clearing field in the expected way.

[11] Valley, Leavitt, and Vitale, Phys. Rev. 75, 201–203 (1949).

We do not find that an unduly long period of time is required to clear dust from the filtered gas after filling the chamber. From twelve to twenty expansions starting at a ratio of 1.01, repeated at four-minute intervals, and graded into the steady regime, suffices. This requires about three hours.

ACKNOWLEDGMENTS

We have been fortunate in having the assistance of Mr. Thomas Mersereau during the assembly and testing of the instrument. Its development was first proposed to us several years ago by Professor Bruno Rossi and we have since enjoyed the support and encouragement of him and of Professor J. R. Zacharias. We avoided many pitfalls because of the mature advice of Mr. M. M. Hubbard.

Thanks are due Mr. Lewis Coonrod and his competant machinists for their excellent machine work on such a complex assembly.

APPENDIX I

The mean square Coulomb scattering angle for a particle of known constant momentum traversing a given thickness of matter is given in Rossi and Greisen's review article.[12] If we call this angle θ, and then calculate the magnetic deflection angle φ for the same path length, the ratio θ/φ can be taken as the fractional error in magnetic deflection caused by scattering. It is obvious that this is also the fractional error in measured momentum due to scattering. If the formulas for scattering and magnetic deflection are combined, we have

$$\theta/\varphi=(K/\beta H)(P/x)^{\frac{1}{2}}, \tag{1}$$

where H is the magnetic field strength in gauss, P is the pressure in atmospheres, and x is the path length in centimeters of the particle whose velocity is $\beta=v/c$.

K is a constant dependent on the material and has the values shown in Table III.

TABLE III. Values of scattering error constant for different gases.

Material	K
Argon	465
Tetra-fluoromethane (CF_4)	500
Air ($Z_{eff}=7.2$)	275
Helium	56
Hydrogen (H_2)	41

APPENDIX II

The ions are originally produced along a line, and then diffuse radially to produce a track of apparent width w at a time t. The problem is to calculate how w depends on t and the initial number of ions, formed per unit length of track, I.

Let the track be vertical, and the x axis be horizontal and perpendicular to the line of sight. Then the observed surface density of ions is just the number which have diffused to the element dx at x during the time t.

This is

$$\rho_x=\frac{I}{2(\pi t/D)^{\frac{1}{2}}}\exp-(x^2/4t/D),$$

where D is the diffusion constant of the ions in the gas.

We now assume that the optical density of the photograph is given by $d=\log\rho_x$. This implies that the light from one droplet is not obscured by another; this needs only be true near the edge of the track where ρ_x is smallest.

Since the tracks appear sharp, and since the film is developed to yield maximum contrast, we identify an optical density d_0 as defining the observable track edge. Then,

$$d_0=\log I_1-\log 2(\pi t/D)^{\frac{1}{2}}-(w_1^2/16t/D)+\text{const.},$$

where w_1 is the apparent width after a time t of a track produced by a particle whose specific ionization was I_1. And for a second particle:

$$d_0=\log I_2-\log 2(\pi t/D)^{\frac{1}{2}}-(w_2^2/16t/D)+\text{const.}$$

Then, if the two specific ionizations are to be compared, we have, if t/D is the same in both cases,

$$I_1/I_2=\exp((w_1^2-w_2^2)/16t/D).$$

Thus, a comparison can be made when t/D is known to be the same for both tracks; this could be done for counter controlled pictures, but the results are very sensitive to the observed width. This in turn depends on the level of illumination in the chamber, a fact which probably means the method is only good for distinguishing between tracks of particles of very different specific ionizations. We regard the comparison of tracks of differing ages to be very rough indeed, although obviously possible in principle.

Differential Counting with Reversible Decade Counting Circuits*

FREDERICK H. MARTENS
University of New Mexico, Albuquerque, New Mexico

(Received March 1, 1949)

Three circuits were designed and built to apply a reversible decade counting circuit to the direct measurement of the difference in the counting rate from two counter tube telescopes used in cosmic-ray research. The circuits are equally applicable to the direct measurement of the difference in the strength of two radioactive samples. An input circuit prevents two pulses from the Geiger tubes from arriving simultaneously at the first ring-of-ten. A driving circuit switches and shapes the pulses for correct bi-directional operation of the ring-of-ten. A coupling circuit permits two decade rings to be operated in cascade, giving a differential electronic scale of 100.

INTRODUCTION

THE difference in the counting rate from two sources of electrical pulses may be measured with a reversible ring-of-ten.[1] The pulses from one source must be applied alternately to each lead of one pair of input terminals in order to advance the pattern of the ring in a clockwise direction. The pulses from the other source must be applied alternately to each lead of the other pair of input terminals to advance the ring counter-clockwise.

An *input circuit* is required to prevent the simultaneous arrival of pulses from both sources. A *driving circuit* must distribute pulses of correct shape alternately to each lead of one pair of input terminals of the ring-of-ten. A *coupling circuit* is needed when two reversible rings-of-ten are placed in cascade. The coupling circuit provides for the transmission of a correct coupling pulse to the second ring-of-ten whenever a full decade is added or subtracted from the first ring-of-ten.

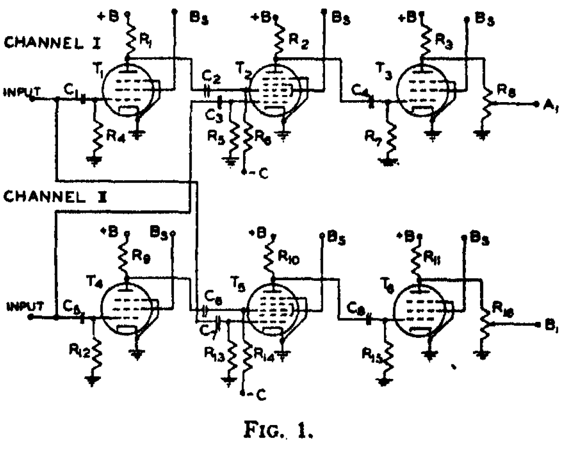

FIG. 1.

T_2, T_5	6SA7

$+B$, +250v; B_s, +180v; $-C$, −20v

THE INPUT CIRCUIT

The input circuit (Fig. 1) is composed of two identical channels, each fed from its respective source of pulses and each designed to drive the first reversible ring in an opposite direction. Each channel is composed essentially of an anti-coincidence circuit required for preventing simultaneous pulses in the two channels. Consider only channel *I* as marked in Fig. 1. The input pulses, negative in sign, are fed to tube T_1 and also to the first control grid of T_5. The positive pulse from T_1 is used to drive T_2, the anti-coincidence tube. This positive pulse on the second control grid of T_2 will be transmitted only if the first control grid is not receiving at the same time a negative pulse from the input to channel *II*. Thus, if two source pulses should occur simultaneously in the two channels, no pulse would be transmitted. This is necessary because two pulses fed simultaneously into the ring circuit would cause an erroneous reading. The pulse from the anti-coincidence tube is inverted by T_3. This gives a positive pulse to trigger the driving circuit described in the next section.

An identical pulse is delivered by tube T_6 in channel *II* for each input pulse from the other source when not simultaneously accompanied by a pulse in channel *I*.

THE DRIVING CIRCUIT

Each pair of input terminals, *PQ* and *ST* (Fig. 2), for the reversible ring-of-ten is fed by a trigger circuit of the type described by Regener.[2] If fed from channel *I* at A_1 (compare Fig. 1) the trigger circuit T_1, T_2, supplies the necessary positive pulses to the "clockwise" pair *PQ* of input terminals of the first ring-of-ten. The cathode follower circuit, T_3, is used to reduce the load on the trigger circuit. An identical trigger circuit is placed between channel *II* at B_1 and the "counter-clockwise" input terminals *ST* of the first ring-of-ten.

R_{11}, R_{14}, R_{15}, R_{18}	470,000 ohms, ½w
R_{12}, R_{13}, R_{16}, R_{17}	2,000 ohms, 2w
T_1, T_2, T_3, T_4	6AK6
T_5, T_6	6SN7
$+B$, +250v; $-C$, −20v	

THE COUPLING CIRCUIT

The coupling circuit providing directional feed from the first ring to the second ring is shown in Fig. 3. It consists of two pentodes, T_1 and T_2, which permit only one pulse to pass for each complete revolution of the first ring-of-ten. As explained below, T_1 will pass such a pulse only when the ring is proceeding in the counter-clockwise direction (from position "0" to position "9"), and T_2 will pass such a pulse only when the ring is proceeding in the clockwise direction (from position "9" to position "0"). A driving circuit of the type shown in Fig. 2 must be connected between points A_2, B_2, and the "clockwise" and "counter-clockwise" pairs of input terminals to the second ring-of-ten, respectively.

The control grids of T_1 and T_2 are biased beyond cut-off. They are coupled by condensers to the plates of two opposite tubes, T_A and T_F, in the first ring. The screens are connected directly to the two plates of two adjacent tubes, T_C and T_D, of the first ring. T_1 can pass a pulse only when its screen is at a high potential, i.e., when tube T_C of the first ring is cut off. Similarly, T_2 can pass a pulse only when tube T_D is cut off.

Let us now assume that tubes T_A, T_B, T_C, T_D, and T_E in the first ring are conducting. Their plates are at a low potential. As the electrical pattern of the ring advances clockwise, tube T_A cuts off and tube T_F turns on. A positive pulse is fed to T_1. However, since the screen grid of T_1 is at a low potential, no pulse is transmitted. A negative pulse is fed to the grid of T_2, but negative pulses have no effect on either T_1 or T_2 because these tubes are biased beyond cut-off anyhow, no matter what their screen potential is. There is no occurrence when tube T_B shuts off next. When tube T_C cuts off, the screen grid of T_1 is raised to a high potential, so that a future positive pulse on the control grid will turn T_1 on and thus feed the second ring by one step in the counter-clockwise direction. Tube T_D turns off next. This puts T_2 in a condition to transmit a future positive pulse which arrives on its control grid. The following pulse causes T_A to conduct and T_F to cut-off. This puts a positive pulse on the control grid of T_2, which feeds the second ring by one step in the clockwise direction. As the electrical pattern continues to advance around the first ring there is no further action, except for the lowering of the screen grid potentials when tubes T_C and T_D turn on. So, for one clockwise revolution of the first ring, we have one pulse transmitted to the clockwise input of the second ring. A similar analysis shows that one pulse is fed through T_1 to the counter-clockwise input B_2 of the second ring when the first ring advances counter-clockwise by one complete revolution.

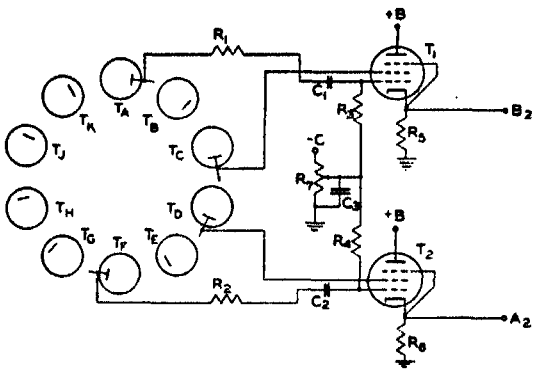

FIG. 3.

Coupling Circuit

C_1, C_2	25 μμf
C_3	4 μf, 50v
R_1, R_2	22,000 ohms, ½w
R_3, R_4	47,000 ohms, ½w
R_5, R_6	22,000 ohms, 2w
R_7	500,000 ohm pot.
T_1, T_2	6AK6
$+B$, +250v; $-C$, −20v	

A small pulse occurs at the plates of T_A and T_F when any of the other tubes in the ring change condition. The control grids of the triodes in the decade rings must be at zero bias so these pulses will not be large enough to disturb the coupling circuit.

The Measurement of the Series-Resonant Resistance of a Quartz Crystal

L. A. Rosenthal and T. A. Peterson, Jr.
Rutgers University, Dept. of Electrical Engineering, New Brunswick, New Jersey

(Received September 10, 1948)

Three instruments are described which will measure the equivalent resistance of commercial quartz crystals in the range of 80 kilocycles to 100 megacycles. Information on the theory and operation of these instruments is given. Some data are shown indicating the results to be expected.

I. INTRODUCTION

IT has long been the desire of the engineer working with crystal oscillators to have available an equivalent circuit for the crystal upon which a design could be based. Unfortunately, certain non-linearities enter the picture and make any equivalent circuit exist for but one current level and temperature. As next best substitutes, the less complex ideas of activity, figure of merit, and performance index[1] were introduced. These ideas serve their purpose in comparing crystal units, but they are all based on the equivalent circuit, in which the resistance is a particularly important parameter.

The instruments described in the following sections were used in the investigation on commercial quartz crystals of the plated and pressure mounted varieties in the frequency range of 80 kilocycles to 60 megacycles.

II. THEORY OF THE CRYSTAL AND ITS RESISTANCE MEASUREMENT

The electro-mechanical equivalent circuit for a crystal operating at any mode has been shown to consist of a series resonant motional arm in parallel with a static holder capacity as in Fig. 1a.[2] The admittance of this parallel combination can be represented as a circle diagram* (Fig. 1b). A vector joining the origin to any point on the circle represents the total admittance. Four critical points are observed on the circle diagram. These are:

a. Minimum impedance } Along the line passing through
b. Maximum impedance } the origin and center of the circle (O').
c. Series resonance-unity power factor } along the real axis.
d. Anti-resonance-unity power factor }

From simple geometry, the points we are concerned with can be expressed in terms of R_x and ωC_0.

$$\text{a.}\quad Z_{\min}=\frac{2R_x}{(1+a^2)^{\frac{1}{2}}+1}\qquad a=2R_x\omega C_0,$$

$$\text{c.}\quad R_s=\frac{2R_x}{1+(1-a^2)^{\frac{1}{2}}}.$$

The two unity power factor conditions cease to exist if "a" is greater than 1. In addition, with no crossing of the real axis, there can be no inductive component associated with the crystal and it is useless for many oscillator applications (e.g. Pierce, Miller).

For the low impedance region that we are concerned with, it is important to realize that minimum impedance and unity power factor occur at different frequencies and that the series resonant resistance for the crystal network is different from the motional arm resistance. These differences depend on the quantity "a" which is generally very small.

In order to measure the resistance, the crystal is made the controlling element of an oscillator which operates the crystal in the vicinity of the low impedance resonance. In this way the frequency stability which is associated with crystal control is maintained by the oscillator for the wide range of crystals accommodated. The test oscillator must have provisions for the measurement of the crystal impedance and a check for operation at unity power factor. Resistance can be measured by a substitution method or a calculation method, each of which is described below.

In the substitution method, a resistor is made to replace the crystal unit keeping the amplitude of oscillation, as measured by the rectified grid current, unchanged. If the frequency does not change upon the substitution of the resistor it can be further assumed that the crystal was operating in a purely resistive fashion. At this single frequency the substituted resistance is equal to the total impedance of the crystal.

In the calculation method, the voltage drop across the crystal, as well as the current through the unit, is measured. As an example, the crystal can be made the series arm of a "half T" section and a resistor the shunt arm. By measuring the input and output voltages of this network, the crystal resistance can be calculated as:

$$R_x=(V_{\text{in}}/V_{\text{out}}-1)R_1$$

where R_1 is the terminating resistance. Of course, the above equation can be applied only for a purely resistive crystal and therefore some series resonance check must be incorporated. The simplest method for the latter check is through the use of a Lissajous phase shift pattern between the input and output voltages. When these voltages are in phase, corresponding to a straight line pattern, the crystal must be purely resistive.

[2] K. S. Van Dyke, Phys. Rev. **25**, 895 (1925).

* Providing "ωC_0" is assumed to be constant.

Combinations of the above methods were used in the test oscillators described in following sections. Problems arise that may disqualify one method or the other in certain cases. The circuits finally chosen gave the most reliable results.

III. THE TEST OSCILLATORS

The low frequency crystal test set (Fig. 2) consists of a two stage tuned amplifier transformer coupled to a "pi" attenuator feedback network, of which the series arm is the crystal. It is basically a modified Heegner[3] oscillator, capable of dissipating large amounts of power in the crystal. The input and output voltages to the attenuator are measured and their relative phase angles observed by a Lissajous figure method.

To operate, a resistor is put across the crystal and the gain adjusted so that the circuit oscillates continuously over the tuning range. When passing through the crystal frequency, the crystal's low impedance shunts the resistor and opens up the phase shift pattern from that of a straight line. The resistor can then be removed, leaving the crystal alone to control the frequency of oscillation. By tuning, the crystal phase shift can be controlled so that series resonance is readily located. Various crystal currents can be obtained under this same condition by adjusting the oscillator's over-all gain. This low frequency apparatus proved to be very reliable in performance between the frequencies of 50 to 150 kilocycles. The transformer provided the chief limitation of the frequency range.

50	42	3
50	19	3
50	68	5
50	52	5
60	23	3
60	17	3
60	31	3
60	42	3
60	15	3

The medium frequency test oscillator used (Fig. 3) was a circuit developed by the Signal Corps Engineering Laboratories and known as the Crystal Impedance Meter.[4] With the proper choice of tuning inductors, crystals between 200 and 15000 kilocycles could be tested. This meter consists of a crystal in a low impedance feedback network with tuned half sections on either side for impedance matching to a pentode power amplifier. Rectified grid current and crystal current are measured. Since the substitution method is used, a calibrated variable resistance network can be made to replace the crystal unit. Series resonance exists at the point where the substitution of a resistor causes no frequency change as determined on a stable receiver.

In operation, a crystal is inserted in the feedback network and the oscillator tuned for a peak in the amplitude of oscillation as indicated by the rectified grid current. This peak is generally accompanied by a maximum of feedback current through the crystal. The crystal is now in the region of minimum impedance and quite close to series resonance for these medium frequency units. Then by a process of repeated substitution of resistance for the crystal, and retuning, a point is obtained where neither the amplitude nor frequency of oscillation change in the substitution. This value of the substituted resistance is then considered to be the series resonant resistance of the crystal. Various crystal currents can be obtained by adjusting the screen grid voltage of the amplifier tube.

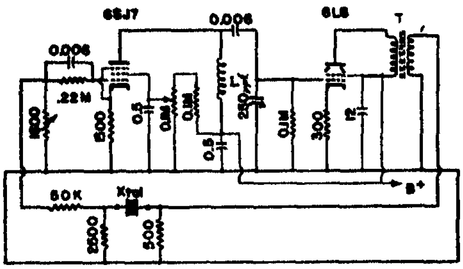

FIG. 2. Low frequency test oscillator.

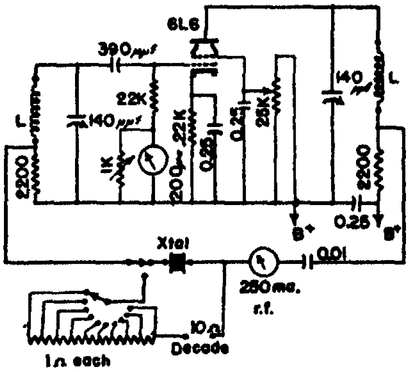

FIG. 3. Medium frequency test set.

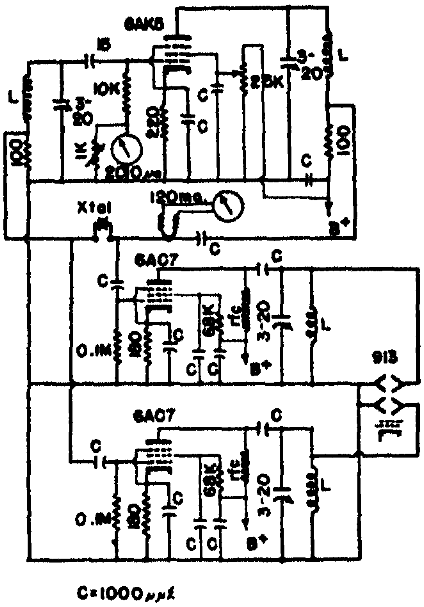

FIG. 4. High frequency test set.

The circuit used for the high frequency meter (Fig. 4) was the same as the medium frequency meter. Components have been changed to allow for differences at the high frequencies, so that the circuit will oscillate up to about 100 megacycles. However, this oscillator will tend to operate the crystal at minimum impedance if the tuning depends upon a maximum of either d.c. grid or feedback crystal current. It has been shown that minimum impedance may have more than a negligible separation from series resonance. To assist in locating series resonance, an oscilloscope with tuned amplifiers was added to indicate the phase shift across the crystal.

The operation of this combination is still simple. A crystal is made to oscillate in the meter and a receiver tuned to that frequency. A short circuit is substituted for the crystal and the meter is retuned to the crystal frequency on the receiver. The two amplifiers on the oscilloscope are then tuned for a maximum deflection which is a straight line at an angle of 45°. The crystal is now put in place of the short circuit and the oscillator is tuned for zero phase shift. By substitution of resistors the resistance of the crystal may be found, as was done with the medium frequency meter.

IV. RESULTS OBTAINED AND DISCUSSION

Some typical curves of the resistance as a function of the current level for low and medium frequency crystals are included (Figs. 5 and 6). The observed data give, firstly, an idea of the impedance level to be expected, and secondly, the variation of resistance with current level or amplitude of oscillation.

On Fig. 5 the four apparently identical low frequency units have impedance levels between 1000 and 3000 ohms. The resistance generally increases with crystal current, but may have erratic variations. The non-linearities that are present in many units can probably be ascribed to the coupling of extraneous modes into the fundamental response. The effect of these parasitic modes will vary with the temperature of the quartz and may increase the resistance by as much as 500 percent.[5] The disturbing fact is that these modes are unpredictable

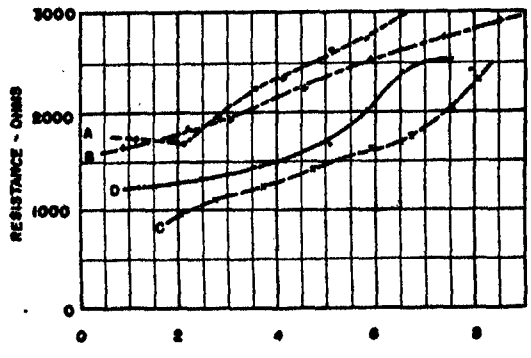

FIG. 5. Crystal resistance *vs.* current for low frequency units. Four crystals "*DT*" cut at 81.94 kc.

[5] Armour Res. Found., *Parasitic Vibrations in Quartz Oscillator Plates*, Report No. 11, July, 1947.

among the usual commercial units as shown by these four units of the same cut, frequency, and manufacturer.

The medium frequency units were all "*AT*" or "*BT*" cuts (Fig. 6). The resistance is more uniform at low current levels, but at higher levels may rise very rapidly.

The high frequency units which were tested were of the harmonic mode shear type. A table of some observed resistances at a level of 50 milliamperes is included.

ACKNOWLEDGMENTS

The results presented in this paper were obtained under the Signal Corps Engineering Laboratories Contract No. W36-039 sc 32081. Our thanks are extended to the Frequency Control Branch which furnished much of the equipment and all of the crystals tested.

THE REVIEW OF SCIENTIFIC INSTRUMENTS VOLUME 20, NUMBER 6 JUNE, 1949

A New High Sensitivity Remanent Magnetometer

ELLIS A. JOHNSON, THOMAS MURPHY, AND P. F. MICHELSEN
Carnegie Institution of Washington, Washington, D. C.

(Received March 8, 1949)

The remanent magnetometer, sturdily constructed for use in a mobile field laboratory, is capable of measuring magnetic moments of rocks as small as 2×10^{-8} c.g.s. unit per cc. A sample of rock of 25- to 50-cc volume is rotated over a pick-up coil at 10 cycles per second, and the induced alternating voltage, after amplification, is measured in both intensity and phase, and the direction and intensity of magnetization determined. The apparatus is calibrated with a needle-magnet of known magnetic moment. It has been used successfully in measurements of polarization of the glacial clays of New England and sedimentary rocks of the western states.

INTRODUCTION

IN September, 1938, one of us[1] published a description of an apparatus designed to measure small magnetic moments such as those encountered in samples of a few cubic centimeters of magnetically polarized clay or rock. This apparatus was found generally satisfactory in the course of a long series of measurements, but some disadvantages were encountered in its use which it was hoped could be avoided when constructing another unit. The synchronous commutator detector was in constant need of attention and adjustment and did not operate satisfactorily over long periods. It was planned to eliminate this unit in any new design.

Furthermore, the apparatus was not sturdy enough to withstand the effects of transportation to a working site in the field, and samples were brought from the field to the laboratory. This procedure was not above criticism for, in the course of handling and transportation, clay or rock specimens would be subjected to shocks and heavy vibrations, and might be exposed to magnetizing fields. Finally, the small sample utilized, a 1.5-cm cube, was difficult and laborious to make, so that a finished sample might easily differ considerably in both size and shape from what was specified.

With these points in mind, it was concluded that further work required a more sturdy apparatus which would need minimum maintenance, and be able to operate for long periods out of range of a laboratory. Greater sensitivity in the new apparatus was desirable. The apparatus described here, while modeled on the old one, fully satisfies the requirements just outlined, and incorporates as well recent improvements in electronic components and techniques.

The old apparatus was used in the laboratory from 1937 to 1939 for measurements of the magnetic polarizations of glacial clays deposited in Connecticut about 20,000 years ago, and of ocean bottom sediments from the North Atlantic, probably dating back 400,000 years. Both clays and ocean sediments

---

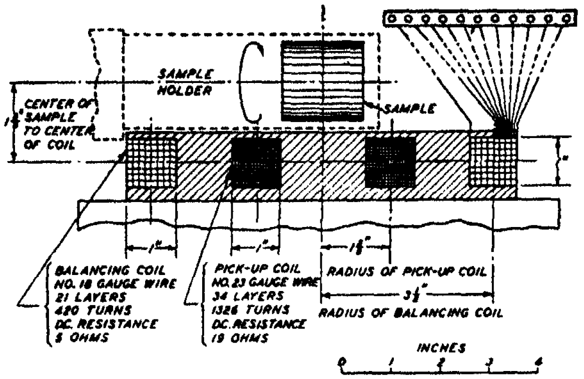

FIG. 1. Pick-up coil.

showed slow and restricted variations with time in the direction of the horizontal component of magnetization (the component corresponding to declination of the earth's magnetic field).[2]

The apparatus described in the present paper was used in New England in 1947 for the measurement of the polarization of 5000 years of deposition of glacial clay[3] and in the western United States in 1948 for measurements on sedimentary rocks ranging in age from 10 million to 150 million years.[4]

The new apparatus has also been used to measure the magnetic moments of very thin films of iron, down to 10^{-7} mm, in an attempt to verify Kittel's[5] theory that very thin films should act as single domains. Preliminary measurements indicate that this is indeed the case, since the moments of films ranging from 10^{-7} to 10^{-4} mm appear to have a natural and constant value per cm of thickness and cannot be demagnetized.

MECHANICAL PARTS

As in the old apparatus, the sample of clay or rock is rotated at the end of a shaft, over a system of coils in which it induces a small alternating voltage. The voltage after amplification is measured both in intensity and phase, and from the results the magnetization of the sample can be deduced.

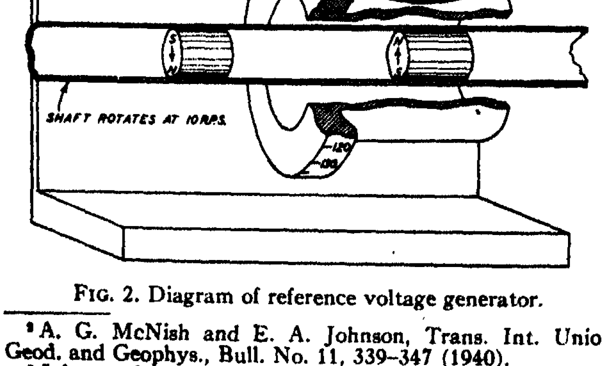

FIG. 2. Diagram of reference voltage generator.

The original theory and design appears to be satisfactory with respect to design parameters. Attempts were made to improve sensitivity using balanced coils on an iron core. These failed because of the critical requirements for shaped pole pieces, and the considerable phase distortion and increased 60-cycle pick-up in the iron-cored detectors.

A shaft consisting of a tube of dural one inch in diameter and four feet long is supported horizontally in bronze sleeve bearings, on massive mounts fixed to the heavy base of the apparatus. The shaft is driven at one end, through a reduction gear, by a standard synchronous motor, and rotates at ten revolutions per second. The motor is shock-mounted on the base and connected to the shaft by a flexible coupling. The base of the apparatus consists of two 4-inch I-beams of dural six feet long, bolted to dural sheet ½ inch thick and one foot wide. On the end of the shaft remote from the motor, any one of a variety of holders, all constructed entirely of a plastic material, can be attached in which to mount the sample under investigation. The pick-up coil system is attached to the base immediately below the sample holder. A large aluminum box, with walls ½ inch thick, which helps to shield the coil and sample holder electrically and also to prevent their being damaged, completely encases the coil and the end of the shaft. Other subsidiary devices necessary for the measurements are attached to the base, but these will be dealt with later. All parts of the apparatus except the motor and the magnets (described later) are constructed of non-magnetic materials.

PICK-UP COIL SYSTEM

Johnson,[1] in the paper cited earlier, described the design of coil systems suitable for his early apparatus; now, however, the development of 10-cycle transformers with a step-up ratio of 275 has reduced the number of turns required on the pick-up coils. The new system, like the old, consists of two coils as shown in Fig. 1. The main coil has 1326 turns, with a mean diameter of 2¾ inches, and the total number of turns on the outer, or "balancing" coil, is 420, the mean diameter being seven inches. The balancing coil has taps taken off at close intervals to permit fine adjustment, and the leads from the two coils are joined in opposition. The number of turns on the outer coil was determined by trial and error, the number being varied until a signal voltage of less than 0.001 volt resulted when the complete system was placed in a uniform 60-cycle a.c. field of 2 oersted, a field very much bigger than one would expect to encounter. The coils are wound on

FIG. 3. Circuit diagram of remanent magnetometer.

a massive form of clear plastic which is bolted rigidly to the longitudinal I-beams of the base.

REFERENCE VOLTAGE GENERATOR

The phase of the signal voltage is measured by an electronic wattmeter. This requires a synchronous generator of variable phase and low noise, and a permanent magnet generator is used for this purpose, as shown in Fig. 2. The magnet of the generator is a cylindrical alnico magnet 0.75 inch long and 0.9 inch diameter, magnetized to saturation along a diametric plane, which is inserted in the shaft near the motor end. The generator coil has 1700 turns and is mounted on a clear plastic drum. The drum, which can be rotated by hand, is coaxial with the shaft and carries a graduated circle, the zero of which can be adjusted. In operation, the magnet rotating with the shaft acts as a line of dipoles of infinitesimal size and induces in the coil a signal of very pure wave form. When the drum carrying the coil is rotated, the phase of the signal is changed, the amount of change being read off on the circle. This signal is referred to in later discussion as the "reference voltage."

The rotating magnet also induces a parasitic voltage in the main pick-up coil and this is balanced out by magnetic and electrical means. First, another similar magnet is inserted in the shaft close to the original one but antiparallel to it. A third and much smaller magnet is mounted nearer the motor at the end of the shaft and, by adjusting its distance and orientation, it is possible to compensate for the signal produced by the magnets, the motor, and the traces of magnetic material in the shaft and components, and reduce the effect to a quite small value, equivalent to a moment of 2×10^{-5} c.g.s. unit at the center of the sample holder. This "residual signal" does not stay constant but varies within small limits, due possibly to temperature differences between the compensating magnets. To eliminate the "residual," resort is had to electrical means. A second generator, very similar to the first, is made by installing a small coil near the second balancing cylindrical magnet. The current from this coil is fed through an attenuator to a small coil located beneath the main pick-up coil, as shown in the circuit diagram of the whole apparatus in Fig. 3. By varying the phase and intensity of the signal from this compensating generator, it is possible, with surprising ease, to reduce the "residual" below the limits of measurement of the detecting apparatus.

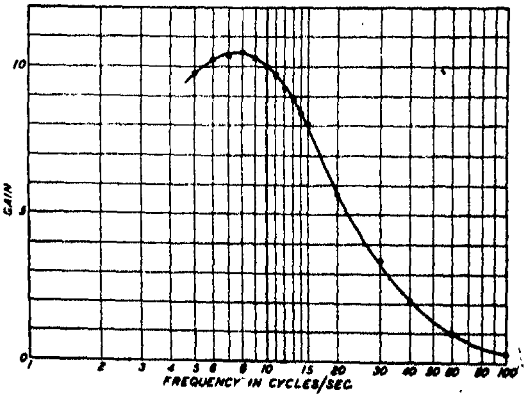

FIG. 4. Frequency response of unit amplifier.

AMPLIFIERS

The main pick-up coil is coupled to the amplifiers by a transformer. This is of a special type made by the United Transformer Company for use at frequencies between 5 and 100 cycles per second. It is made to match impedances of 10 and 750,000 ohms. The turns' ratio is 275/1. A small capacitor is joined across the output terminals, acting as a filter for frequencies higher than 10.

The amplifier is constructed in eight units, the units being almost identical. Each unit amplifier has a high gain pentode (6SJ7) operating with about two percent feedback, and an *R–C* filter network. The values of the impedances and the feedback are so chosen that the over-all gain per stage is ten at ten cycles per second, the final adjustment being obtained by changing the value of the cathode resistor within narrow limits.

Each of the first six of the unit stages has at its terminal a pair of resistors with values in the ratio of 9 to 1. A relay-operated switch connects the grid of the tube of the next unit stage across one or both of these resistors to provide either one of two gains, ten or one. The seventh stage has ten equal resistors at its terminal, to provide any unit gain from one to ten. The eighth stage always operates at a gain of ten.

By means of two controls, one operating the switches between stages, the other the ten-position potentiometer of the seventh stage, it is possible to choose the over-all gain of the amplifier in a range of values from 10 to 10^7. All the stages are always in operation.

The filter network serves several purposes. It discriminates strongly against 60-cycle signals arising from large 60-cycle gradients, and it decreases the band width, which prevents overloading of the final stages by noise when the amplifier is used at high gain. It also filters out undesired harmonics. Figure 4 shows the frequency discrimination for each stage.

The negative feedback stabilizes each stage so that it is independent of large changes in plate and filament supply. The gain of each stage is found to stay constant within one percent over long periods.

The grid bias on the tubes in each stage except the last one is approximately one volt. In the last stage it is 1.8 volts. The impedances in the plate circuit are so chosen that no damage can result if any stage is accidentally overloaded.

The over-all frequency response of the apparatus, including the coils, transformer, amplifiers, output stage, and voltmeter, is given in Fig. 5. The band width measures 6.5 cycles. The peak occurs at 7 cycles and is the result of trying to achieve a narrow band width and a large discrimination against 60 cycles at the same time, without too elaborate a filter and too much loss in gain. The first tube was chosen for low flicker noise. The measured noise at ten cycles is about twice the thermal noise in the first grid circuit.

POWER SUPPLY

Power for the amplifiers and the remainder of the electronic equipment is obtained from the 60-cycle commercial power circuits or from a 60-cycle portable generator. One regulated 300-volt d.c. power pack provides a "*B*" supply for the first six amplifier stages, each stage incorporating its own decoupling circuit. The other two stages and equipment are fed from a similar power pack. In the remaining parts of the circuit, a constant-voltage "*A*" supply is necessary, so the complete filament supply comes from a regulated d.c. power pack of variable voltage. The voltage is about 6.2 volts. The amplifiers will operate quite well with no noticeable increase in noise if a 6.3-a.c. voltage is used in the filament circuits instead of a d.c. supply.

INTENSITY MEASUREMENT

The signal picked up by the coil is amplified at a chosen gain value until the output voltage of the amplifier lies between two and eight volts, as read from a meter on the instrument panel. A cathode follower is used in an output stage and the signal, split into two parts, is fed into the remainder of the circuit. For the intensity measurement, one part is measured in a vacuum-tube voltmeter circuit, which uses germanium diodes for rectification and has a period of four seconds.

The intensity meter reading in volts is readily converted to intensity of magnetization when the apparatus is calibrated. Calibrating is done with a small alnico magnet embedded in a piece of plastic of the same size and shape as the specimen. The magnetic moment of this magnet, of the order of 1 c.g.s. unit, is known from magnetometer readings. Since the gain of the amplifier is known, moments within the range from 10^{-6} c.g.s. to 20 c.g.s. units can be measured easily in absolute magnitude to an accuracy of a few percent.

DIRECTION OF MAGNETIZATION

The direction of magnetization is determined by measuring the phase of the amplified signal with respect to an arbitrary zero. The arbitrary zero is chosen along one side of the cubical specimen. To measure phase the signal voltage is compared to the reference voltage, the latter amplified to eight volts to approximately equal the signal voltage, in an electronic wattmeter using a ring modulator circuit. The d.c. output of the ring circuit, amplified in a d.c. amplifier having a time constant of four seconds, operates a meter with a central zero on the instrument panel. The phase of the reference voltage is varied until the meter reading is zero. In this position, the two voltages differ in phase by $\pi/2$ and hence, by geometry, the direction of magnetization in the sample can be obtained.

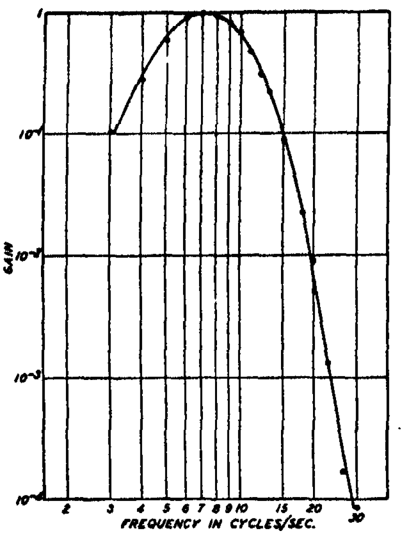

FIG. 5. Frequency response of remanent magnetometer.

The particular advantage of the wattmeter is that it acts as a very narrow band detector. Even when the signal is of the same order as the noise of the first tube, the wattmeter responds, on the average, only to the steady 10-cycle component and is relatively unaffected by the noise, which, although it has the same frequency, has random and rapid changes of phase. It is possible therefore to measure the phase of signals whose intensity is about one-tenth that of the thermal noise in the grid of the first tube. Furthermore, for such weak signals, by changing the phase of the reference voltage until it agrees with that of the weak signal, the bridge circuit measures intensity. Voltages as low as 8×10^{-11} volt can be detected in the pick-up coil circuit by this means. This corresponds to a rotating moment in the specimen holder of 5×10^{-7} c.g.s. unit.

FIELD EQUIPMENT

The complete equipment is solidly constructed and installed in a large "six by six" Army truck. The electronic equipment is mounted in a relay rack which is shock-mounted from the truck body.

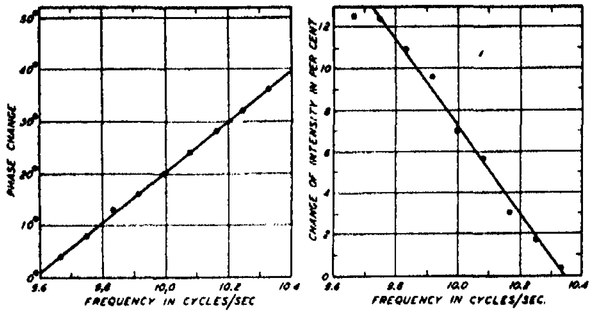

Fig. 6. Change of phase and of intensity with frequency of remanent magnetometer.

The rotary apparatus is mounted on a heavy wooden table-top with a thin layer of rubber between to allow some relative movement. The table-top is rigidly fastened to the truck body. All the metallic parts of the equipment are joined electrically together through the screening in the connecting cables. A separate ground system for the electronic equipment is used, and this is joined to the outside screen at only one place, namely, at the cathode of the first tube. No outside ground is used and has never been found necessary either in the laboratory or in the field.

METHOD OF MEASUREMENT

The samples used in the apparatus are of two kinds, cylinders and cubes. When working with clay, the sample is taken by inserting a cylindrical cup of bakelite bonded paper directly into the clay bank. Suitable means of recording the orientation are used. The cup holding the sample fits directly into the specimen holder. The sample so taken measures 1½ inches long and 1½ inches in diameter. Rock samples 1⅝ inches in diameter are taken with a diamond coring tool and cut with diamond-impregnated saws to 1⅝ inches in length. These cylindrical samples fit into the holder of the apparatus exactly like the cups of clay. Using cylinders, the direction and intensity of magnetization can be measured in only one plane which is sufficient in some cases. For a complete evaluation of the magnetization, the cylinders are cut into cubes 3 cm on a side. These specimens are measured in the apparatus by rotating on the three different axes. Computation gives the intensity, but the direction is usually plotted on a stereographic net. The volumes of the clay and rock cylinders are approximately 40 and 50 cc, respectively, as compared with 27 cc for the cubes.

The chief source of error in the apparatus is in the use of a synchronous motor to drive the shaft. As the frequency of the power supply varies, so does the frequency of the signal induced in the coil. The amplifiers are tuned quite sharply and a small change in frequency produces a moderate change in intensity of the amplified signal and a large change in phase. Figure 6 shows this effect.

A frequency meter with a range of 58 to 62 cycles per second is used to measure the frequency of the power supply and to indicate any sudden changes. In practice, whenever the power frequency fluctuates more than 0.1 cycle per second over a few minutes while measurements are being made, the small standardizing magnet is used at frequent intervals to check the phase and intensity readings. The portable power supply is used in the field and is fitted with a frequency control. Although its frequency fluctuates rather rapidly over a range of 0.3 cycle per second, the average stays fairly constant and the resultant effect is to increase the over-all noise in the apparatus slightly. However, in work so far undertaken, any error attributable to this cause has been much smaller than the other experimental errors encountered and no remedial changes have been considered necessary.

It has been found that the apparatus is capable of measuring magnetic moments in the range from 20 to 10^{-4} c.g.s. unit to an accuracy of two percent in intensity and to within 0.2° in direction. In the range 10^{-4} to 10^{-5} the intensity can be measured within three percent and the direction within 2°. For values less than 10^{-5} c.g.s. the intensity is probably accurate to 10 percent and the direction to 5°. The value of 2×10^{-6} c.g.s. unit is looked on as the practical limit of measurement; below this value traces of impurities and inhomogeneities in the sample are thought to play a big role, and external electrostatic effects on the specimen and the specimen holder become prominent. The smallest moment which is detectable is 5×10^{-7} c.g.s. unit which corresponds to about 2×10^{-8} c.g.s. unit per cc of sample. When the humidity is very low the plastic sample holder collects large electrostatic charges and the pick-up coil must be electrostatically shielded from the holder if the limit of measurement is to be reached.

Effect of Temperature on the Steady-State Sensitivity of Vacuum Radiation Detectors

I. AMDUR AND N. L. BROWN
Department of Chemistry, Massachusetts Institute of Technology, Cambridge, Massachusetts

(Received March 28, 1949)

The steady-state sensitivities of two vacuum radiation thermocouples of very different design and a vacuum compensated bolometer have been measured at 298°, 205°, and 96°K, and the effect of temperature has been found to vary widely for the three detectors. The observed results have been accounted for quantitatively in terms of theoretical sensitivity relations which are based on exact heat flow theory and take into account the specific structural characteristics of the detectors. The treatment is sufficiently general to permit the prediction of steady-state sensitivities as a function of temperature for any vacuum radiation thermocouple or bolometer whose structural characteristics are known.

THE temperature dependence of the steady-state sensitivity of a vacuum radiation detector, such as a radiation thermocouple or a bolometer, does not seem to have been systematically investigated although occasional experiments have been performed near liquid air temperature.[1] These particular experiments showed a greatly enhanced sensitivity at the low temperature for the specific detectors which were used, and, as a result, it is frequently assumed that the steady-state sensitivity of all types of detectors may be expected to increase rapidly with decreasing temperature.[2] Since this is not universally true, it seems desirable to study carefully the temperature dependence of radiation detectors of widely different design, and to attempt to correlate the results with theoretical predictions based on heat flow equations appropriate to the various detectors.

THEORETICAL

Since experimental results were obtained for two radiation thermocouples (of very different design) as well as for a compensated bolometer, it is necessary to derive sensitivity relations for both types of detectors, whose important features may be summarized as follows:

I. Radiation thermocouples

A. Detector with very large receiver area (detector A)

This thermocouple contains a circular platinum receiver, 0.279 cm in diameter, blackened with Aquadag on its upper surface and tinned with solder on its under surface. The receiver is fastened to two constantan wires (one of which serves only as a support), 0.0013 cm in diameter, and to a Chromel *P* wire, 0.0015 cm in diameter, which are symmetrically spaced, 120° apart, and mounted so that the electrical length of each wire, 0.257 cm, is greater than its thermal length, 0.178 cm. A previous description[3] of this detector gives complete structural details and shows the reason for assigning different lengths to the wires for purposes of estimating electrical resistance as compared with thermal resistance.

B. Detector with very small receiver area (detector B)

This thermocouple was made by using a condenser discharge to butt weld a 0.0013 cm diameter constantan wire, 0.318 cm long, to a 0.0015 cm diameter Chromel *P* wire, 0.318 cm long. No receiver is attached to the welded wires which are merely covered with a coating of Aquadag (thereby increasing the diameters to 0.00164 cm and 0.00184 cm, respectively) and mounted so that the thermal and electrical lengths are the same, namely, 0.318 cm. Additional structural details for this detector appear elsewhere.[4]

II. Compensated bolometer (detector *C*)

The bolometer has a detector element consisting of an Aquadag covered platinum wire, 5.6×10^{-4} cm in diameter (diameter of wire core $=2.74\times10^{-4}$ cm) and 0.476 cm long, which, like the welded thermocouple, acts as its own receiver. A bolometer of this type has also been described previously.[5]

The temperature rise experienced by a radiation thermocouple is usually so small (less than 0.05 degree) that it is not necessary, in considering the effect of ambient temperature, to distinguish between the temperature of the cold junction (assumed to be equal to that of the surroundings) and the average temperature of the entire thermocouple. This is not the case for a bolometer whose heating current may cause temperature differences as high as 100° between the midpoint and ends, so that a true average temperature must be used in deriving the sensitivity relation. In order, therefore, to use

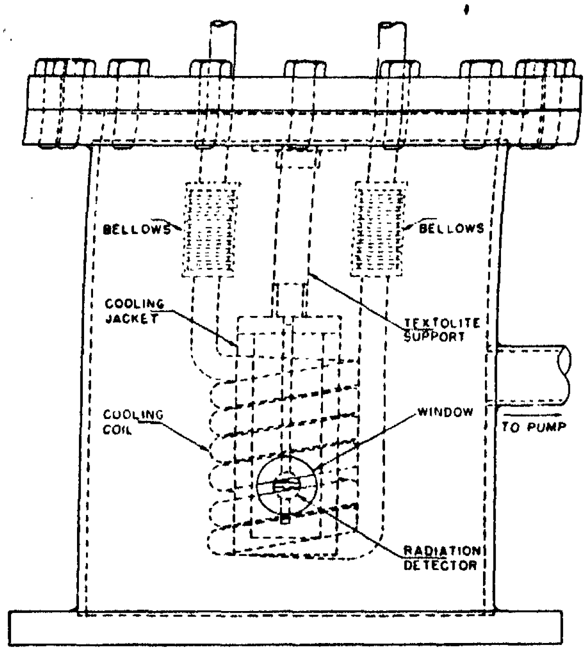

FIG. 1. Vacuum chamber.

a minimum number of symbols, temperatures and temperature differences, averaged over the active receiver area of the detector, will be used for the radiation thermocouples as well as for the bolometer.

The derivation of the sensitivity equation for a radiation thermocouple of the type of detector *A* is very similar to that given by Cartwright[6] and, in view of its brevity, is repeated as an effective method of indicating the basic assumptions involved in arriving at the final relation. The symbols which will be used are as follows:

E = power absorption by thermocouple
E_r = power loss by radiation
E_c = power loss by wire conduction
E_p = power loss by Peltier-heat effect
σ = Stefan-Boltzmann radiation constant
S = radiating surface of thermocouple
$\langle T\rangle_{\text{Av}}$ = average absolute temperature of receiver
ϵ = emissivity of radiating surface
$\langle \Delta t\rangle_{\text{Av}}$ = average temperature difference between receiver and cold junction
K_1 = thermal conductivity of constantan at $\langle T\rangle_{\text{Av}}$
K_2 = thermal conductivity of Chromel *P* at $\langle T\rangle_{\text{Av}}$
r_1 = radius of constantan wire
r_2 = radius of Chromel *P* wire
l = thermal length of constantan or Chromel *P* wire
P = thermoelectric power of thermocouple at $\langle T\rangle_{\text{Av}}$
i_g = current through galvanometer
V = emf developed by thermocouple
G = resistance of galvanometer
R = resistance of thermocouple at $\langle T\rangle_{\text{Av}} = \rho_1 L/(\pi r_1^2) + \rho_2 L/(\pi r_2^2)$
ρ_1 = resistivity of constantan at $\langle T\rangle_{\text{Av}}$
ρ_2 = resistivity of Chromel *P* at $\langle T\rangle_{\text{Av}}$
L = electrical length of constantan or Chromel *P* wire

When steady-state conditions are reached, the power lost by the thermocouple through radiation, wire conduction, and Peltier-heat effect, becomes equal to the power which it absorbs, so that

$$E = E_r + E_c + E_p \tag{1}$$

where

$$E_r = 4\sigma S\langle T\rangle_{\text{Av}}^3 \epsilon \langle \Delta t\rangle_{\text{Av}} \tag{2}$$

$$E_c = (2K_1\pi r_1^2/l + K_2\pi r_2^2/l)\langle \Delta t\rangle_{\text{Av}} \tag{3}$$

and

$$E_p = P i_g \langle T\rangle_{\text{Av}}. \tag{4}$$

Since the e.m.f. developed by the thermocouple, connected directly across the galvanometer terminals, is

$$V = i_g(G+R) = P\langle \Delta t\rangle_{\text{Av}}, \tag{5}$$

the galvanometer current may be written

$$i_g = P\langle \Delta t\rangle_{\text{Av}}/(G+R) \tag{6}$$

and the sensitivity as defined by Cartwright, namely,

$$Q = i_g(G+R)^{\frac{1}{2}}/E, \tag{7}$$

becomes

$$Q = \frac{P}{(G+R)^{\frac{1}{2}}}\left[4\sigma S\langle T\rangle_{\text{Av}}^3\epsilon + 2K_1\pi r_1^2/l + K_2\pi r_2^2/l + \frac{P^2\langle T\rangle_{\text{Av}}}{G+R}\right]^{-1}. \tag{8}$$

For detector *B*, the relation for *Q* is somewhat different, because the absorbed power, instead of

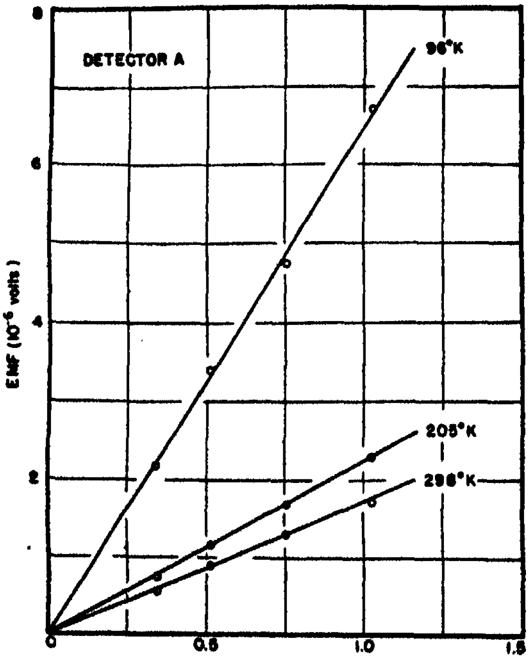

FIG. 2. Response of radiation thermocouple with large receiver area.

---

[6] C. H. Cartwright, Zeits. f. Physik 92, 153 (1934).

being concentrated on a central receiver of essentially uniform temperature, is distributed over the entire length of the detector wires. The heat flow equations for the latter case are the same as those for an electrically heated wire, heat stationed at the ends, and have been considered in connection with the theory of the steady-state sensitivity of a vacuum bolometer.[5] Application of the bolometer results to detector B results in replacing Eq. (3) by

$$E_c=(1+1.1\times10^{-9}\langle T\rangle_{Av}^3)(3K_1\pi r_1^2/l+3K_2\pi r_2^2/l)\langle\Delta t\rangle_{Av}\quad(9)$$

where $(1+1.1\times10^{-9}\langle T\rangle_{Av}^3)$ is a small correction term resulting from the loss of a small fraction of absorbed power by radiation. Since, in the present

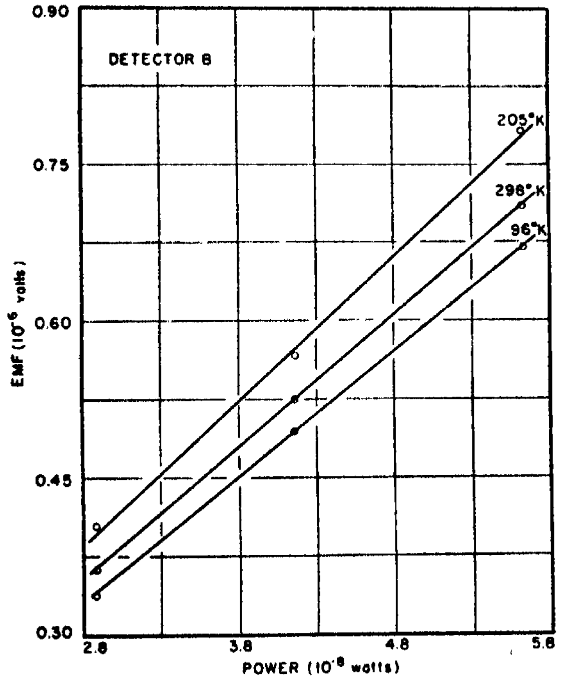

FIG. 3. Response of radiation thermocouple with small receiver area.

application, this correction has a maximum value of only 3 percent at room temperature, it is given in the above form, specific for detector B, rather than in its general form. Substitution of numerical values into Eq. (9) reveals that the power lost by wire conduction is nearly equally divided between the two wires. The junction of these wires, therefore, will have a maximum temperature difference, $\langle\Delta t\rangle_{\max}$, which, for the present case where radiation losses are small, has the following relation to the average temperature difference, $\langle\Delta t\rangle_{Av}$,

$$\langle\Delta t\rangle_{\max}=1.5\langle\Delta t\rangle_{Av}.\quad(10)$$

Equation (5) must therefore be replaced by

$$V=i_s(G+R)=P\langle\Delta t\rangle_{\max}=1.5P\langle\Delta t\rangle_{Av}\quad(11)$$

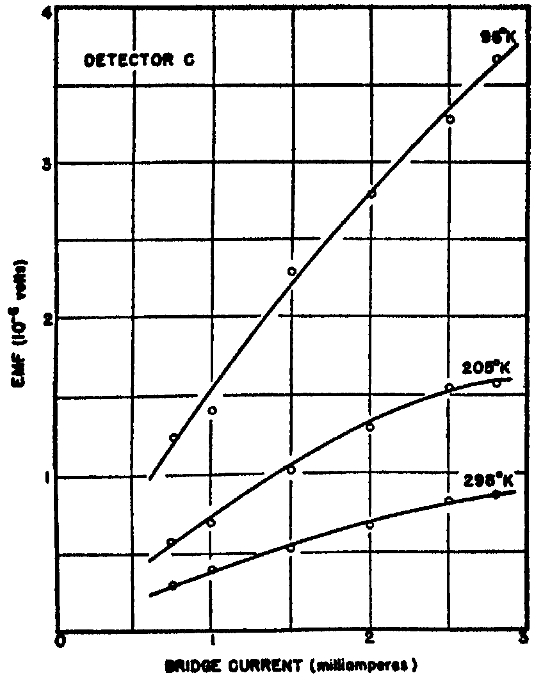

FIG. 4. Response of bolometer.

and the sensitivity equation appropriate to detector B becomes

$$Q=\frac{1.5P}{(G+R)^{\frac{1}{2}}}\bigg[4\sigma S\langle T\rangle_{Av}^3\epsilon+(1+1.1\times10^{-9}\langle T\rangle_{Av}^3)\times(3K_1\pi r_1^2/l+3K_2\pi r_2^2/l)+\frac{1.5P^2\langle T\rangle_{Av}}{G+R}\bigg]^{-1}.\quad(12)$$

The sensitivity equation for a compensated bolometer contains many of the symbols already listed, except that the subscripts 1 and 2 are not used with K, r, or ρ, since the sensitive element of the bolometer is a single platinum wire whose thermal and electrical lengths are equal. Additional symbols which appear are:

α = temperature coefficient of resistance of bolometer and of compensator
T_0 = absolute temperature of surroundings and of ends of bolometer
R_0 = resistance of bolometer and of compensator at T_0 $=\rho_0 l/(\pi r^2)$
ρ_0 = resistivity of bolometer at T_0
K_0 = thermal conductivity of bolometer and of compensator at T_0
N = resistance of each of manganin resistors in Wheatstone network
r' = radius of bolometer including blackening

The expression for Q for a compensated vacuum bolometer, in the type of Wheatstone network used in the present experiments, has been previously derived[5] and has the form

$$Q=\frac{\alpha R_0(G+R)^{\frac{1}{2}}}{R^{\frac{1}{2}}(R+N+2G)}\frac{\left[4\sigma S\epsilon\langle T\rangle_{\mathrm{Av}}{}^3\langle\Delta t\rangle_{\mathrm{Av}}+\frac{12}{l}K_0\pi r^2\langle\Delta t\rangle_{\mathrm{Av}}(m+n\langle\Delta t\rangle_{\mathrm{Av}})\right]^{\frac{1}{2}}}{\left\{4\sigma S\epsilon(\langle T\rangle_{\mathrm{Av}}{}^3+3\langle T\rangle_{\mathrm{Av}}{}^2\langle\Delta t\rangle_{\mathrm{Av}})+\frac{12}{l}K_0\pi r^2(m+2n\langle\Delta t\rangle_{\mathrm{Av}})+\frac{\alpha R_0}{R+N+2G}\left[4\sigma S\epsilon\langle T\rangle_{\mathrm{Av}}{}^3\langle\Delta t\rangle_{\mathrm{Av}}+\frac{12}{l}K_0\pi r^2\langle\Delta t\rangle_{\mathrm{Av}}(m+n\langle\Delta t\rangle_{\mathrm{Av}})\right]\right\}} \tag{13}$$

where

$$m=1+\frac{2\epsilon\sigma r'T_0{}^3l^2}{15r^2K}\quad\text{and}\quad n=\frac{2\epsilon\sigma r'T_0{}^2l^2}{5r^2K}-\frac{\alpha}{5}.$$

To the first order of small quantities, Eq. (13) is valid for both positive and negative differences between radiation loss and self-heating due to the increase of wire resistance with temperature, although the original derivation assumed that the difference was positive (which is usually the case at room temperature or higher). The general applicability of the end result is due to relationships between hyperbolic trigonometric and circular trigonometric functions which appear in solutions of the second order differential heat flow equations for the two cases. The original derivation should be consulted for the basic assumptions and for a description of the procedure for calculating theoretical values of Q.

EXPERIMENTAL

Each detector was suspended inside a cylindrical copper cooling jacket, 1 inch I.D., 1¼ inch O.D., and 3$\frac{9}{16}$ inch long, which was slotted to permit radiation to strike the receiver surface. Refrigerant (acetone at dry ice temperature or liquid nitrogen) was circulated through ⅜-inch copper tubing coiled around and soldered to the cylinder which was supported and thermally insulated from the cover of a metal vacuum chamber (6 inch O.D. and 8 inch high) by a Textolite rod and Adnic (high thermal resistance alloy) bellows. Two copper-constantan thermocouples, one soldered to the bottom of the cooling jacket, and the other, to the detector case, emerged, together with the detector leads, through metal-glass seals in the vacuum chamber cover. National Bureau of Standards carbon filament lamps were used as sources of radiation which entered the vacuum chamber through a plane Pyrex window (calibrated for transmission and reflection) sealed to a copper-glass Housekeeper seal in the chamber wall.

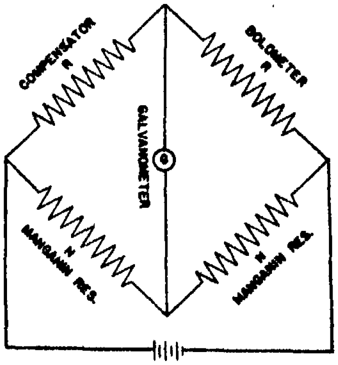

FIG. 5. Wheatstone bridge network.

The essential features of the cooling jacket and vacuum chamber are shown in Fig. 1. All surfaces inside the vacuum chamber were blackened to reduce scattered radiation.

At the lower temperatures, refrigerant was circulated through the coil of the cooling jacket in the presence of about 1 cm of helium to improve heat conduction between the radiation detector and the surrounding cylinder. After temperature equilibrium had been reached, the pressure was reduced to 10^{-5} mm or lower for the duration of the runs, during which circulation of refrigerant was continued to prevent temperature rise resulting from radiation and heat leak through supports and lead wires. Responses of the detectors were measured with a special potentiometer using a galvanometer amplification device[7] as in previous experiments.[5, 6]

Detector A was irradiated with a standard lamp which had been calibrated at four currents, and detector B, with a lamp which had been calibrated at three currents. The bolometer, detector C, was irradiated with a single power density at six different Wheatstone bridge currents. The experimental results are shown in Figs. 2–4, where the temperatures are those corresponding to the readings of the copper-constantan thermocouple fastened to the detector case inside the cooling jacket. The ordinates in Figs. 2 and 3 are the open circuit potentials developed by the radiation thermocouples, and the abscissas, the powers absorbed by the detector receivers. For detector A this power is given by

$$E=\gamma E_a\pi(r')^2 \tag{14}$$

---

[7] I. Amdur and H. Pearlman, Rev. Sci. Inst. 9, 194 (1938).

where: γ, the absorptivity of the Aquadag surface, is taken as 0.67, independent of temperature, for all lamp currents; E_a, the power density reaching the receiver, is known from the National Bureau of Standards lamp calibration and the window transmission (0.839 to 0.763 for lamp currents between 0.400 and 0.250 amperes); and r', the radius of the hole in a mask above the receiver is 0.0813 cm. For detector B the absorbed power is

$$E=\gamma E_a 2(r_1'+r_2')l \qquad (15)$$

where l, the length of the constantan or Chromel P wire, is 0.318 cm; and r_1' and r_2', the radii of the constantan and Chromel P wires (including the Aquadag coating) are 8.2×10^{-4} and 9.2×10^{-4} cm, respectively. The ordinate in Fig. 4 is the open circuit potential produced upon irradiation as measured by connecting the galvanometer leads in Fig. 5 to the special potentiometer. (Figure 5 shows the circuit corresponding to the definition of Q in Eq. (7).) The abscissa is the total network current, of which a known fraction passes through the bolometer. The constant power, E, absorbed by the bolometer was 1.15×10^{-8} watt corresponding to values of 0.67, 64.4×10^{-6} watt/cm², 2.8×10^{-4} cm, and 0.476 cm, respectively, for, γ, E_a, r', and l in the relation

$$E=\gamma E_a 2r'l. \qquad (16)$$

DISCUSSION

Figures 2 and 3 show extremely different characteristics for detectors A and B whose important difference is the absence of a relatively large receiver in detector B. The slopes of the straight lines define one type of sensitivity, S^*, namely the open circuit potential produced upon absorption of unit radiant power. For detector A, decreasing temperature increases this sensitivity markedly, the values being 1.70, 2.23, and 6.48 volts/watt at 298°, 205°, and 96°K, respectively, whereas detector B exhibits very little effect as shown by sensitivity values of 12.6, 13.8, and 11.8 volts/watt at the same respective temperatures. In the case of the bolometer, detector C, the experimental potentials are directly proportional to the sensitivity, S^*, at any bridge current since the absorbed power was constant at 1.15×10^{-8} watt. At low values of the bridge current, there is relatively little effect of temperature on sensitivity (in fact, as the current approaches zero, the sensitivity approaches zero at any temperature). As the temperature of the bolometer wire is raised by increasing the bridge current, the temperature effect on the sensitivity becomes very marked as shown by values of 74.7, 135, and 319 volts/watt for a bridge current of 2.80 ma at 298°, 205°, and 96°K, respectively. Except for the very large difference in absolute values, the change of sensitivity with temperature for detector C parallels that of detector A. It is the primary purpose of this paper to show that the widely different results which have been observed are sufficiently in accord with theory to permit a reasonably accurate prediction of the effect of temperature upon the sensitivity of a radiation detector of known structural characteristics.

TABLE I. Parameters and constants for calculating Q for detectors A and B.

A. Temperature independent values.

	Detector A	Detector B
σ, watts/deg.⁴-cm²	5.74×10^{-12}	5.74×10^{-12}
S, cm²	0.127	3.48×10^{-3}
ϵ	$0.55=\frac{1}{2}(0.47+0.63)$	0.47
r_1, cm	6.50×10^{-4}	6.50×10^{-4}
r_2, cm	7.50×10^{-4}	7.50×10^{-4}
l, cm	0.178	0.318
L, cm	0.257	0.318
G, ohms	55	55

B. Temperature dependent values.
1. Values common to both detectors.

	298°K	205°K	96°K
K_1, watts/deg.-cm	0.242	0.206	0.163

K_0, watts/deg.-cm	0.700	0.682	0.767

results, the observed sensitivities must be put into the form of Eq. (7). The case of detectors A and B, which must be considered separately from that of detector C, will be treated first.

Since the responses of the radiation thermocouples were measured as open circuit potentials, no current flowed through the galvanometer and the Peltier-heat effect given in Eq. (4) was absent. Under these conditions, a somewhat larger value of $\langle\Delta t\rangle_{Av}$ results from a given power absorption by the detector and the open circuit potential, V_{exp}, is somewhat larger than V as defined in Eqs. (5) or (11). In practice, however, the magnitude of $(P^2\langle T\rangle_{Av})/(G+R)$ or $(1.5P^2\langle T\rangle_{Av})/(G+R)$ is negligible in comparison with the other terms in Eqs. (8) or (12), so that the value of V_{exp} differs negligibly from V and the experimental value of Q for comparison with theory may be written

$$Q_{\mathrm{exp}}=\frac{V_{\mathrm{exp}}}{E(G+R)^{\frac{1}{2}}}=\frac{S^*}{(G+R)^{\frac{1}{2}}} \qquad (17)$$

where S^* has been previously defined as the open circuit potential produced by unit power absorption and is therefore equal to V_{exp}/E.

Before theoretical Q values can be calculated from Eqs. (8) or (12), it is necessary to have values of P, K_1, K_2, and R as functions of temperature. A constantan-Chromel P thermocouple was calibrated from 76.9°K to 300°K and the results represented by the equation

$$V=(10.26-0.0149T-8.30\times10^{-5}T^2)\times10^{-3}\text{ volt} \qquad (18)$$

so that the desired relation for P becomes

$$dV/dT=P=-(0.0149+16.60\times10^{-5}T)\times10^{-3}\text{ volt/deg.} \qquad (19)$$

In calculating numerical values of P from Eq. (19), the results are expressed as absolute values in order to obtain positive sensitivities from Eqs. (8) or (12).

Eucken and Dittrich[8] give values of the thermal conductivity, K_1, and resistivity, ρ_1, for samples of constantan which were subjected to a variety of annealing and working treatments. Since the sample which they describe as "strongly deformed" was judged to correspond most closely to the bare drawn, unannealed wires which were used in detectors A and B, it was decided to use the values which they give for this sample, namely: at 80°K, $K_1=0.157$ watt/deg.-cm, $\rho_1=4.98\times10^{-5}$ ohm-cm; at 273°K, $K_1=0.232$ watt/deg.-cm, $\rho_1=5.01\times10^{-5}$ ohm-cm. Values at the desired temperatures, 298°, 205°, and 96°K, were obtained by linear extrapolation and interpolation. In the case of Chromel P, the literature provides insufficient information on K_2 and ρ_2. However, the values $K_2=0.189$ watt/deg.-cm at 373°K and $\rho_2=7.06\times10^{-5}$ ohm-cm at 293°K were given by the manufacturer as appropriate values for the wire which was used in the construction of the detectors. The temperature coefficient of resistivity was determined experimentally from measurements of the resistance of a sample of Chromel P and values of ρ_2 were computed from the relation

$$\rho_2(T)=7.07\times10^{-5}[1+3.98\times10^{-4}(T-298)]\text{ ohm-cm.} \qquad (20)$$

Values of K_2 were then obtained by assuming that, at any given temperature, the Wiedemann-Franz

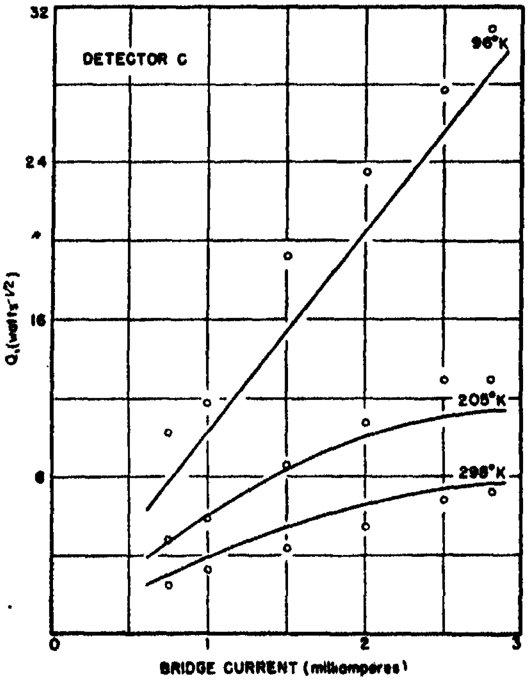

FIG. 7. Theoretical and experimental sensitivities of bolometer.

---

[8] A. Eucken and K. Dittrich, Zeits. f. physik. Chemie 125, 211 (1927).

relation could be expressed by

$$K_1\rho_1 = K_2\rho_2. \tag{21}$$

The reliability of this method of estimating K_2 appears to be confirmed by the fact that it predicts a value at 373°K which is within 1 percent of that given by the manufacturer. The desired values of the detector resistance, R, were computed from the ρ_1 and ρ_2 values since the electrical lengths and radii of the constantan and Chromel P wires were known.

Numerical values of all the parameters and constants which are required for the calculation of Q as a function of $\langle T\rangle_{Av}$ are collected in Table I.

A comparison of calculated and experimental values of Q for detectors A and B is shown in Fig. 6 where the curves correspond to values calculated from Eqs. (8) and (12) and the points to values from Eq. (17). For detector A, the average absolute deviation between calculated and experimental sensitivities is 15.6 percent, and for detector B, 9.7 percent. This agreement is considered satisfactory in view of the extremely large difference in the values of Q_{exp} for the two detectors, both with respect to absolute values and temperature dependence.

The procedure for calculating the average absolute temperature, $\langle T\rangle_{Av}$, of the bolometer wire at any network current, and the theoretical value of Q as a function of $\langle T\rangle_{Av}$ from Eq. (13) has been presented in detail.[5] Results for the present bolometer will be given without repetition of derivations or explanations which appear in the original reference.

Table II lists all the parameters and constants which are required for calculating experimental and theoretical values of Q. The entries for α, ρ, and K have been obtained by graphical interpolation of results for platinum given by Rolf.[9] Table II does not include σ, $\epsilon(=0.47)$, and G since these appear in Table I.

A comparison of calculated and experimental values of Q for detector C is shown in Fig. 7 where, for simplification in plotting, the bridge current, rather than the average bolometer wire temperature, $\langle T\rangle_{Av}$, has been used as the abscissa. The relation between $\langle T\rangle_{Av}$ and bridge current for the three ambient temperatures of the bolometer (entered as $\langle T\rangle_{Av}$ for zero bridge current) is shown in Table III.

TABLE III. Values of $\langle T\rangle_{Av}$ as function of bridge current.

Bridge current (milliamperes)		$\langle T\rangle_{Av}$ (deg. K)	
0	298	205	96
0.75	303.0	211.3	101.5
1.00	306.5	216.4	106.4
1.50	317.2	229.6	121.2
2.00	330.5	248.0	145.0
2.50	345.6	268.5	176.5
2.80	356.0	282.1	196.0

The curves in Fig. 7 correspond to values calculated from Eq. (13), and the points to values calculated from the relation

$$Q_{exp} = \frac{2V_{exp}(G+R)^{\frac{1}{2}}}{E(R+N+2G)} = \frac{2S^*(G+R)^{\frac{1}{2}}}{R+N+2G} \tag{22}$$

which has been derived previously. The agreement between calculated and experimental sensitivities for detector C is about as satisfactory as that for detectors A and B, since the average absolute deviation for all the points is 12.8 percent.

The present results can be summarized in qualitative terms as follows:

The steady-state sensitivity of a vacuum radiation thermocouple may be expected to increase with decreasing temperature if it has a very large receiver area (detector A), and therefore, at room temperature, loses most of its incident energy by radiation. The increase in sensitivity will be due to the diminution of this radiation loss at the lower temperatures. It must be remembered, however, that the decrease of thermoelectric power of the thermocouple with decreasing temperature will tend to offset the advantage gained from the decreased radiation loss. As a result, a vacuum radiation thermocouple with a very small receiver area (detector B) which, at room temperature, loses little of its incident energy by radiation, may be expected to gain relatively little sensitivity, or actually to lose sensitivity, with decreasing temperature.

The steady-state sensitivity of a vacuum wire bolometer (detector C) may be expected to increase with decreasing temperature due primarily to the decrease of bolometer resistance at the lower temperatures. If the radiating area of the detector is large (as in a ribbon bolometer) the decrease in radiation loss with decreasing temperature will augment the effect of decreased resistance and result in a still larger increase in sensitivity.

Modified String Flowmeter for Measuring Breath Velocity

H. SPECHT[*] AND H. F. BRUBACH[**]
Laboratory of Physical Biology, Experimental Biology and Medicine Institute, National Institutes of Health,
U. S. Public Health Service, Bethesda, Maryland

(Received October 18, 1948)

An instrument is described which measures instantaneous breath velocities without incurring high flow resistances. It records reciprocating flows, such as those of the full breath cycle, within the limits of normal breath velocities with high frequency resolution and yields accurate and reproducible measurements when suitably calibrated. The system described incorporates an automatic control over a valve system insuring directed flow of the respired gases through a closed breathing circuit, permitting measurement of breath velocities at simulated high altitudes. The advantages, disadvantages, and idiosyncracies of this type of instrument as used in physiological measurement are discussed.

IN the course of work requiring measurement of breath velocities a flowmeter has been developed in this laboratory patterned after that constructed by Lee and Silverman[1] but with modifications which permit its use at low atmospheric pressures, as in a decompression chamber where pure oxygen must be supplied to the subject, for the recording of expiratory and inspiratory flows in a continuous fashion. This instrument, although largely a composite of equipment components already at hand in the laboratory, has certain characteristics which may be of critical interest to others contemplating work in this field. It is recommended that reference 1 be read for details of structures common to both instruments, and their aerodynamic characteristics.

CONSTRUCTION

The apparatus, as used to collect data on breath velocities at different densities of inhaled gases,[2] consists grossly of a mask, flowmeter unit, valve, and connecting tubing as shown in Fig. 1. The spirometer and carbon dioxide removing filter are not shown.

A McKesson Metabolor type mask (*A*) is fixed in a stand in such a manner that pressing the face into the inflated rim (*B*)[***] will not deflect the flowmeter unit from the optical path directed to the recording system. The mask provides for nasal breathing but does not preclude mouth breathing if the subject cannot properly breath through his nose. The opening (*C*) in the mask for the passage of the breath is made directly before the subject's nose and mouth, but some deflection of the breath is unavoidable due to the fact that the lead-off is horizontal. The subject sits before the mask on an adjustable seat integral with the mask stand and flowmeter bench so that head position in the mask is comfortable with the spine erect. A second opening (*D*) in the mask, approximately in a direct line with the air stream from the nose is provided for a control unit to be described subsequently.

The mask and valve unit are hermetically integrated with the flowmeter unit by means of thin-walled rubber tubes (*E*) made of dental dam which serve to isolate the flowmeter unit from shock or vibration. The gap between these units covered by the tubing is about one millimeter.

The flowmeter consists of a 1.25-inch i.d. brass tube (*F*) which is placed in the breathing circuit as an integral part through which all air entering or leaving the mask must pass. It is made 10 diameters long to minimize turbulent flow during quiet breathing. This is aided by a set of collimating surfaces (*G*) placed in the ends of the tube to correct cross currents due to irregular inflow from the mask and valve. These collimators are made from a one inch ribbon of brass shim stock folded into a screen with approximately hexagonal openings about 5 mm in diameter. At right angles and passing through the axis of the tube midway in its length is a fine nickel wire (*H*) (0.001-inch diameter) which is deflected by the air passing through the tube. At right angles to the tube and to the axis of the wire a pair of opposing windows (*I*) permits the passage of a beam of light focused in the plane of the wire. The shadow thrown by the wire is optically magnified and photographically recorded. The wire is constructed long enough (*ca.* 20 cm) to allow angular displacement at the points of suspension to be negligible with the maximum deflection expected in use. The wire is suspended vertically from an adjusting head and is maintained under tension by a small tungsten spring (*Y*) (filament from a flashlight bulb) similar to the method used in reference 1. Free oscillation of the wire is effectively prevented without recordable effect on the timing of the response by passing it through 3 drops of spermacetti oil each suspended in a small wire loop surrounding the wire. These damping droplets (*Z*) are spaced in such a manner as to affect the larger harmonic oscillations that might be expected to interfere grossly with the legibility of the respiratory velocity pattern.

[***] In order to prevent excessive inflation at altitude due to the change in barometric pressure the rim of the mask was evacuated and then snugly filled with water, providing a good fit to the face under all our experimental conditions.

The source of illumination (*J*) was first a Hanovia Labarc unit which gave enough visible light for inspection of the projected image and made good photographic records. It also served to give very fine time lines, inasmuch as the light is interrupted twice during each cycle of the voltage change in the current supply. Later, a motion picture projection lamp replaced the Labarc and has been found quite satisfactory for recording. A Pyrex #3966-M-829 heat filter (*K*) is interposed between the source and the focusing lens (*L*) to reduce the heat transmitted by the projection lamp. The focusing lens is mounted on the frame of the flowmeter on an adjustable bracket, and the focal point of the source adjusted to maximum brilliance on the wire within the expected limits of deflection.

The shadow of the wire is projected by means of a telescope system (*M*) giving about 350× magnification and a field large enough to cover the maximum expected deflection of the wire. In this instance this is achieved by using the inner element (*N*) of an old Leitz #5 microscope objective and the focusing element (*O*) of a motion picture projector lens system mounted integrally on an optical bench with the flowmeter and the light source. It was found desirable to install a ring-shaped warming element (*P*) at the telescope window of the flowmeter in order to prevent condensation of the breath moisture on the window. Heat from the source is apparently sufficient to prevent fogging of the opposite window.

Photographic registration is made by means of a long paper camera (*Q*) fitted with a cylindrical lens (*R*) of about 2-inch aperture in order to gather sufficient light for proper contrast on the photographic paper.

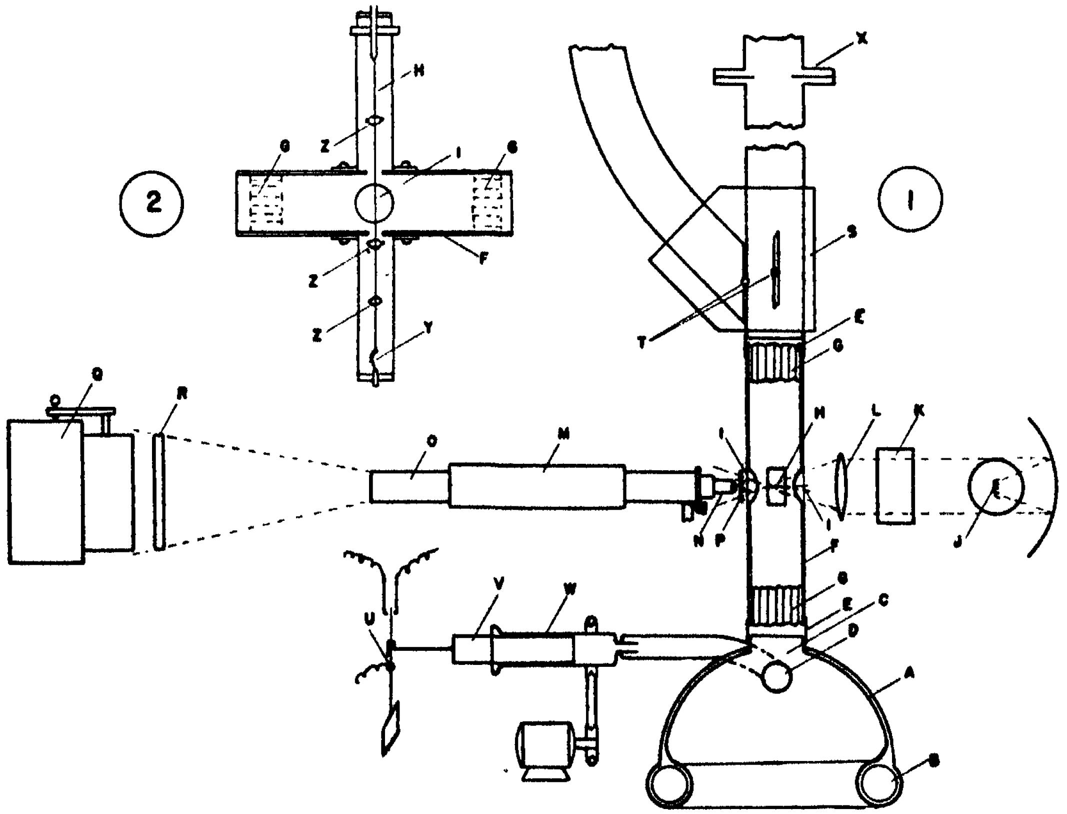

Fig. 1. Schematic layout of flowmeter and accessory devices (1) and a vertical detail of the flowmeter unit (2). See text for description of labeled parts.

Since a record of both expiratory and inspiratory flows was desired it was decided to use the same instrument for both measurements, thus eliminating discrepancies in timing between separate instruments. This choice necessitated a valve (*S*) distal to the flowmeter and thus introduced dead space whose effect must be recognized.†[3]

In the interest of reducing the resistance of the circuit, a valve was developed which does not require the force of the breath for closure except in that it initiates this action. This valve offers a very low resistance to all flows in the range we encountered. It is completely open to inspiration or expiration as alternately set by the breath pressure. The valve is a gang-connected butterfly doublet (*T*) mounted in a block bored for the breathing circuit. It is moved by a spring opposed solenoid. The latter is energized by a breath pressure switch (*U*) of special design, requiring only minute pressure differences to be operated. Inspiration is arranged straight through the valve and expiration at an angle of 45°.

The timing of the automatic valve is adjustable. In most instances it was loaded in the direction of automatic operation after expiration, thus anticipating the following inspiration. Many patterns show a vibration mark at the instant of valve action, and thus we were able to calculate the efficiency, a measurement which is not possible with other types of valves during use. The inherent lag of this system is about 1/10 second, and at rest, the breath patterns indicate a 50 cc backflow. This

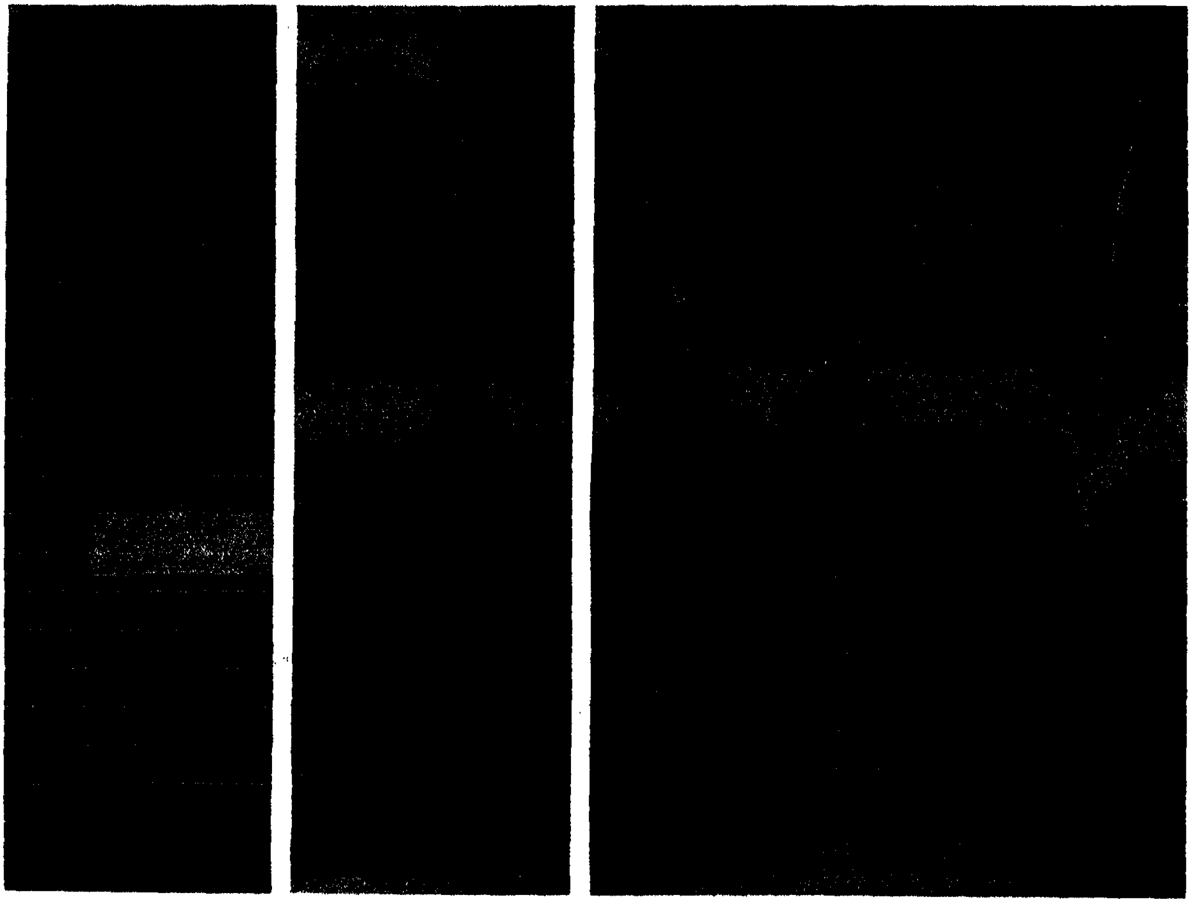

FIG. 2. (a) Trace of the response of the flowmeter to mechanical deflection, i.e., restoration from half-scale deflection. The displaced position is above the upper margin of the figure and the first trace is only faintly seen. Four reversals are distinguishable before the resting position is assumed. The period is about 1/80 second. Time lines of 1/240 sec., alternately black and white, form the background of the figure. (b) Trace beginning at upper left shows the displacement of a plunger in a cylinder connected to the flowmeter. Trace beginning at the center of the figure shows the response of the flowmeter to the air movement induced by the plunger. The upward sweep of the first trace has no counterpart in the flowmeter trace since it was caused by accidental parting of the connecting line. (c) Same as (b) but at somewhat slower rate of displacement. Ink lines show the beginning and end of plunger displacement and, in the first displacement, the attainment of maximum velocity is marked by an ink line across both traces.

---

† Data presented by Stannard and Russ (see reference 3) on the effects of added dead space of about 150 cc, slightly more than the volume of this flowmeter, resulted in a gain of about 16 percent in the tidal volume, but they found no consistent effect on the breathing rate.

[3] J. N. Stannard and E. Russ, J. App. Phys. 1, 326 (1948).

is comparable to that given for sensitive rubber valves developed for similar purposes.[1] In common with the latter, efficiency rises with ventilation.

The valve is actuated by a relay system tripped through a switch operated by the breath pressure through the floating plunger (*V*) of a rotated dry syringe barrel (*W*)[4] connected to the mask aperture (*D*) mentioned earlier. This control system can be balanced or unbalanced to anticipate either inspiration or expiration. In its final form it is arranged to reset itself for tripping the valve at the earliest possible moment after reversal of the breath velocity.

The valve openings are connected distally to a closed oxygen circuit of 1.25-inch rubber tubing disposed in such a manner as to avoid sharp turns and connect with a recording spirometer which has a CO$_2$ absorption filter in the exhalation line. An adjustable iris diaphragm (*X*) for selected resistance in the inspiratory line was provided for demonstrating effects of high resistance on the breath velocity pattern.

OPERATING CHARACTERISTICS

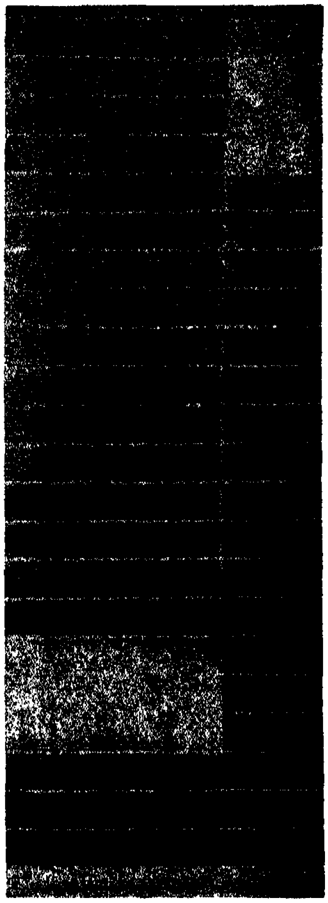

FIG. 3. Response of the flowmeter to a stepwise change in airflow, from about 30 to 100 liters per minute. Time for the change is 0.04 sec.

The natural period of the wire and spring is very short (*ca.* 1/80 sec.) and with damping shows a 95 percent restoration from half-scale deflection within 1/20 second, as shown in Fig. 2(a). It will be seen here also that the first crossing of the baseline occurs within 1/240 second of release. Figures 2(b) and 2(c) show the record of the manual displacement of a piston and the concomitant response of the wire. In Fig. 2(b) the piston marker was accidentally released at the end of the stroke showing an upstroke which is spurious. Figure 2(c) shows a similar run at a slightly slower rate of movement and then a return movement at a still slower rate. Vertical lines have been drawn to indicate the correspondence of the beginnings and endings of the piston movements and in the first stroke the time of attainment of peak velocity is marked by a vertical line. Figure 3 shows the response of the wire to a step change in flow, *ca.* 30 to 100 *L*/min., which was effected by clapping a flat plate over a bypass duct as air was drawn through the flowmeter. The time from low to high flow is about 0.04 second. Our calibrations of this wire as illustrated in Fig. 4 show it to be linear only on log-log plot. This would be in contrast to the findings of Lee and Silverman,[1] who assume linearity on arithmetic coordinates, if it were not a matter of degree, since they actually show certain deviations from linearity and dismiss them as minor. It is likely that the magnitude of this deviation is dependent on the wire diameter and spring characteristics which are obviously not the same in the two instruments. Our calibrations were made with a rotameter whose range is indicated by the data in Fig. 4. Readings at the low flows cannot be made accurately and thus account at least in part for gross internal inconsistencies. It is seen, however, that the curves form well-defined families which indicate good internal consistency over the rest of the range. These considerations led us to calculate regression lines for each calibration run and to base our flow measurements on such derived curves. It was found necessary to make calibrations for each day that experiments were run because there were real but unpredictable changes in the level of response of the wire as shown in Fig. 4 by the families of unbroken and broken lines, respectively, taken on 5 different days. There are several probable causes of these changes, the most frequently applicable being temperature changes which alter the spring tension, and relaxation of the spring suspension through constant stress. It was also found accidentally that otherwise unaccountable changes in shadow width of the wire were related to deposition of material on the wire either during use or in calibration. This was most easily recognized after the calibrating gas source had been drawn through the CO$_2$ filter bed

---

TABLE I.

	Expiration	Inspiration
20 *L*/min.	1.4 mm H_2O	1.1 mm H_2O
40	2.2	—
50	3.9	2.0
70	5.8	3.0
80	7.5	—
100	9.0	4.0

inadvertently. In this instance, a noticeable deposit could be removed from the wire with a fine brush. While this was a gross effect, it is possible that the moisture carried over the wire by the exhaled breath may cause the accretion of particles, or solids in solution, on the wire which alters its resistance to air flow.

It was found necessary to make separate calibrations for opposed flows as shown in Fig. 4; unbroken lines being "inspiratory" and broken lines being "expiratory" calibrations. The observance of respective zero positions as shown in Fig. 2(c) was also necessary. This change in resting position is a common difficulty with lightly stretched suspensions which are required to pass through the zero position, as in the registration of deflections of opposite sign. This behavior of the wire was not due to the damping system used here since such displacements were also observed and recorded when the oil droplets were absent. Although the magnitude of this effect may not be great, it should be recognized in all cases where the wire is allowed to come to rest before registering an opposed flow, as is the case in breath velocity patterns in which a post-expiratory pause is interposed, as shown in Fig. 5(b) and 5(d).

Measurement of the overall flow pressure from mask to spirometer with a series of constant flows through a rotameter in place of the subject was made with a slant manometer. "Expiration" pressures were measured across the circuit including the CO_2 filtering bed, while "inspiration" pressures were measured only across the duct and flowmeter. The pressures at the several rates of flow are given in Table I.

Measurements with oxygen instead of air gave essentially equivalent values indicating that orifices in this system were large enough to have only a negligible influence with this difference in density at the flows tested. It should be emphasized that the velocities in exercise may reach beyond the range indicated. The calculated critical velocity for turbulent flow for the flowmeter tube is 48 *L*/min., which happens to coincide with the break in slope of the expiratory pressure-flow table values. We feel that this is fortuitous, since the inspiratory pressure drop values follow a linear course. It is likely that the change in slope of the expiration values is due to characteristics of the CO_2 filter

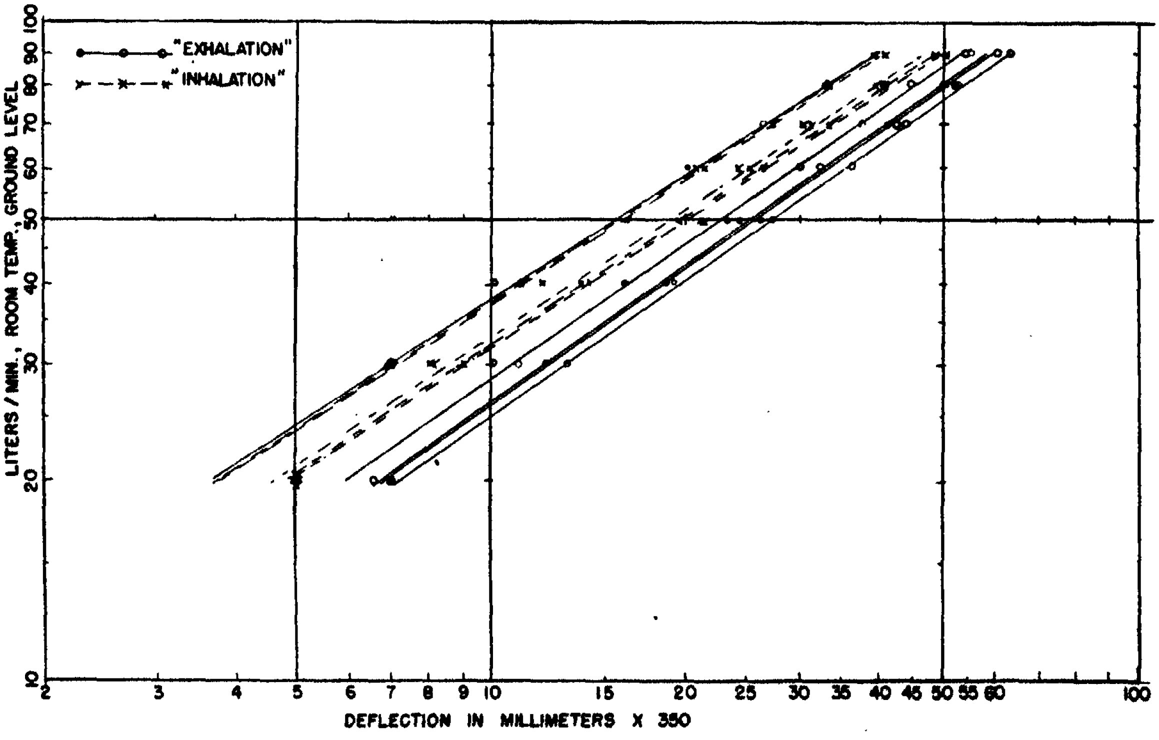

FIG. 4. Sample calibrations of the flowmeter for five different days. Calibrations were made with a rotameter covering the whole range shown on the ordinate. Pairing of exhalation and inhalation data is not indicated in the figure but the relatively independent variation of these values is indicated by the position of one set of exhalation values at the extreme left of the whole group.

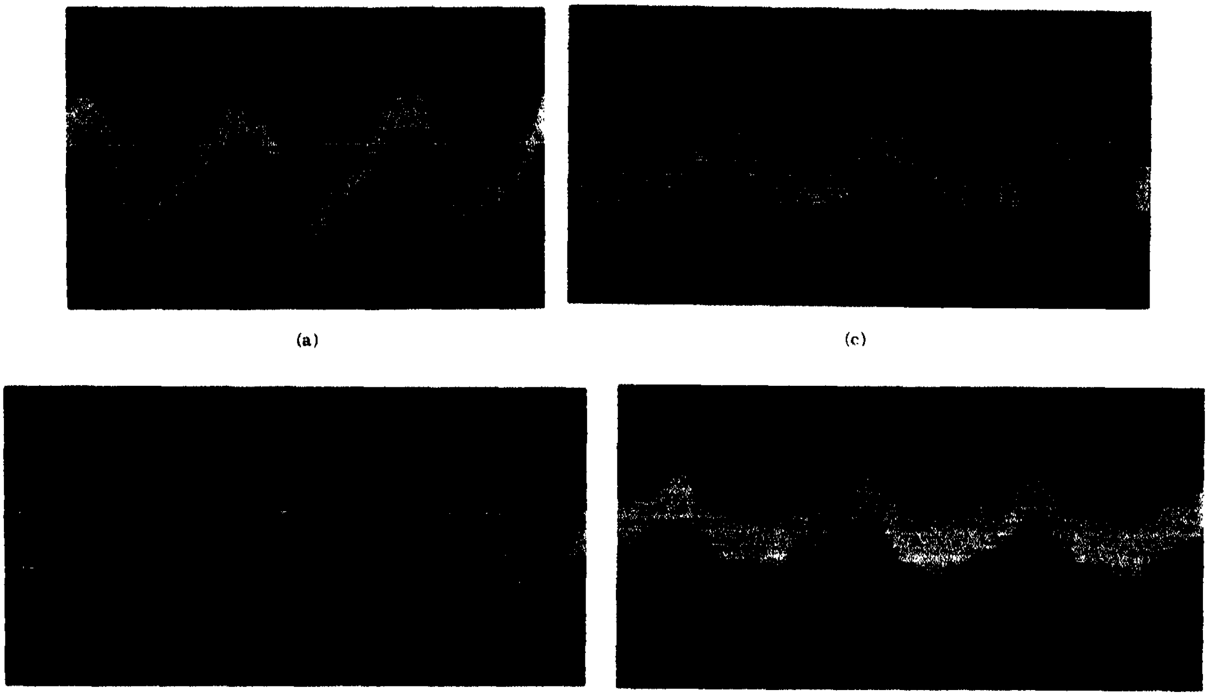

(a) (c)

(b) (d)

FIG. 5. Breath velocity patterns made on each of two subjects in full oxygen at ground level (a and c) and at 30,000 feet simulated altitude (b and d). In each record the upper margin of the shadow trace is to be compared to the control level marked by a grid line superimposed on the 5 mm uniform grid. Time, in seconds, proceeds from left to right. Inhalation rises and exhalation falls below the control level. The sensitivities of the ground level and altitude deflections differ, the latter being the less sensitive; maximum velocities for inhalation and exhalation respectively are (a) 52 and 58 *L*/min., (b) 80 and 96 *L*/min., (c) 40 and 35 *L*/min., (d) 38 and 42 *L*/min. It is to be noted that in the altitude records (b and d) there appears a protracted arrest of the breath flow after exhalation.

bed. There is little reason to believe that the flow pressures throughout the range usually encountered in exercise (up to *ca.* 120 *L*/min.) would be greater than a linear extrapolation of the values given here. It is not clear, however, that pressures exerted by constant flows are comparable to those encountered in intermittent flows such as the breath cycle presents. Apparatus for measuring such transient pressures accurately has not been available to us, but our attempts to compare the velocity patterns from pressure-drop methods as devised by Silverman, Plotkin, and Lee,[5]†† to those from the wire deflection method used here show that transients are seriously damped out, even though the recommended precautions regarding resistance of the pressure conducting lines were fully considered.

We feel, furthermore, that the range of the present instrument is limited in its application not so much through the resistance of its own structure but mainly that of the ducts which are used for various purposes such as in our own experiments.[2] While it is obvious that the diameter of the trachea must itself induce turbulence under these conditions, the mounting pressure drop through the whole test system places additional high and unnatural loads on the physiological mechanisms which are to be studied. Thus it might be possible to work at a higher range of flow values by using larger bores in the flowmeter and ducting but sacrificing sentitivity at low flows since the instrument depends on linear velocity for the deflecting force.

---

Erratum

The Central Research Laboratories, Inc., Red Wing, Minnesota, has called our attention to an error in publishing the stated range of the pre-focused interchangeable optics for their monochromator. In an advertisement on page xxxvii of the May, 1949, *Review of Scientific Instruments*, the range was given as from 0.15 to 52 microns. The range should have been given as from 0.15 to 25 microns. The publisher was responsible for this error and regrets the inconvenience to readers and to the Central Research Laboratories, Inc., which might have arisen from inquiries based on this error.

Book Reviews

Microwaves and Radar Electronics

By E. C. Pollard and Julian M. Sturtevant. Pp. 426 +vii, Figs. 192, Tables 12. John Wiley & Sons, Inc., New York, 1948. Price $5.00.

The authors of this book have drawn upon their wide experience in the development of microwave radar to put together a survey of the by-products of that tremendous concentration of scientific and technological effort by which the Allies turned a wave-length into a weapon. Their subject is not radar as a function, but the new devices and techniques that comprise, in patent language, the radar art, with special emphasis on the role of these techniques in postwar research. One chapter near the end of the book contains an explanation of the elements of the radar problem, illustrated by a few typical radar systems, but the rest of the book is devoted to magnetrons, klystrons, wave guides, pulse circuits, cathode-ray tubes, amplifiers, servo-mechanisms, and so on.

This vast assortment could not have been covered without drastic condensation and many compromises—compromises that will make the specialist wince when he turns to the chapter on his specialty. But the microwave specialist is not the reader the authors had in mind. The success of the book can properly be judged only by the student who turns to it to find out what this elaborate microwave business is all about, and what one can do with microwaves and the circuit tricks of radar that he could not do before. If the student is willing to move rapidly from exhibit to exhibit, accepting ingeniously condensed explanations, he will cover a lot of ground and accumulate a staggering load of facts.

A small amount of misinformation, and several careless statements, will be found along the way: We are told that "waveguide does not have the property of a guaranteed mode of excitation which is so useful in a coaxial line" (p. 112); the field configuration in the celebrated TE_{01} mode is misrepresented in Fig. 4.13; an antenna matching device is said to do two *different* things, (a) cancel the reflection, (b) build up the intensity so that all the power can be radiated—hence two variables are needed (p. 100); "Like charges should repel, but the observed fact is that moving charges attract one another" (p. 7). Another small fraction of the information is now obsolete, which is not surprising, but it is surprising that in a book described as a "postwar book on postwar problems" such flat statements as the following should be left unqualified: "Powers up to 3 megawatts in pulse form at 9 centimeters or longer, or 30 kilowatts at 1 centimeter, can be obtained with magnetrons."

Much of the book, in short, reads like a 1945 status report; the authors are describing the trees, not the woods or the vistas beyond. They have not entirely abandoned the point of view of the radar systems engineer who is concerned mainly with what a piece of "plumbing" will do, not why it does it. In its relation to the electronic art, the cathode is one of the most remarkable and important parts of the magnetron; in the 14-page section on magnetrons the cathode is allotted two or three sentences, one of which describes it as the source of r-f energy! The section on crystal detectors begins, "Crystals are usually mounted in a special cartridge, one of which is illustrated in Figure 4.1", and continues in the same vein. No hint here of the intense research in the physics of semiconductors which has led to the widely used germanium diode and, more recently, the transistor.

Despite their shortcomings, these chapters do give as compact and fast-moving an account of a rich field as could well be devised. The figures are abundant and excellent; carefully selected and condensed explanations of the basic electromagnetic theory are inserted where they will be most helpful. The very comprehensive index—so complete as to include the entry "main bang"—is a substantial asset.

In the last two chapters, "Microwave Communications," and "Microwaves in Physical Research," the authors make good on their promise to give us a glimpse in the direction of future developments. Certainly much remains to be done to exploit the microwave art for communication purposes as fully as it was exploited for radar. It is good to see an adequate description of the experiments of the pioneers in microwave spectroscopy, Cleeton and Williams. Pollard and Sturtevant also explain the peculiar feature of the ammonia molecule that accounts for its unique role in the story of microwave spectroscopy. The Lamb-Retherford experiment gets only two sentences, however—surely a perfunctory treatment of the most important physics experiment the microwave development has yet fostered. The inclusion of a good discussion of thermal radiation at radiofrequencies, and of Dicke's microwave radiometer, was an excellent idea, for the implications of this work are not yet widely appreciated. All of this material, together with brief discussions of microwave particle accelerators and microwave measurements of superconductivity, will certainly leave the reader sharing some of the authors' enthusiasm for the shiny contents of our new toolbox.

E. M. Purcell
Harvard University

Rocket Propulsion Elements

By George P. Sutton. Pp. 294, Figs. 130. John Wiley & Sons, Inc., New York, 1949. Price $4.50.

The major new developments of World War II—atomic bombs, radar, proximity fuzes, and rockets—were produced without benefit of standard text books and reference books on these subjects. In the first three cases this is understandable since the basic principles underlying these developments had been discovered in the years just preceding the beginning of the war. In the case of rocket aircraft and ordnance it may appear surprising as the fundamental principles of rocket propulsion have been known for many years. The answer is of course to be found in the fact that prior to World War II the number of professional scientists and engineers interested in rocket propulsion was very small. Rocket development was largely pursued by amateurs primarily interested in space navigation. Few schools presented courses in the subject and thus there was no great demand for textbooks, and in fact, there were no teachers with teaching experience in the subject to write them.

The situation is considerably different at the present time but only a few textbooks for undergraduates and first-year graduate students have appeared since the war, presumably because of security restrictions. One of these few texts is *Rocket Propulsion Elements, An Introduction to the Engineering of Rockets*, by George P. Sutton, Supervisor, Propulsion Development, North American Aviation, Inc. and Instructor, University Extension, University of California. Even in this book as noted in the preface, "The text and the figures have been submitted and checked by military authorities. This requirement limited in part the amount of experimental and calculated data which could be presented, since a large part of the technical information on this subject cannot be published for security reasons." Nonetheless, the book brings together many of the fundamental mechanical, thermodynamic, thermochemical, and ballistic principles which were known at the start of World War II as well as some applications developed during the war which are no longer classified. As such it will be very useful in the instruction of present-day students on whom to a large extent our future security depends.

The treatment of nozzle theory and thermodynamic relations and of rocket propellant performance is conventional, but the material on these subjects is presented in an excellent manner for the student familiar with the basic physical, chemical, and engineering laws who is approaching rocket problems for the first time. No attempt is made to derive or to elaborate upon the fundamental laws but the application of these laws to rocket propulsion is made directly and discussed in some detail. Copious references to existing texts on the basic principles are given.

The major portion of the text is devoted to rocket devices employing liquid propellants, three chapters being devoted to the propellants, motors, and feed systems of such devices. The treatment of solid propellant rockets in the final chapter is admittedly sketchy. The chapters on flight performance and rocket testing are satisfactory for an introductory text.

Unfortunately the treatment of the basic mechanism of rocket flight given in the first chapter is not too well done. Momentum is correctly defined as mass times velocity, but the quantity called momentum in Eq. (1-1) is actually the impulse transmitted to the rocket per second. To make the confusion complete, momentum is given the units of ft.-lb. at the end of the chapter when it should be in lb.-sec. or slugs-ft./sec. The difficulty arises from the fact that mass flow rate rather than mass appears in the equation for the force on the rocket. In addition, the discussion of efficiencies which are rarely used in designing rocket units will only lead the student into the apparent paradoxes which always arise in this connection without being explicit or detailed enough to be of real help. The efficiencies defined are all instantaneous efficiencies dependent on instantaneous power considerations and yet they are all defined initially in terms of relative energy values.

The book contains a considerable number of good illustrations and there are many tables of data. There are good problems and a summary of symbols at the end of each chapter. English engineering units are used consistently throughout. The sketch of rocket history in Chapter II is readable and interesting. With the exception of the points noted above, the book is an excellent one and should be of wide use in introductory courses on rocket aircraft and ordnance.

California Institute of Technology

The Optical Principles of the Diffraction of X-rays

By R. W. James. Pp. 623+xv, Figs. 217+vii, 22×14 cm, Vol. II of *The Crystalline State* edited by Sir Lawrence Bragg. The Macmillan Company, New York, 1948. Price $17.50.

Under the title *The Optical Principles of the Diffraction of X-rays*, Professor R. W. James of the University of Cape Town has written the second volume of the series entitled *The Crystalline State*, originally planned and edited by W. H. and W. L. Bragg and now continued under the editorship of W. L. Bragg. The first volume *A General Survey* covered, as its title implied, the whole field of the x-ray analysis of crystals, and provided a continuation of the series of editions of *X-rays and Crystal Structure* in which the Braggs summarized so elegantly their original researches and those of others into the field of the x-ray analysis of the fine structure of matter.

In this volume, Professor James treats of the basic problem of x-ray analysis. He discusses the way in which the intensities of the x-ray diffraction pattern depend on the arrangement of the atoms within the scattering material and on the quantum mechanics of the electrons within the atoms of that material. His program is comprehensive and he carries it through in a way which is astounding to one who has worked for many years in the study of a few small parts of this large field.

It is impossible within the space and the time allotted to this review to examine critically all the chapters of the present work, even if the reviewer felt himself qualified to do so. The book provides basic material for those who are interested in the use of x-ray diffraction and other diffraction techniques for the determination of the electronic configurations of atoms, and also for those who are completely disinterested in the detailed structure of atoms and are only interested in the gross stereochemistry of large organic and inorganic molecules. It is concerned with the way in which the texture of natural crystals, in their departure from the ideal crystalline state, affects the diffraction phenomena. It is, of course, this last phase of the problem which is the crux of the situation as far as the x-ray analysis of material structures is concerned. We have a fairly complete theory, and Professor James presents it well, of the diffraction of x-rays from a "perfect" crystal. The reader of the book will find himself with a very good summary of the theory and the experimental results of the literature and will be well prepared to find and read the original papers on the subject. We also have a very complete theory of the "perfectly imperfect" crystal and this is also admirably presented here. Of real importance to the subject of x-ray analysis of structures of crystal molecules and of texture problems of the crystals themselves, is the region between the "perfect" crystal and the "perfectly imperfect" crystal, for it is in this region that almost all crystals which can be grown or which occur naturally are to be found. In this section of the book Professor James excels, for he has himself been involved in many of the most fundamental experimental and theoretical investigations in the field. His treatment of the effect of thermal motion seems admirable to the reviewer who has read it largely for his own education, and without any real qualification for criticism.

At the present moment the attitude of the x-ray analyst is that the values of $|F(hkl)|^2$ can be determined from the x-ray diffraction intensities. The only problem which remains is the determination of the phases of the Fourier coefficients $F(hkl)$ of the electron density distribution. Professor James discusses this problem also and gives an excellent summary of the various processes which had been developed up to the time of completion of his manuscript. In the reviewer's opinion, however, the timeliness of this book lies in its application to researches which have been published in the last year and which are now in progress. It now seems that given *accurate* values of $|F(hkl)|^2$, it will be possible in the not too distant future to select by routine procedures, a relatively small number of structures which will be consistent with the x-ray data. The power of the procedures which have been proposed by Harker and Kasper and the generalizations of these methods which are under development by Karle and others will depend on the availability of highly accurate values of $|F(hkl)|^2$. Professor James does not provide the complete secret for such accurate determinations, but he does summarize very completely the work which has been carried out so far in this direction, and the future developments which are needed can well be based on his summary.

Individual research workers in a particular small subdivision of the field covered by this book will undoubtedly be able to criticize it. The reviewer has found one or two places in which his own taste differs from that of Professor James. Objective thought indicates however that these differences are only in methods of treatment and the reviewer gladly forgoes his priviledge of minor criticism in return for the inspiration of the first reading and the tremendous value of the continued use of the book as a reference. Sections of the book will provide potent material for graduate seminars in x-ray diffraction, if the students and the professor are willing to face concentrated material of great importance. The book can be recommended without reservation to any one who has any interest in research in any one of the many fields included in the title.

Technically the book is excellently produced. The reviewer has found only a few typographical errors. The price seems high to one who wishes that the book could reach the hands of many students, but the number of text and plate figures and the number of formulas indicate that the book would be difficult to produce at a lower figure.

A. L. Patterson
Bryn Mawr College

Recent Advances in Biological and Medical Physics

EDITED BY JOHN H. LAWRENCE AND JOSEPH G. HAMILTON. Pp. 450+xi, Figs. 49, Tables 60. Academic Press, Inc., New York, 1948. Price $8.60.

The title of this book is somewhat misleading for the subject matter is concerned not with biophysics but with the application of stable and radioactive isotopes to problems in biochemistry and medicine. The misnomer reflects a growing tendency on the part of biologists and physicists alike to regard biophysics as any biological study which utilizes a mass spectrograph or a Geiger counter as its method of analysis. One might equally well define biophysics as the study of renal function because elaborate physical methods are sometimes employed for analysis of the urinary constituents. Biophysics is more properly concerned with the physical properties of cells and tissues but this is not the subject matter of the volume under review.

Although the title is misleading, this book fulfills an important need for a comprehensive reference source in a field which is expanding with great rapidity. The volume consists of ten chapters, each chapter being written in review form by an outstanding contributor to the field. Five chapters are devoted to those recent advances in the biochemistry of intermediate metabolism, which have been made possible through the use of isotopic tracers. These chapters include the metabolism of carbon and nitrogen in vivo, phospholipid metabolism, the nucleic acids, and the metabolism of iodine and iron. In the opinion of the reviewer, these sections supply the most valuable material of the book. Two chapters are offered on the fundamentals of radioactivity, its nature, production, and detection. Both chapters are masterpieces of condensation, but the scope of the subject is too broad to be clearly presented in 98 pages. The remaining chapters are concerned with clinical applications of radioactive materials to the control of malignancies, with the effects of radiation on the human organism as a whole, and with protection from radiation.

The scientist who is unfamiliar with applications of nuclear physics to biochemistry will find this book valuable as a general survey of the field. From this point of view the book may be particularly helpful to workers in countries which have not, as yet, had full access to the detailed literature. To the biochemist, the book will be constantly useful as a reference source.

JOHN R. PAPPENHEIMER
Harvard University

The Structure of Matter

BY F. O. RICE AND E. TELLER. Pp. 361, Illustrations 77, John Wiley & Sons, Inc., New York, 1949, Price $5.00.

The Structure of Matter is a clear, absorbing, non-mathematical account of the entire broad field indicated by its title. Omitting only a discussion of fundamental particles (which from the point of view of the book are presumably matter without structure), the reader is taken from that simplest form of matter, the hydrogen atom, uniformly into more and complex aggregates to find himself finally dealing familiarly with problems of composition and stability of the stars. The course of this progression to the stars includes the structure of atoms, atomic spectra, the chemical bond and structure of molecules, molecular dipoles, Van der Waals' forces, molecular spectra, the solid state, electric and magnetic properties of matter, radioactivity, and nuclear chemistry.

Naturally this book of 350 pages cannot serve as a reference for the broad field covered, or as a rigorous development, but only as an incisive introduction. It's style and scope reminds the reviewer of Wells' *Pocket History of the World*, where each century of history rushes past—but not before the reader is made to feel he is satisfyingly aware of its true meaning and relation to the entirety of human experience. The book is not a superficial summary of physical and chemical information, but a logical and penetrating presentation of ideas, principles, and results. The authors' thorough familiarity with wide areas of the material covered have enabled them to choose the important ideas, to express them simply and yet accurately, and to correlate and give perspective to the many phases of their account.

Perhaps the most delighted readers will be the trained physicists and physical chemists—even though the book is non-mathematical and very simply written. They will find in *The Structure of Matter* a fascinating and easily read story, new points of view, a general cultural education in physics and chemistry, and some sparks of humor.

The success of this book as a classroom text is debatable. An advanced undergraduate of first-year graduate course based on it would certainly be an interesting and worth while experiment. The words will be easily read by a student of this level. However, quantum mechanics is used as a basis for discussion almost throughout, and many advanced ideas are introduced. The hazards are that in spite of the clarity of style the student may be left breathless by the wealth of new ideas or because of difficulties in assimulation may come to regard the whole discourse as somewhat unreal. He may be better served by a slower and more rigorous approach.

Mathematics is avoided almost to a fault. Although many advanced quantum-mechanical ideas are used and discussed, no mathematics as complicated as a differential equation (including Schrödinger's equation) is involved. This is, of course, contrary to usual practice since students advanced enough in our present educational system to deal with probability distribution, quantum-mechanical resonances, and tunneling effects are usually capable of handling somewhat more mathematics than the authors allow themselves.

As supplementary material for advanced students, *The Structure of Matter* should be readable and valuable. In fact, for most physicists and physical chemists the only unreadable part will be the closing expression of "that's all" in Greek.

CHAS. H. TOWNES
Columbia University

Principles of Radar

BY DENIS TAYLOR AND C. H. WESTCOTT. Pp. 141, 8 in. × 6 in. Figs. 51. The Macmillan Company, New York, 1948. Price $3.50.

This compact little book forms one of a series on modern radio technique which is intended to describe advances in radio technique made during the war. The whole subject of radar is included in this volume which covers essentially the entire British technique ranging from long wave flood lighting radar to microwave radar. The elements of radar beacons are also included, again over a wide range of wave-lengths. Ground and airborne radars are both included.

This is, of course, a very considerable subject to cover and the authors have attempted to present the fundamental features which underlie radar rather than spend much time on the description of specific sets. This is a very desirable approach and indeed a little volume such as this published during the war would have been invaluable to those who were struggling with the whole problem of the wise choice in radar for various purposes. The authors succeed in their aim and the result is a very attractive presentation of the way in which the problems of radar have been solved for equipment over a wide range of wave-lengths.

As an example of topics which are covered simply and adequately, we can include the calculation of maximum range, propagation problems, methods of height finding, and a rather interesting appendix on scattering areas.

By way of a certain amount of criticism, one wonders why the book is so entirely confined to techniques which are primarily British. There is no doubt that the British contribution to radar was the most significant and of the first magnitude, still there did result methods which are present in American sets which could have been included to make the book more complete. For example, there is no mention of rapid scanning radar such as the GCA or the APQ7, both of which represent important contributions to radar methods. This slant in the direction of British methods is also expressed in the language and one feels a sense of profound regret that a subject which was so entirely interlinked in research effort during the war should nevertheless be developing a national form of language. Thus, one sees "centimetric" radar in place of "microwave" and "time base" in place of sweep and so on. This is not at all significant, but it does underline the fact that there is a tendency for language to diverge even in the technical field.

The book does not look forward very much and one feels that it represents a description of the whole art as it applied in early 1945, with very little included beyond this time. It is also interesting to note that the one serious divergence of thinking between English and American practice, namely, that of feeding an antenna, is markedly shown in the illustrations in this book.

The book should be read by anyone with a certain amount of knowledge of radar who wishes to widen his understanding of the subject. For English readers it could well serve as an introductory book, but it would be found by American readers that the illustrations were not apt, although the method of presentation is excellent, the language clear and well conserved and the actual material very well chosen. One small defect lies in the fact that no more advanced reading is suggested and this is rather an omission in an elementary book.

Ernest C. Pollard
Yale University

General Techniques of the Physics Laboratory, Vol. 1

Edited by J. Surugue. Pp. 433, Figs. 438. Centre de Documentation due Centre National de la Recherche Scientifique, Paris, 1947. In French.

This book constitutes the first volume of a series which promises to be a detailed collection of useful experimental procedures for the physicist. It is not written for the specialist in a given field, but for the experimenter who has to make use of or choose between certain techniques with which he is not too familiar.

In the foreword to this volume, Professor Joliot-Curie points out that scientific research is furthered in part by manufactured equipment (which is especially true in this country), but to a larger extent by special apparatus which every research worker must design and construct for himself and put into operation. It is during the latter process that one often encounters technical problems which may have been solved already in a satisfactory manner by other people, perhaps working in an unfamiliar field. A good compilation of modern research techniques is therefore a welcome aid and convenience for the experimenter.

The present volume, written by various experts, treats the following subject matter: Principles of Construction of Scientific Apparatus (H. Gondet), Principal Operations of Glass Blowing (Ch. Amate), Vacuum Technique (J. Surugue), Production of High Temperatures (G. Ribaud), General Techniques of Optics (A. Arnulf), Light Sources and Filters (G. Dupuy), Photoelectric Cells (A. Lallemand and M. Munsch), Procedures of Recording (H. Gondet), and Regulation and Rectification of Voltages and Currents (M. Demontvignier).

The book is perhaps best compared to *Procedures in Experimental Physics* by J. Strong (Prentice-Hall, Inc., New York, 1945), which is widely used in this country. Many of the techniques described are similar to those given by Strong. Some parts are treated in greater detail, as, for example, the subject of ovens and furnaces and the use, adjustment, and testing of various optical instruments. The material in the last two chapters of the volume is for the most part not mentioned by Strong: the chapter on recording techniques presents chemical, mechanical, electrical, and optical methods for recording. The chapter on electrical regulation and rectification discusses resistance, inductance, and discharge tube regulators, various solid and vacuum tube rectifiers, and has a section on the operation and construction of filters.

From the point of view of the contents, *General Techniques of the Physics Laboratory* is excellently written. The material is organized in a clear and logical manner, which is a speciality of French scientists. The index, which is important in this kind of a book, is good. The clarity of some of the figures might perhaps be improved.

As far as the usefulness of the presented information to an American physicist is concerned, it is more difficult to give a completely enthusiastic opinion. For there exists in different countries a vague pattern of certain preferred techniques, which is generally determined by practical circumstances. For example, due to the very high industrial development in this country, the American physicist makes use of many techniques which lean heavily upon industrial equipment (which does not mean that these techniques are necessarily better than those used elsewhere). Therefore, in some cases a book like Strong's will give more useful information to an experimenter in this country. This is especially true with respect to comparative performance characteristics of apparatus manufactured by competitive firms, which the French book lacks completely.

Yet, many American physicists will find this book a source of most welcome and useful information.

W. E. Meyerhof
University of Illinois

Waveforms

Edited by Britton Chance, Frederick C. Williams, Vernon Hughes, Edward F. MacNichol, and David Syre. Pp. 535+vii–xxii, Figs. 704. McGraw-Hill Book Company, Inc., New York, 1949. Price $10.00.

The Radiation Laboratory series has once again presented us with a volume packed from cover to cover with useful, practical information. In spite of the fact that some twenty-odd thick volumes have already appeared in this series, which, after all, covers only a relatively small segment of applied physics, the books continue to present new material and to present it divorced from the original application so that the reader interested in the general fields of electronics and applied physics cannot fail to find the series of major importance.

Waveforms is an excellent example. Starting with the radar problem of generating suitable waveforms for timing and indicating purposes, the authors have assembled material covering the circuits and techniques for generating and handling wave forms of almost any conceivable type. Having developed this circuitry, they then illustrate some of the applications, to modulation, to frequency division and counting, and to numerous mathematical operations. Although much of the fundamental material dates back to prewar days, the demands of radar required the development of precision circuits, and it is primarily because this precision is available that many of the applications discussed in the book are possible.

The merits of the book, then, lie in its encyclopedic discussion of the techniques of generating precision waveforms and its indication of the present and future applications of these circuits.

Early in the book two particularly interesting chapters deal with operations on waveforms with linear and with non-linear circuit elements. In discussing the non-linear elements, a large number of unusual tube characteristics are presented. It is refreshing to see such material emphasizing the non-linear behavior of tubes in contrast to the conventional linear approximations. The treatment of linear circuit elements is interesting but not altogether satisfying. In view of the widespread use of operational methods, it would seem that they deserve more than a cursory reference.

The book is liberally illustrated with actual circuit diagrams and cathode-ray oscilloscope photographs. The diagrams generally contain the circuit constants and therefore should be of inestimable value to the engineer and physicist interested in applying the material to practical problems. It is interesting to note the inclusion of some circuits and techniques developed in England. These have not always been translated into American tube types. It would have been helpful to include a table of approximate equivalents, or better yet, a brief technical description of the few British tubes mentioned.

The scope of this work is such as to appeal to a wide variety of interests. For example, the chapters on generating waveforms and on modulation, particularly time modulation, will prove of interest to communication and television engineers. The chapters on mathematical operations on waveforms, storage tubes, delay lines are of immediate application to the field of high speed electronic computation. Form the point of view of the experimental physicist, the techniques of measuring and controlling waveforms occurring in intervals of a microsecond or less, present him with a new tool which should prove of increasing importance in the future.

The book ends with a glossary of terms which includes a number of words and phrases new to those of us who are not specialists in this field. The authors state that they are attempting to replace the colloquialisms currently used by more precisely defined terms. For example, a flip-flop is changed to a monostable circuit. They are to be congratulated on their efforts, but when a picturesque colloquialism is once entrenched in the language it cannot be removed, it can only be paralleled by the scientific term. In this particular case, the classification of multivibrator type circuits into astable, bistable, and monostable would seem particularly apt and it is to be hoped that these terms will receive general currency.

This reviewer must confess that once again he is delighted to find a volume of the Radiation Laboratory series which, although the work of many contributing authors, has the continuity and readability of a first class reference book. The editorial staff and the authors have done an excellent job. Let us hope that the title does not imply to prospective readers that the book is limited to some specific radar problems, for it is indeed a book of wide scope and general interest with applications to numerous fields. No experimentalist can afford to overlook it.

W. H. Pickering
California Institute of Technology

Microwave Antenna Theory and Design

Edited by Samuel Silver. Pp. 721+vii–xviii, Figs. 300. McGraw-Hill Book Company, Inc., New York, 1948. Price $8.00.

The extension of radiofrequency techniques to the microwave range marks a new era in antenna theory and design. In this range, the conventional low frequency techniques are combined with the optical techniques on the one hand to achieve directivity, gain, and efficiency; on the other hand, new design principles are made available to obtain special effects. This book, edited by Samuel Silver, represents a documentary report covering the important antenna development during the war at the Radiation Laboratory, M.I.T., and to a limited extent other allied laboratories.

According to the subject material, the book can be divided into two parts. The first half of the book from Chapter 2 to Chapter 7, written by Silver, deals with the general principles of microwave antennas. The author collects material which is scattered among textbooks and articles of diversified topics. It covers circuit theorems, microwave transmission lines, radiation from current distributions, geometrical optics, and scattering and diffraction. The author has placed enough emphasis on mathematical rigor, and the material is well arranged, so that the first part is appropriate for classroom use.

The second part of the book deals with the design principles of various types of antennas. It starts with a chapter on dipole antennas and feeds used in connection with reflectors and other optical systems. In spite of their simple geometry and dimensions, they are not readily susceptible to accurate analysis. Experimental results and descriptions of different dipole arrangements are presented. The wave guide and horn feeds are covered in another chapter by J. R. Risser who has made a thorough and highly creditable experimental study of the impedance and radiation properties of electromagnetic horns. The results are presented here together with some theoretical analysis. The practical matter of pressurization is also touched upon.

In the chapter on "Linear Array Antennas and Feeds" by J. E. Eaton, L. J. Eyges, and G. G. Macfarlane, the latter from Telecommunication Research Establishment, England, the first third is devoted to the pattern theory, general formulas, uniform array, and beam synthesis. This is followed by a discussion of array elements. The outstanding work on slot radiators by British and Canadian scientists during the war is included. The impedance aspect of arrays, a few typical broadside arrays for beacons and feeds, and endfire arrays are described in detail.

Lenses and reflectors are treated in two chapters by Risser and Silver, respectively. The well-known metal-plate lenses developed by W. E. Kock, and the briefly mentioned parallel-plate systems, represent two of the radical departures from the optical systems at optical frequencies.

Although beam shaping is a standard practice at the standard broadcasting frequencies, the stringent requirements to provide proper coverages for radar mapping from the air, or air search from the ground, necessitated the development of new techniques. L. C. Van Atta and T. J. Keary give a well-balanced treatment of the theory, experimental results, and applications. Some early development, however, is omitted.

The practical aspects of microwave antennas are treated in the last three chapters. In "Antenna Installation Problems" by Van Atta and R. M. Redheffer a description of importnat considerations of installing antenna systems on ground, ship, and aircraft is given. A condensed treatment of the electrical aspect of the dielectric housing, or radome, is included.

Microwave antennas usually involve four-dimensional problems. Theoretical analysis can, at best, serve as a guide to the design of a practical system. One relies heavily upon the measurements of the performance of the components for most of the detailed design information. "Antenna Measurements—Techniques" by H. Krutter, who is personally responsible for many of the techniques, summarizes the practical techniques and their fine points instrumental to microwave antenna designs. The book is concluded with a brief chapter on "Antenna Measurements Equipment" by O. A. Tyson, who made the research work possible in the antenna group of the Radiation Laboratory by supplying them with new instruments for reliable and accurate measurement.

As a whole, the second half of the book contains a tremendous amount of reference material which is invaluable to designers and others seeking practical understanding of microwave antennas. The general organization of the book is to the credit of the authors and the editor.

The antenna systems discussed in this book are necessarily restricted to those used in microwave radar systems, although most of them can be used for other applications. There are, unfortunately, a few omissions, among which are the off-focus properties of optical systems and special systems for rapid scanning.

L. J. Chu
Massachusetts Institute of Technology

Scientific Foundations of Vacuum Technique

By Saul Dushman. Pp. 882, Fig. 324. John Wiley & Sons, Inc., New York, 1949. Price $15.00.

Of many books of undoubted value, it can be said that any one of a number of authors could have accomplished as much. It is doubtful whether anyone else could have done this piece of work. Dr. Dushman, recently retired as assistant director of the General Electric Company Research Laboratory, has spent nearly forty years working and studying in this field and its associated phases and has been a leader all the way.

His 1922 volume, *The Production and Measurement of High Vacua* brought together at that early date the known vacuum information. In a conversation during the preparation of his present volume, Dr. Dushman told this reviewer that he was not too happy about some of the things in the earlier book and this time he was giving every effort to produce a comprehensive, scholarly treatise of permanence and of which he could be proud. The result is a beautiful piece of work.

For those who do not already know the author by his works, it may be said that the writing style is clear and concise and the presentation orderly. The book is extremely readable.

The contents, by their nature, require many references. These are taken in stride with facility and without adverse effect on the subject matter. Liberal use has been made of direct quotations of sections of references as well as of illustrations. When expertly done this is a good thing. Valuable information, often lost thru interpretation of anothers work, can be saved by skillful quotation of pertinent material.

Apparently every effort has been made to give credit to all sources of information. The name index runs to well over a thousand. The footnotes are studded with acknowledgments of "private communication" and "copy of manuscript before publication," testifying to a wide and active acquaintanceship among workers in the field and assuring that no source of information has been neglected.

The above paragraphs bear witness to the capabilities of the author and the quality of his work. In his choice of contents he has drawn upon the fields of physics, chemistry, and metallurgy—the applications and fundamentals of vacuum technology extend into all of them with increasing importance.

The first two chapters contain a treatment of the kinetic theory of gases and of gas flow through orifices. The pertinent information is included without padding and together with some of the material of the later chapters would serve as an excellent basis for a practical course in kinetic theory.

Three chapters cover the various types of mechanical and vapor pumps. Descriptions and characteristics of many pumps, both historical and presently available are given. Information on pump speeds and design of pumping systems are included. In the case of vapor pumps such items as design information, nozzle characteristics, and available types of pump fluids are adequately discussed.

Chapter 6, entitled "Manometers for Low Pressures," contains about 125 pages and illustrates well the ingenuity of man as well as the effectiveness of the author's literature dragnet. Over one hundred different gauge constructions are referred to. Admittedly many are variations of a common principle. Certainly there exist only half a dozen or so basic physical phenomena upon which gauges may be built. Examples of ingenuity, although perhaps not of convenience, are the application of a Michelson interferometer to the measurement of small mercury displacements in a manometer, and the construction of a hot wire gauge in the capillary of a McLeod gauge! Those gauges more commonly in use, such as the McLeod, the ionization gauge, and various hot wire gauges, have been given thorough treatment. This chapter also includes a section on leak detection in which the mass spectrograph and the halogen ion detector are discussed.

Up to this point, about the halfway mark, the material, although masterfully and thoroughly presented, would be available without too much reference work. It is the second half of the book which, in the reviewers opinion, will prove to be of greatest ultimate value. The mere gathering of this material would have been a forbidding undertaking. Its intelligent interpretation in the interests of vacuum technology is a real contribution.

Two chapters are used in the presentation of sorption phenomena, one for metal, the other for charcoal, silicates (glasses), and cellulose. Particularly detailed are the sorption data for charcoal and glass. One chapter discusses the solubility of gases in metal and techniques of degassing.

Clean-up of gases at low pressures is discussed under two headings. In chemical clean-up are discussed the use of getters and the reaction of gases with incandescent filaments. Under electrical clean-up are found some of the explanations which have been offered for that rather nebulous but real phenomena, the disappearance of gas under certain conditions of low pressure discharge.

A chapter on vapor pressures contains extensive tables of vapor pressures of metal and other materials, and describes practical methods of evaporation. The final chapter gives numerous data on dissociation pressures and oxidation rates and discusses the logarithmic and parabolic laws of rates of oxidation.

The completeness of this work must be emphasized. Where gaps appeared the author, when possible, performed the necessary experiments or calculations to close them. Such an instance is found in the case of the vapor pressure tables 1 and 2 of Chapter 11.

By virtue of its scope, this is a reference book. It is also a book in which to browse. It will be serving both purposes adequately for many years to come.

Principles and Methods of Telemetering

By Perry A. Borden and Gustave M. Thynell. Pp. 230, Illustrated. Reinhold Publishing Corporation, New York, 1948. Price $4.50.

Instrumentation which provides remote indication or recording of variable physical quantities has added a distinct phase to the field of electrical communications. This phase of communications, called telemetering, has fostered the development and application of many unique systems and measurement devices. Although telemetering systems have been employed for many years, there has been a relatively small amount of literature which deals exclusively with the field. This book provides a description of many types of telemetering equipment which are presently in use or have been employed in the past. Consideration of the principles of telemetering is chiefly related to the specific equipment being discussed.

With consideration of the electrical variable, the telemetering systems are classified as: (1) current, (2) voltage, (3) frequency, (4) position, (5) impulse. Seven chapters are devoted to the description of representative equipments in each of the classifications together with a brief discussion of the system principles and methods. Consideration of basic characteristics and limitations of the systems is almost nonexistent. In many instances the reader must deduce the principal characteristics of the system from the method of operation of the described apparatus. In this respect, however.

the authors define their position as compilers of information relating to the essentials of the various apparatus.

The measurement field is considered with a reasonable breadth of types of apparatus. Emphasis is given the measurement of liquid level and flow, mechanism displacement and position, and electrical quantities related to power applications. The descriptions of the apparatus and the methods of operation are presented fully and the reader should have no difficulty in understanding the devices.

One chapter deals specifically with interconnecting circuits and channels. Illustrations are given of the use of simplex, phantom, and other similar methods for the transmission of telemetering signals over circuits which carry other intelligence. The chapter on carrier current goes into some detail on the equipment employed and discusses the application methods and problems.

The practical application of telemetering apparatus establishes additional requirements for equipment to properly associate information from various sources. It is necessary to perform operations upon this information so that the desired result is presented in the most easily used form. Consideration of these problems together with a description of typical apparatus is contained in the chapter on coordinating, totalizing, computing, and integrating. The final chapter discusses the general relationship of typical application problems and the type of telemetry which should be employed.

An interesting classified list of patents in telemetering and allied fields is included.

The authors' viewpoint is "prior to the advent of the electron tube" which does not bring forth discussion of some of the more promising possibilities of telemetry. In addition, practically no consideration is given to telemetering via a radio link. This is felt to be a serious omission since radio telemetering provides the means for a vast new field of instrumentation.

The book will undoubtedly be of considerable interest for those desiring descriptive information about commercial apparatus employed in stationary installations. It will be of little value to those seeking knowledge of the fundamentals of telemetering.

Methods in Medical Research, Vol. I

Edited by V. R. Potter. Pp. 372+xiii, Illustrated, 16×24 cm. The Yearbook Publishers, Inc., Chicago, 1948. Price $8.00.

The annual volumes, of which this is the first, should be valuable additions to the biological literature, since there has been no similar systematic presentation of current methodology in this field. Although intended primarily to cover techniques of particular concern to medical research, many of the articles are of broader biological interest. It is also possible that some of the methods, such as those for measuring fluid flow and those for certain chemical studies, contain ideas of use to experimenters in non-bilolgical fields.

Each volume is to "be divided into four or five principal, self-contained sections, each of which shall, for that volume, represent one of the broad fields of medical research: biochemistry, physiology and pharmacology, microbiology and immunology, and biophysics, including radiobiology." Within each of these broad fields it is planned "year by year, to select various topics wherein a restatement of techniques seems timely." The stated purpose is to provide a place for appraisal of the various methods proposed for solution of a particular experimental problem and to offset the present difficulty of obtaining publication of adequate descriptions of technique, especially in the field of physiology. For each topic selected, an expert is chosen to serve as associate editor who picks contributors to describe particular methods.

The subjects treated in this volume include the following: Section I: Assay of antibiotics (65 pages). This covers the assay of potency of penicillin, streptomycin, tyrothricin, and bacitracin, by biological, chemical, and physical methods.

Section II: Circulation and blood flow measurements (188 pages). This includes an extraordinary number of devices for measuring flow of blood, mostly contrived to cause a minimum disturbance in pressure relations of the system in which flow is measured. There are volume-displacement methods, drop recorders, a "bubble" flow meter, a critical and condemning discussion of thermostromuhrs, differential pressure flow meters, and a section on methods for following pulsatile flow. In an electromagnetic flow meter, measurement is made of the voltage generated between two electrodes on opposite sides of an intact blood vessel as the blood crosses a strong magnetic field. Systems for perfusing various organs are considered. Methods are discussed for measuring blood flow indirectly in certain regions by microscopic observation, by skin temperature recording, by plethysmographs, by nitrous oxide exchange (human brain), etc. There is also a discussion of several methods for determining cardiac output and for studying vascular tone.

Section III: Selected methods in gastroenterological research (18 pages). These concern the study of gastric acidity in man and the use of animals for certain tests of liver function and for evaluation of treatments for peptic ulcer.

Section IV: Cellular respiration (74 pages). This section briefly covers the measurement of respiration of intact animals of various sizes by a closed volume method and then more extensively considers applications of the Warburg manometer technique to slices and homogenates of excised tissues. The biochemical details are given for determining the concentrations of particular enzymes in homogenized tissues. Finally, a system is described for rapid freezing of tissue samples and subsequent analysis for various substances, including enzymes, of interest in carbohydrate metabolism.

The authoritativeness of each contribution has been increased in a way which may recommend itself to future editors of similar surveys. Each article has been submitted to at least one other experienced investigator for review. The reviewer is given real responsibility for critical comment by noting his name at the end of the article, frequently the comments themselves are printed. This appears to be of considerable value in assessing many of the methods now employed in biological research, where procedures are often not standardized and where additional precautions and controls seem needed for almost every new application.

University of Pennsylvania

Sources of Engineering Information

By Blanche H. Dalton. Pp. 109. University of California Press, Berkeley, 1948. Price $4.00.

To meet the need for "a compilation listing source material (in engineering) for American engineers and librarians," the engineering librarian of the University of California has prepared a revised edition of a syllabus originally written for use with lectures on library materials for those engaged in research in engineering.

The organization of the compilation makes it an excellent tool for students and librarians. Mrs. Dalton correctly places the emphasis on periodical literature, where the chief attention belongs in tracing scientific information. The first three sections of the book form a unit—"Indexes to Periodical and Serial Literature," "Abstracts," and "Location of Articles and Identification of Periodicals." The third section contains suggestions for the searcher not familiar with the services a library can offer in finding the periodicals needed.

The fourth section, "Bibliography," should be useful to the researcher who needs not only a list of bibliographies, but also directions for preparing a bibliography for himself; and the fifth section is a list of reference books, classified by general type—for example, technical dictionaries and handbooks—and by subject within the type. The brief section on the trade catalog collection describes the organization of such a collection, and the four pages devoted to standards and specifications gather into a good working-list the names of national standardizing bodies and of important publications in this diffuse and frequently confusing field.

The various lists cover the ground thoroughly; the organization under headings and subheadings follows familiar library patterns, and the book will not only guide librarians in organization and method, but also provide a check list for library holdings. Whether the practicing engineer or research worker will take the time and trouble to look through the classifications till he finds what he needs is another matter; he would doubtless prefer a subject index for quick reference rather than the subject classification only, which he must first learn before he can use the book with speed or can be sure he has not overlooked the source of the information he needs.

Vacuum-Tube Circuits

BY LAWRENCE BAKER ARGUIMBAU. Pp. 668 Figs. 676. John Wiley & Sons, New York, 1948. Price $6.00.

The text *Vacuum-Tube Circuits* presents no new material but does bring together, under one cover and in a coherent manner, many of the necessary relationships between vacuum tubes and present-day communication circuits. The title does not indicate that the book covers only applications of vacuum tubes to the communications fields.

The text assumes a firm foundation in alternating current circuit theory and the associated mathematics. Some previous knowledge of the fundamental concepts of vacuum tubes themselves is assumed even though the second and third chapters (Diodes and Rectifiers and Triodes, Pentodes, and Linear Amplifiers [Including Random Noise]) review these facts to some degree. The first and foremost consideration is the association of the tube to its circuit which is brought about with expedience.

Chapter Four is entitled "Transient Response of Video Amplifiers." The chapter begins with a discussion of the fundamentals of television in an attempt to place restrictions on the operation of the video amplifiers. This discussion is necessarily brief and somewhat out of place here, particularly in view of the wide application of the term "video amplifier" to broad-band amplifiers in general. The presentation of the subject is, however, thorough and of great practical worth. Design criteria are given for broad-band amplifiers under all conditions of operation, with special reference to transient response.

Chapter Five discusses "Amplitude Modulation and Tuned Amplifiers" which includes the relationship between modulation band width, circuit Q and the operation of the radio-frequency coupling circuits in current use.

"Power Amplifiers," Chapter Six, discusses the theory of class A, B, and C amplifiers. Of particular interest is the fact that the author devoted time and space to the step-by-step determination of the correct operating conditions for class B and C amplifiers. Although this information can most certainly be found elsewhere, it is a valuable addition in providing background for a book of wide coverage such as this.

The chapter on oscillators (Chapter Seven) provides all the usual ramifications, including well presented design criteria. The best portion of the chapter is the section on stabilized oscillators of many forms. Amplitude and frequency stability under varying operating conditions are discussed in detail.

The cathode-follower as an example of inverse feedback (Chapter Eight) receives complete treatment including the choosing of proper quiescent operating conditions. Negative feedback as a whole is presented with lucidity by the use of equivalent circuits and examples. The effect of negative feedback on noise, distortion, band width, and amplifier stability is illustrated.

Chapter Nine (Amplitude Modulation) continues the study of class C amplifiers as applied to the modulated output stage of an amplitude-modulated transmitter. Improvement of linearity of modulation by the use of negative feedback is shown. Other topics discussed are: single-side-band transmission, frequency changers, detectors, and automatic volume control as applied to amplitude modulation. Particular attention is paid to the correct operation of the diode detector in minimizing the different types of distortion which might arise in such a circuit.

In Chapter Ten, frequency modulation theory and history, transmitters and receivers are discussed. The advantages of FM over AM are brought out. The effect of pre-emphasis on signal-to-noise ratio is discussed. The relationship between modulation index, deviation ratio, pre-emphasis, and signal-to-noise ratio is not clearly defined. The ratio detector (or discriminator) is omitted.

The problems connected with television pulse generators, sweep circuits, and synchronism of television signals are the concern of Chapter Eleven. For the allotted space the coverage is good, but many items of importance such as d.c. restorers and sound "traps" are eliminated.

The last chapter discusses the generation of microwave frequencies by triodes, magnetrons, and klystrons. Multiple-cavity and reflex klystrons are both considered.

The text as a whole should be of much practical value due to its wide, up-to-date coverage, clear presentation, and frequent practical references and examples. The value of the author's bibliography is increased by brief summaries of the content of articles in many cases.

Laboratory and Shop Notes

Lead-In Seals for Kinetic High Vacuum Systems Using Rubbers

Ralph C. Taylor and Carnot W. Ward
Naval Research Laboratory, Washington, D. C.

IN using kinetic high vacuum systems in tube development, metal sputtering, and other applications, the effective sealing of leads is often a perplexing problem. The common methods employed using low vapor pressure waxes and resins, have the disadvantage of being clumsy and time consuming.

While working with high vacuum systems requiring electrical leads it was found that metallic conductors imbedded in a rubber matrix could be used successfully for seals in the range 10^{-6} to 10^{-7} mm. Designs similar to that shown in Fig. 1 have proved most satisfactory.

Various types of synthetic rubbers have been used, but it was noted that many of the compounding ingredients, such as carbon black, oils, and plasticizers in the rubbers contribute in making the elastomers gassy.

Silicone and neoprene elastomers, when properly compounded with low vapor pressure materials, give good results but a butyl rubber GR-I was used because of its low permeability and good electrical properties. The following recipe, Table I, has been tried and found to function well and permit rapid evacuation of the system.

Table I.

Butyl Rubber GR-I	100.00
Zinc Oxide	5.00
Stearic Acid	2.00
Sulfur	2.00
Tuads	1.00
M.B.T.	0.50
Titanium Dioxide	40.00
	150.50
Gaskets Vulcanized 35 in. at 300°F.	

Various designs have been used, hollow tubes, solid rods or flat metal strips have been employed as conductors, but the gasket most often used has been of the type shown in Fig. 1.

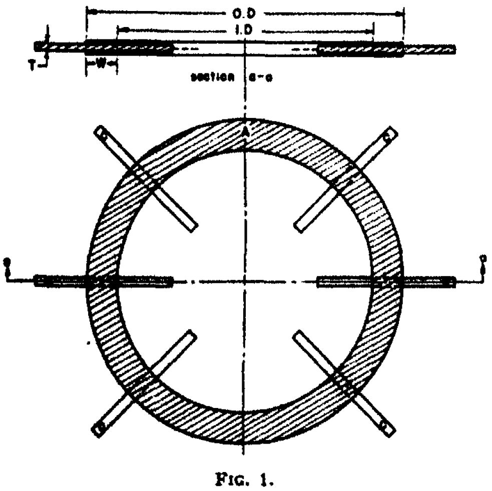

Fig. 1.

The gasket is a flat rubber ring (*A*), with the dimensions governed by the application, i.e., the I.D. of the bell jar or flange of the tube. Any metal may be used as the conductor (*C*) but silver, copper or nickel ribbons or tubing plated with brass have been found to give best adhesion to the rubber. The total thickness (*T*) is sufficient to give approximately $\frac{1}{16}$–$\frac{1}{8}$ in. on the top and bottom of the metal. The width (*W*) is usually $\frac{1}{2}$ to 1 in.

The gasket is vulcanized in a mold with the metal inserts in place. Adhesion is obtained to the metal by the usual methods common in the rubber industry utilizing commercial adhesive cements such as Ty-Ply Reanite or Cycle-Weld.

Gaskets of this design with as many as eight conductors imbedded in the vulcanized rubber have been successfully used for a period of nine months.

Measurement of the Thickness of Thin Nylon Films

A. I. McPherson and D. G. Douglas
McGill University, Montreal

April 4, 1949

AN optical method of measuring the thickness, and from it the mass per unit area, of thin mica windows has recently been described in this journal.[1] This method however is not applicable to the very thin windows currently being used in most beta-ray spectrometers. For these an optical method is especially desirable since a small window is too light to be weighed with acceptable precision on an ordinary chemical balance. Furthermore, if the film is removed from its supporting frame for weighing or testing, cementing it in place becomes much more difficult.

We have recently made some thin nylon films for use as windows for a Geiger counter, following rather closely the method of Brown, Felber, Richards, and Saxon.[2] It has proved convenient to pick up the films on a frame cut from mica, as many as 8 layers being picked up on one frame to build up any desired thickness.

We have found it possible to measure the thickness of these thin films quickly with a Michelson interferometer set for white-light fringes, and showing fringes from yellow sodium light at the same time. The film on its frame was introduced into one arm of the interferometer, and the amount of displacement of the central black fringe was measured.

For example, for two circular films 1.5 cm across, made up of 6 and 8 layers respectively, the displacement of the dark fringe was 0.8 fringe-width and 1.2 fringe-width. This corresponds to an increase of optical path $n\lambda = 2t\ (\mu - 1)$ and thus is equal to 0.8λ and 1.2λ where λ is the effective wavelength of the light used, t the thickness and μ the refractive index of the nylon film. The refractive index μ was found to be between 1.50 and 1.62, as determined from Brewster's angle for the film for sodium yellow light measured with a spectrometer and Nicol prism. The thickness of these films is thus determined within about 10 percent, being between 0.38 and 0.47 micron for one, and between 0.57 and 0.71 microns for the other. (Since our mean value $\mu = 1.56$ agrees well with the mean value $\mu = 1.55$ for nylon fibres kindly furnished by Dr. R. D. Bennett of the Nylon Division, Canadian Industries Limited, the accuracy obtained by using the mean is probably very much better than 10 percent.

The density of the nylon chips from which the thin films were made was found to be 1.10 gm per cm^3 by weighing in air and in water; assuming the same density for the films and the chips this gives for the two films discussed, masses between 0.042 and 0.052 mg per cm^2, and 0.063 and 0.078 mg per cm^2, or using the mean value of $\mu = 1.56$, masses of 0.046 and 0.069 mg per cm^2.

This method of measurement of thickness is quick, and its accuracy is satisfactory for the purpose, especially for comparing one film with another, and also for examining a film for uniformity of thickness and constitution in terms of the distortion it produces in the fringe pattern. Our films are uniform over their entire area to better than one-twentieth of a fringe-width. Since the films are measured and examined on the mica frames on which they are formed, it is possible to select a film suitable for the particular purpose considered.

---

Ultimate Vacua of Diffusion Pumps

G. W. Sears*
General Electric Company, Schenectady, New York

February 25, 1949

Any evacuated system represents a balancing of rates of evolution and rates of removal of gases to give a steady state pressure characteristic of this balance. Any arbitrary distinction between static and dynamic vacuum systems tends to obscure the utility of this principle for static systems.

In at least one important instance the elementary procedure of material balancing appears to have been over-looked. A typical curve of pumping speed *vs.* log pressure for a diffusion pump is shown in Fig. 1, curve *A*, in accordance with Dayton.[1] It will be noted that the pumping speed slowly rises to a plateau value with decreasing pressure. It then remains constant over a long range of pressure and falls rather rapidly to zero at the ultimate or limiting pressure of the pump.

For clarity a brief description of a pumping speed determination is given, Gas is admitted to the high vacuum side of a diffusion pump at a measured rate (volume/time), a measured pressure, and a known temperature. The steady state pressure at the throat of the pump is measured and the temperature of the flowing gas is assumed to be equal to the temperature of the admittance chamber. If S^* is the effective pumping speed at the throat of the pump (volume/time), S_M is the measured rate of introduction (volume/time), p is the admittance pressure, and P is the throat pressure, we write

$$S^* = pS_M/P. \tag{1}$$

The various factors which complicate the absolute measurement of pumping speed do not concern the present paper and will not be considered.

This paper is concerned with the behavior of the pumping speed curve in the low pressure cut-off region. The operation, of a diffusion pump depends on gas molecules from the region being evacuated effusing into the directed vapor stream of the pump. Some of the directed momentum of the vapor molecules is imparted to the gas molecules. The vapor stream effectively exerts a pressure gradient on the gas causing it to flow through the pump. This process would seem to be independent of pressure once the pressure had been lowered by a backing pump to a value at which molecular flow or effusion could occur. It is indicated that the pumping speed should rise to a plateau value and remain there for all lower pressures.

It is postulated that such is actually the case and that effective pumping speeds in the cut-off region are not true pumping speeds. This is explained on the basis that the rate of gas evolution by the pump becomes appreciable and even exceeds the measured rate of introduction of gases into the vacuum during pumping speed measurements.

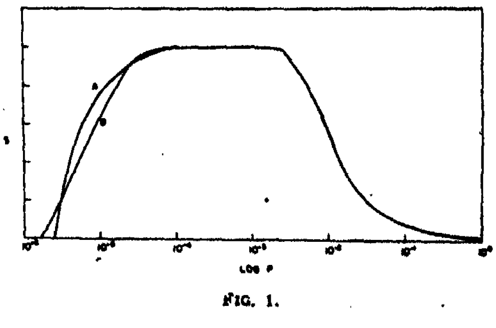

FIG. 1.

If the ultimate pressure of a diffusion pump is P_0, the true pumping speed is S, and the mass rate of evolution of gases by the pump is π, we may write

$$P_0SM/RT = \pi \tag{2}$$

where M is the average molecular weight of the evolved gas, T is the absolute temperature of the evolved gas, and R is the gas constant. For pressures P, greater than P_0, but still on the plateau, we write as a consequence of Eqs. (1) and (2)

$$S^* = S(1 - P_0/P). \tag{3}$$
